ACKNOWLEDGEMENTS

I am greatly indebted to

Richard S. Palais

without his encouragement
these volumes would have remained
a short set of mimeographed notes

and

Donald E. Knuth

without his T_EX program they would
never have become typeset books

PREFACE

The preface to the first edition, reprinted on the succeeding pages, excused this book's deficiencies on grounds that can hardly be justified now that these "notes" truly have become a book.

At one time I had optimistically planned to completely revise all this material for the momentous occasion, but I soon realized the futility of such an undertaking. As I examined these five volumes, written so many years ago, I could scarcely believe that I had once had the energy to learn so much material, or even recall how I had unearthed some of it.

So I have contented myself with the correction of errors brought to my attention by diligent readers, together with a few expository ameliorations; among these is the inclusion of a translation of Gauss' paper in Volume 2.

Aside from that, this third and final edition differs from the previous ones only in being typeset, and with figures redrawn. I have merely endeavored to typeset these books in a manner befitting a subject of such importance and beauty.

As a final note, it should be pointed out that since the first volumes of this series made their appearance in 1970, references in the text to "recent" results should be placed in context.

Preface to the First Edition

HOW THESE NOTES CAME TO BE

and how they did not come to be a book

For many years I have wanted to write the Great American Differential Geometry book. Today a dilemma confronts any one intent on penetrating the mysteries of differential geometry. On the one hand, one can consult numerous classical treatments of the subject in an attempt to form some idea how the concepts within it developed. Unfortunately, a modern mathematical education tends to make classical mathematical works inaccessible, particularly those in differential geometry. On the other hand, one can now find texts as modern in spirit, and as clean in exposition, as Bourbaki's Algebra. But a thorough study of these books usually leaves one unprepared to consult classical works, and entirely ignorant of the relationship between elegant modern constructions and their classical counterparts. Most students eventually find that this ignorance of the roots of the subject has its price -- no one denies that modern definitions are clear, elegant, and precise; it's just that it's impossible to comprehend how any one ever thought of them. And even after one does master a modern treatment of differential geometry, other modern treatments often appear simply to be about totally different subjects.

Of course, these remarks merely mean that no matter how well some of the present day texts achieve their objective, I nevertheless feel that an introduction to differential geometry ought to have quite different aims. There are two main premises on which these notes are based. The first premise is that it is absurdly inefficient to eschew the modern language of manifolds, bundles, forms, etc., which was developed precisely in order to rigorize the concepts of classical differential geometry. Rephrasing everything in more elementary terms involves incredible

contortions which are not only unnecessary, but misleading. The work of Gauss, for example, which uses infinitesimals throughout, is most naturally rephrased in terms of differentials, even if it is possible to rewrite it in terms of derivatives. For this reason, the entire first volume of these notes is devoted to the theory of differentiable manifolds, the basic language of modern differential geometry. This language is compared whenever possible with the classical language, so that classical works can then be read.

The second premise for these notes is that in order for an introduction to differential geometry to expose the geometric aspect of the subject, an historical approach is necessary; there is no point in introducing the curvature tensor without explaining how it was invented and what it has to do with curvature. I personally felt that I could never acquire a satisfactory understanding of differentiable geometry until I read the original works. The second volume of these notes gives a detailed exposition of the fundamental papers of Gauss and Riemann. Gauss' work is now available in English (General Investigations of Curved Surfaces; Raven Press). There are also two English translations of Riemann's work, but I have provided a (very free) translation in the second volume.

Of course, I do not think that one should follow all the intricacies of the historical process, with its inevitable duplications and false leads. What is intended, rather, is a presentation of the subject along the lines which its development might have followed; as Bernard Morin said to me, there is no reason, in mathematics any more than in biology, why ontogeny must recapitulate phylogeny. When modern terminology finally is introduced, it should be as an outgrowth of this (mythical) historical development. And all the major approaches have to be presented, for they were all related to each other, and all still play an important role.

At this point I am reminded of a paper described in Littlewood's Mathematician's Miscellany. The paper began "The aim of this paper is to prove ..." and it transpired only much later that this aim was not achieved (the author hadn't claimed that it was). What I have outlined above is the content of a book the realization of whose basic plan and the incorporation of whose details would perhaps be impossible; what I have written is a second or third draft of a preliminary version of this book. I have had to restrict myself to what I could write and learn about within the present academic year, and all revisions and corrections have had to be made within this same period of time. Although I may some day be able to devote to its completion the time which such an undertaking deserves, at present I have no plans for this. Consequently, I would like to make these notes available now, despite their deficiencies, and with all the compromises I learned to make in the early hours of the morning.

These notes were written while I was teaching a year course in differential geometry at Brandeis University, during the academic year 1969-70. The course was taken by six juniors and seniors, and audited by a few graduate students. Most of them were familiar with the material in Calculus on Manifolds, which is essentially regarded as a prerequisite. More precisely, the complete prerequisites are advanced calculus using linear algebra and a basic knowledge of metric spaces. An acquaintance with topological spaces is even better, since it allows one to avoid the technical troubles which are sometimes relegated to the Problems, but I tried hard to make everything work without it.

The material in the present volume was covered in the first term, except for Chapter 10, which occupied the first couple of weeks of the second term, and Chapter 11, which was not covered in class at all. We found it necessary to take rest cures of nearly a week after completing Chapters 2, 3, and 7. The same material could easily be expanded to a full year course

in manifold theory with a pace that few would describe as excessively leisurely. I am grateful to the class for keeping up with my accelerated pace, for otherwise the second half of these notes would not have been written. I am also extremely grateful to Richard Palais, whose expert knowledge saved me innumerable hours of labor.

TABLE OF CONTENTS

Although the chapters are not divided into sections,
the listing for each chapter gives some indication
which topics are treated, and on what pages.

CHAPTER 1. MANIFOLDS

Elementary properties of manifolds	1
Examples of manifolds	6
Problems	20

CHAPTER 2. DIFFERENTIAL STRUCTURES

C^∞ structures	27
C^∞ functions	31
Partial derivatives	35
Critical points	40
Immersion theorems	42
Partitions of unity	50
Problems	53

CHAPTER 3. THE TANGENT BUNDLE

The tangent space of \mathbb{R}^n	63
The tangent space of an imbedded manifold	67
Vector bundles	71
The tangent bundle of a manifold	75
Equivalence classes of curves, and derivations	77
Vector fields	82
Orientation	84
Addendum. Equivalence of Tangent Bundles	89
Problems	95

CHAPTER 4. TENSORS

The dual bundle	107
The differential of a function	109
Classical <i>versus</i> modern terminology	111
Multilinear functions	115
Covariant and contravariant tensors	117
Mixed tensors, and contraction	121
Problems	127

CHAPTER 5. VECTOR FIELDS AND DIFFERENTIAL EQUATIONS

Integral curves	135
Existence and uniqueness theorems	139
The local flow	143
One-parameter groups of diffeomorphisms	148
Lie derivatives	150
Brackets	153
Addendum 1. Differential Equations	164
Addendum 2. Parameter Curves in Two Dimensions	167
Problems	169

CHAPTER 6. INTEGRAL MANIFOLDS

Prologue; classical integrability theorems	179
Local Theory; Frobenius integrability theorem	190
Global Theory	194
Problems	198

CHAPTER 7. DIFFERENTIAL FORMS

Alternating functions	201
The wedge product	203
Forms	207
Differential of a form	210
Frobenius integrability theorem (second version)	215
Closed and exact forms	218
The Poincaré Lemma	225
Problems	227

CHAPTER 8. INTEGRATION

Classical line and surface integrals	239
Integrals over singular k -cubes	246
The boundary of a chain	248
Stokes' Theorem	253
Integrals over manifolds	256
Volume elements	258
Stokes' Theorem	261
de Rham cohomology	263
Problems	283

CHAPTER 9. RIEMANNIAN METRICS

Inner products	301
Riemannian metrics	308
Length of curves	312
The calculus of variations	316
The First Variation Formula and geodesics	323
The exponential map	334
Geodesic completeness	341
Addendum. Tubular Neighborhoods	344
Problems	348

CHAPTER 10. LIE GROUPS

Lie groups	371
Left invariant vector fields	374
Lie algebras	376
Subgroups and subalgebras	379
Homomorphisms	380
One-parameter subgroups	382
The exponential map	384
Closed subgroups	391
Left invariant forms	394
Bi-invariant metrics	400
The equations of structure	402
Problems	406

CHAPTER 11. EXCURSION IN THE REALM OF ALGEBRAIC TOPOLOGY

Complexes and exact sequences	419
The Mayer-Vietoris sequence	424
Triangulations	426
The Euler characteristic	428
Mayer-Vietoris sequence for compact supports	430
The exact sequence of a pair	432
Poincaré Duality	439
The Thom class	442
Index of a vector field	446
Poincaré-Hopf Theorem	450
Problems	453

APPENDIX A

To Chapter 1	459
Problems	467
To Chapter 2	471
Problems	472
To Chapter 6	473
To Chapters 7, 9, 10	474
Problem	475

A
Comprehensive Introduction
to
DIFFERENTIAL GEOMETRY

VOLUME ONE

CHAPTER 1

MANIFOLDS

The nicest example of a metric space is Euclidean n -space \mathbb{R}^n , consisting of all n -tuples $x = (x^1, \dots, x^n)$ with each $x^i \in \mathbb{R}$, where \mathbb{R} is the set of real numbers. Whenever we speak of \mathbb{R}^n as a metric space, we shall assume that it has the “usual metric”

$$d(x, y) = \sqrt{\sum_{i=1}^n (y^i - x^i)^2},$$

unless another metric is explicitly suggested. For $n = 0$ we will interpret \mathbb{R}^0 as the single point $0 \in \mathbb{R}$.

A manifold is supposed to be “locally” like one of these exemplary metric spaces \mathbb{R}^n . To be precise, a manifold is a metric space M with the following property:

If $x \in M$, then there is some neighborhood U of x and some integer $n \geq 0$ such that U is homeomorphic to \mathbb{R}^n .

The simplest example of a manifold is, of course, just \mathbb{R}^n itself; for each $x \in \mathbb{R}^n$ we can take U to be all of \mathbb{R}^n . Clearly, \mathbb{R}^n supplied with an equivalent metric (one which makes it homeomorphic to \mathbb{R}^n with the usual metric), is also a manifold. Indeed, a hasty recollection of the definition shows that anything homeomorphic to a manifold is also a manifold—the specific metric with which M is endowed plays almost no role, and we shall almost never mention it.

[If you know anything about topological spaces, you can replace “metric space” by “topological space” in our definition; this new definition allows some pathological creatures which are not metrizable and which fail to have other properties one might carelessly assume must be possessed by spaces which are locally so nice. Appendix A contains remarks, supplementing various chapters, which should be consulted if one allows a manifold to be non-metrizable.]

The second simplest example of a manifold is an open ball in \mathbb{R}^n ; in this case we can take U to be the entire open ball since an open ball in \mathbb{R}^n is homeomorphic to \mathbb{R}^n . This example immediately suggests the next: any open

subset V of \mathbb{R}^n is a manifold—for each $x \in V$ we can choose U to be some open ball with $x \in U \subset V$. Exercising a mathematician's penchant for generalization,

we immediately announce a proposition whose proof is left to the reader: An open subset of a manifold is also a manifold (called, quite naturally, an open submanifold of the original manifold).

The open subsets of \mathbb{R}^n already provide many different examples of manifolds (just how many is the subject of Problem 24), though by no means all. Before proceeding to examine other examples, which constitute most of this chapter, some preliminary remarks need to be made.

If x is a point of a manifold M , and U is a neighborhood of x (U contains some open set V with $x \in V$) which is homeomorphic to \mathbb{R}^n by a homeomorphism $\phi: U \rightarrow \mathbb{R}^n$, then $\phi(V) \subset \mathbb{R}^n$ is an open set containing $\phi(x)$. Conse-

quently, there is an open ball W with $\phi(x) \in W \subset \phi(V)$. Thus $x \in \phi^{-1}(W) \subset V \subset U$. Since $\phi: V \rightarrow \mathbb{R}^n$ is continuous, the set $\phi^{-1}(W)$ is open in V , and thus open in M ; it is, of course, homeomorphic to W , and thus to \mathbb{R}^n . This complicated little argument just shows that we can always choose the neighborhood U in our definition to be an open neighborhood.

With a little thought, it begins to appear that, in fact, U *must* be open. But to prove this, we need the following theorem, stated here without proof.*

1. THEOREM. If $U \subset \mathbb{R}^n$ is open and $f: U \rightarrow \mathbb{R}^n$ is one-one and continuous, then $f(U) \subset \mathbb{R}^n$ is open. (It follows that $f(V)$ is open for any open $V \subset U$, so f^{-1} is continuous, and f is a homeomorphism.)

Theorem 1 is called “Invariance of Domain”, for it implies that the property of being a “domain” (a connected open set) is invariant under one-one continuous maps into \mathbb{R}^n . The proof that the neighborhood U in our definition must be open is a simple deduction from Invariance of Domain, left to the reader as an easy exercise (it is also easy to see that if Theorem 1 were false, then there would be an example where the U in our definition was not open).

We next turn our attention to the integer n appearing in our definition. Notice that n may depend on the point x . For example, if $M \subset \mathbb{R}^3$ is

$$\begin{aligned} M &= \{(x, y, z) : z = 0\} \cup \{(x, y, z) : x = 0 \text{ and } z = 1\} \\ &= M_1 \cup M_2, \end{aligned}$$

then we can choose $n = 2$ for points in M_1 and $n = 1$ for points in M_2 . This

example, by the way, is an unnecessarily complicated device for producing one manifold from two. In general, given M_1 and M_2 , with metrics d_1 and d_2 , we can first replace each d_i with an equivalent metric \bar{d}_i such that $\bar{d}_i(x, y) < 1$ for all $x, y \in M_i$; for example, we can define

$$\bar{d}_i = \frac{d_i}{1 + d_i} \quad \text{or} \quad \bar{d}_i = \min(d_i, 1).$$

* All proofs require some amount of machinery. The quickest routes are probably provided by Vick, *Homology Theory* and Massey, *Singular Homology Theory*. An old-fashioned, but pleasantly geometric, treatment may be found in Newman, *Topology of Plane Sets*.

Then we can define a metric d on $M = M_1 \cup M_2$ by

$$d(x, y) = \begin{cases} \bar{d}_i(x, y) & \text{if there is some } i \text{ such that } x, y \in M_i \\ 1 & \text{otherwise} \end{cases}$$

(we assume that M_1 and M_2 are disjoint; if not, they can be replaced by new sets which are). In the new space M , both M_1 and M_2 are open sets. If M_1 and M_2 are manifolds, M is clearly a manifold also. This construction can be applied to any number of spaces—even uncountably many; the resulting metric space is called the **disjoint union** of the metric spaces M_i . A disjoint union of manifolds is a manifold. In particular, since a space with one point is a manifold, so is any discrete space M , defined by the metric

$$d(x, y) = \begin{cases} 0 & \text{if } x = y \\ 1 & \text{if } x \neq y. \end{cases}$$

Although different n 's may be required at different points of a manifold M , it would seem that only one n can work at a given point $x \in M$. For the proof of this intuitively obvious assertion we have recourse once again to Invariance of Domain. As a first step, we note that \mathbb{R}^n is not homeomorphic to \mathbb{R}^m when $n \neq m$, for if $n > m$, then there is a one-one continuous map from \mathbb{R}^m into a non-open subset of \mathbb{R}^n . The further deduction, that the n of our definition is unique at each $x \in M$, is left to the reader. This unique n is called the **dimension of M at x** . A manifold has **dimension n** or is **n -dimensional** or is an **n -manifold** if it has dimension n at each point. It is convenient to refer to the manifold M as M^n when we want to indicate that M has dimension n .

Consider once more a discrete space, which is a 0-dimensional manifold. The only compact subsets of such a space are finite subsets. Consequently, an uncountable discrete space is not σ -compact (it cannot be written as a countable union of compact subsets). The same phenomenon occurs with higher-dimensional manifolds, as we see by taking a disjoint union of uncountably many manifolds homeomorphic to \mathbb{R}^n . In these examples, however, the manifold is not connected. We will often need to know that this is the only way in which σ -compactness can fail to hold.

2. THEOREM. If X is a connected, locally compact metric space, then X is σ -compact.

PROOF. For each $x \in X$ consider those numbers $r > 0$ such that the closed ball

$$\{y \in X : d(x, y) \leq r\}$$

is a compact set (there is at least one such $r > 0$, since X is locally compact). The set of all such $r > 0$ is an interval. If, for some x , this set includes all $r > 0$, then X is σ -compact, since

$$X = \bigcup_{n=1}^{\infty} \{y \in X : d(x, y) \leq n\}.$$

If not, then for each $x \in X$ define $r(x)$ to be one-half the least upper bound of all such r .

The triangle inequality implies that

$$\{y \in X : d(x_1, y) \leq r\} \subset \{y \in X : d(x_2, y) \leq r + d(x_1, x_2)\},$$

so that

$$\{y \in X : d(x_1, y) \leq r - d(x_1, x_2)\} \subset \{y \in X : d(x_2, y) \leq r\},$$

which implies that

$$(1) \quad r(x_1) \geq r(x_2) - \frac{1}{2}d(x_1, x_2).$$

Interchanging x_1 and x_2 gives

$$(2) \quad |r(x_1) - r(x_2)| \leq \frac{1}{2}d(x_1, x_2),$$

so the function $r: X \rightarrow \mathbb{R}$ is continuous. This has the following important consequence. Suppose $A \subset X$ is compact. Let A' be the union of all closed balls of radius $r(y)$ and center y , for all $y \in A$. Then A' is also compact. The proof is as follows.

Let z_1, z_2, z_3, \dots be a sequence in A' . For each i there is a $y_i \in A$ such that z_i is in the ball of radius $r(y_i)$ with center y_i . Since A is compact, some subsequence of the y_i , which we might as well assume is the sequence itself, converges to some point $y \in A$. Now the closed ball B of radius $\frac{3}{2}r(y)$ and

center y is compact. Since $y_i \rightarrow y$ and since the function r is continuous, eventually the closed balls

$$\{y \in X : d(y, y_i) \leq r(y_i)\}$$

are contained in B . So the sequence z_i is eventually in the compact set B , and consequently some subsequence converges. Moreover, the limit point is actually in the closed ball of radius $r(y)$ and center y (Problem 10). Thus A' is compact.

Now let $x_0 \in X$ and consider the compact sets

$$\begin{aligned} A_1 &= \{x_0\} \\ A_{n+1} &= A_n'. \end{aligned}$$

Their union A is clearly open. It is also closed. To see this, suppose that x is a point in the closure of A . Then there is some $y \in A$ with $d(x, y) < \frac{2}{3}r(x)$.

By (1),

$$\begin{aligned} r(y) &\geq r(x) - \frac{1}{2}d(x, y) \\ &> r(x) - \frac{1}{2} \cdot \frac{2}{3}r(x) = \frac{2}{3}r(x) \\ &> d(x, y). \end{aligned}$$

This shows that if $y \in A_n$, then $x \in A_n'$, so $x \in A$.

Since X is connected, and $A \neq \emptyset$ is open and closed, it must be that $X = A$, which is σ -compact. ♦

After this hassle with point-set topology, we present the long-promised examples of manifolds. The only connected 1-manifolds are the line \mathbb{R} and the circle, or 1-dimensional sphere, S^1 , defined by

$$S^1 = \{x \in \mathbb{R}^2 : d(x, 0) = 1\}.$$

The function $f: (0, 2\pi) \rightarrow S^1$ defined by $f(\theta) = (\cos \theta, \sin \theta)$ is a homeomorphism; it is even continuous, though not one-one, on $[0, 2\pi]$. We will often denote the point $(\cos \theta, \sin \theta) \in S^1$ simply by $\theta \in [0, 2\pi]$. (Of course, it is always necessary to check that use of this notation is valid.) The function $g: (-\pi, \pi) \rightarrow S^1$, defined by the same formula, is also a homeomorphism; together with f it shows that S^1 is indeed a manifold.

There is another way to prove this, better suited to generalization. The projection P from the point $(0, 1)$ onto the line $\mathbb{R} \times \{-1\} \subset \mathbb{R} \times \mathbb{R}$, illustrated in

the above diagram, is a homeomorphism of $S^1 - \{(0, 1)\}$ onto $\mathbb{R} \times \{-1\}$: this is proved most simply by calculating $P: S^1 - \{(0, 1)\} \rightarrow \mathbb{R} \times \{-1\}$ explicitly. The point $(0, 1)$ may be taken care of similarly, by projecting onto $\mathbb{R} \times \{1\}$, or it suffices to note that S^1 is “homogeneous”—there is a homeomorphism taking any point into any other (namely, an appropriate rotation of \mathbb{R}^2). Considerations similar to these now show that the n -sphere

$$S^n = \{x \in \mathbb{R}^{n+1} : d(x, 0) = 1\}$$

is an n -manifold. The 2-sphere S^2 , commonly known as “the sphere”, is our first example of a compact 2-manifold or surface.

From these few manifolds we can already construct many others by noting that if M_i are manifolds of dimension n_i ($i = 1, 2$), then $M_1 \times M_2$ is an $(n_1 + n_2)$ -manifold. In particular

$$\underbrace{S^1 \times \cdots \times S^1}_{n \text{ times}}$$

is called the n -torus, while $S^1 \times S^1$ is commonly called “the torus”. It is obviously homeomorphic to a subset of \mathbb{R}^4 , and it is also homeomorphic to a certain subset of \mathbb{R}^3 which is what most people have in mind when they speak of

“the torus”: This subset may be obtained by revolving the circle

$$\{(0, y, z) \in \mathbb{R}^3 : (y - 1)^2 + z^2 = 1/4\}$$

around the z -axis. The same construction may be applied to any 1-manifold

contained in $\{(0, y, z) \in \mathbb{R}^3 : y > 0\}$. The resulting surface, called a **surface of revolution**, has components homeomorphic either to the torus or to the cylinder $S^1 \times \mathbb{R}$, the latter of which is also homeomorphic to the annulus, the region of the plane contained between two concentric circles.

The next simplest compact 2-manifold is the 2-holed torus. To provide a more

explicit description of the 2-holed torus, it is easiest to begin with a “handle”, a space homeomorphic to a torus with a hole cut out; more precisely, we throw

away all the points on one side of a certain circle, which remains in our handle, and which will be referred to as the boundary of the handle. The 2-holed

torus may be obtained by piecing two of these together; it is also described as

the disjoint union of two handles with corresponding points on the boundaries "identified".

The n -holed torus may be obtained by repeated applications of this procedure. It is homeomorphic to the space obtained by starting with the disjoint

union of n handles and a sphere with n holes, and then identifying points on the boundary of the i^{th} handle with corresponding points on the i^{th} boundary piece of the sphere.

There is one 2-manifold of which most budding mathematicians make the acquaintance when they still know more about paper and paste than about

metric spaces—the famous *Möbius strip*, which you “make” by giving a strip of paper a half twist before pasting its ends together. This can be described

analytically as the image in \mathbb{R}^3 of the function $f : [0, 2\pi] \times (-1, 1) \rightarrow \mathbb{R}^3$ defined by

$$f(\theta, t) = \left(2 \cos \theta + t \cos \frac{\theta}{2} \cos \theta, 2 \sin \theta + t \cos \frac{\theta}{2} \sin \theta, t \sin \frac{\theta}{2} \right).$$

If we define f on $[0, 2\pi] \times [-1, 1]$ instead, we obtain the Möbius strip with a boundary; as investigation of the paper model will show, this boundary is homeomorphic to a circle, not to two disjoint circles. With our recently introduced terminology, the Möbius strip can also be described as $[0, 1] \times (-1, 1)$ with $(0, t)$ and $(1, -t)$ “identified”.

We have not yet had to make precise this notion of “identification”, but our next example will force the issue. We wish to identify each point $x \in S^2$ with

its antipodal point $-x \in S^2$. The space which results, the **projective plane**, \mathbb{P}^2 , is a lot harder to visualize than previous examples; indeed, there is no subset of \mathbb{R}^3 which represents it adequately.

The precise definition of \mathbb{P}^2 uses the same trick that mathematicians always use when they want two things which are not equal to be equal. The *points* of \mathbb{P}^2 are defined to be the sets $\{p, -p\}$ for $p \in S^2$. We will denote this set by $[p] \in \mathbb{P}^2$, so that $[-p] = [p]$. We thus have a map $f: S^2 \rightarrow \mathbb{P}^2$ given by $f(p) = [p]$, for which $f(p) = f(q)$ implies $p = \pm q$. We will postpone for a while the problem of defining the metric giving the distance between two points $[p]$ and $[q]$, but we can easily say what the open sets will turn out to be (and this is all you need to know in order to check that \mathbb{P}^2 is a surface). A subset $U \subset \mathbb{P}^2$ will be open if and only if $f^{-1}(U) \subset S^2$ is open. This just means that the open sets of \mathbb{P}^2 are of the form $f(V)$ where $V \subset S^2$ is an open set with the additional important property that if it contains p it also contains $-p$.

In exactly the same way, we could have defined the points of the Möbius strip M to be

$$\text{all points } (s, t) \in (0, 1) \times (-1, 1)$$

together with

$$\text{all sets } \{(0, t), (1, -t)\}, \quad \text{denoted by } [(0, t)] \text{ or } [(1, -t)].$$

There is a map $f: [0, 1] \times (-1, 1) \rightarrow M$ given by

$$f((s, t)) = \begin{cases} (s, t) & \text{if } s \neq 0, 1 \\ [(s, t)] & \text{if } s = 0 \text{ or } 1, \end{cases}$$

and $U \subset M$ is open if and only if $f^{-1}(U) \subset [0, 1] \times (-1, 1)$ is open, so that the open sets of M are of the form $f(V)$ where V is open and contains $(s, -t)$ whenever it contains (s, t) for $s = 0$ or 1 .

To get an idea of what \mathbb{P}^2 looks like, we can make things easier for ourselves by first throwing away all points of S^2 below the (x, y) -plane, since they are identified with points above the (x, y) -plane anyway. This leaves the upper hemisphere (including the bounding circle), which is homeomorphic to the disc

$$D^2 = \{x \in \mathbb{R}^2 : d(x, 0) \leq 1\},$$

and we must identify each $p \in S^1$ with $-p \in S^1$. Squaring things off a bit, this is the same as identifying points on the sides of a square according to the scheme shown below (points on sides with the same label are identified in such a way that the heads of the arrows are identified with each other). The dotted lines in this picture are the key to understanding \mathbb{P}^2 . If we distort the

region between them a bit we see that the front part of B followed by the back part of A , at the upper left, is to be identified with the same thing at the lower right, in reverse direction; in other words, we obtain a Möbius strip with

a boundary (namely, the dotted line, which is a single circle). If this Möbius strip is removed, we are left with two pieces which can be rearranged to form something homeomorphic to a disc. The projective plane is thus obtained from

the disjoint union of a disc and a Möbius strip with a boundary, by identifying points on the boundary and points on the boundary of the disc, both of which are circles. Thus to make a model of \mathbb{P}^2 we just have to sew a circular piece of cloth and a cloth Möbius strip together along their edges. Unfortunately, a little experimentation will convince you that this cannot be done (without having the two pieces of cloth pass through each other).

The subset of \mathbb{R}^3 obtained as the union of the Möbius strip and a disc, although not homeomorphic to \mathbb{P}^2 , can still be described mathematically in terms

of \mathbb{P}^2 . There is clearly a continuous function $f: \mathbb{P}^2 \rightarrow \mathbb{R}^3$ whose image is this subset; moreover, although f is not one-one, it is **locally one-one**, that is, every point $p \in \mathbb{P}^2$ has a neighborhood U on which f is one-one. Such a function f

is called a **topological immersion** (the single word “immersion” has a more specialized meaning, explained in Chapter 2). We can thus say that \mathbb{P}^2 can be topologically immersed in \mathbb{R}^3 , although not topologically imbedded (there is no homeomorphism f from \mathbb{P}^2 to a subset of \mathbb{R}^3). In \mathbb{R}^4 , however, with an extra dimension to play around with, the disc can be added so as not to intersect the Möbius strip.

Another topological immersion of \mathbb{P}^2 in \mathbb{R}^3 can be obtained by first immersing the Möbius strip so that its boundary circle lies in a plane; this can be done in the following way. The figures below show that the Möbius strip may be obtained from an annulus by identifying opposite points of the inner circle. (This is also obvious from the fact that the Möbius strip is the projective plane with a disc removed.) This inner circle can be replaced by a quadrilateral. When the

resulting figure is drawn up into 3-space and the appropriate identifications are made we obtain the “cross-cap”. The cross-cap together with the disc at the bottom is a topologically immersed \mathbb{P}^2 .

The one gap in the preceding discussion is the definition of a metric for \mathbb{P}^2 . The missing metric can be supplied by an appeal to Problem 3-1, which will later be used quite often, and which the reader should peruse sometime before reading Chapter 3. Roughly speaking, it shows that things like \mathbb{P}^2 , which ought to be manifolds, are. (Those who know about topological spaces will recognize it as a disguised case of the Urysohn Metrization Theorem.) For the present, however, we will obtain our metric by a trick that simultaneously provides an imbedding of \mathbb{P}^2 in \mathbb{R}^4 . Consider the function $f: S^2 \rightarrow \mathbb{R}^4$ defined by

$$f(x, y, z) = (yz, xz, xy, x^2 + 2y^2 + 3z^2).$$

(Clearly $f(p) = f(-p)$.) We maintain that $f(p) = f(q)$ implies that $p = \pm q$. To prove this, suppose that $f(x, y, z) = f(a, b, c)$. We have, first of all

$$(1) \quad \begin{aligned} yz &= bc \\ xz &= ac \\ xy &= ab. \end{aligned}$$

If $a, b, c \neq 0$, this leads to

$$(2) \quad \begin{aligned} y &= \frac{bx}{a} \\ z &= \frac{cx}{a}. \end{aligned}$$

Now

$$\begin{aligned} (x + y + z)^2 &= x^2 + y^2 + z^2 + 2(xy + xz + yz) \\ &= 1 + 2(xy + xz + yz), \end{aligned}$$

so we also have

$$(x + y + z)^2 = (a + b + c)^2,$$

hence

$$(3) \quad a + b + c = \pm(x + y + z).$$

Using (2), this gives

$$a + b + c = \pm x \left(1 + \frac{b}{a} + \frac{c}{a} \right) = \pm x \left(\frac{a + b + c}{a} \right),$$

so $x = \pm a$. Similarly, we obtain $y = \pm b$, $z = \pm b$, with the same sign (which comes from (3)) holding for all three equations. In this case we have proved our contention without even using the fourth coordinate of f . Now suppose $a = 0$. If $x \neq 0$, then (1) would immediately give $y = z = 0$, so that

$$(x, y, z) = (\pm 1, 0, 0).$$

But $y = z = 0$ implies (by (1) again) that $bc = 0$, so $b = 0$ or $c = 0$ and

$$(a, b, c) = (0, \pm 1, 0) \text{ or } (0, 0, \pm 1).$$

These equations clearly contradict

$$x^2 + 2y^2 + 3z^2 = a^2 + 2b^2 + 3c^2.$$

Thus $x = 0$ also, and we have

$$(4) \quad yz = bc$$

$$(5) \quad 2y^2 + 3z^2 = 2b^2 + 3c^2$$

$$(6) \quad y^2 + z^2 = 1$$

$$b^2 + c^2 = 1.$$

But (6) implies that

$$\begin{aligned} 2y^2 + 3z^2 &= 2y^2 + 3(1 - y^2) \\ &= 3 - y^2, \end{aligned}$$

and similarly for b and c , so (5) gives

$$(7) \quad \begin{aligned} 3 - y^2 &= 3 - b^2 \\ y &= \pm b. \end{aligned}$$

Now (4) gives

$$(8) \quad z = \pm c$$

(this holds even if $y = b = 0$, since then $z, c = \pm 1$). Clearly, (4) also shows that the same sign holds in (7) and (8), which completes the proof.

Since $f(p) = f(q)$ precisely when $p = \pm q$, we can define $\tilde{f}: \mathbb{P}^2 \rightarrow \mathbb{R}^4$ by

$$\tilde{f}([p]) = f(p).$$

This map is one-one and we can use it to define the metric in \mathbb{P}^2 :

$$\tilde{d}([p], [q]) = d(\tilde{f}([p]), \tilde{f}([q])) = d(f(p), f(q)).$$

Then one can check that the open sets are indeed the ones described above.

By the way, the map $g: \mathbb{P}^2 \rightarrow \mathbb{R}^3$ defined by the first 3 components of f ,

$$g([x, y, z]) = (yz, xz, xy)$$

is a topological immersion of \mathbb{P}^2 in \mathbb{R}^3 . The image in \mathbb{R}^3 is Steiner's "Roman surface".

With the new surface \mathbb{P}^2 at our disposal, we can create other surfaces in the same way as the n -holed torus. For example, to a handle we can attach a projective space with a hole cut out, or, what amounts to the same thing, a Möbius strip. The closest we can come to picturing this is by drawing a cross-cap sticking on a torus. We can also join together a pair of projective planes with holes cut out, which amounts to sewing two Möbius strips together along their boundary. Although this can be pictured as two cross-caps joined together, it has a nicer, and famous, representation. Consider the surface obtained from the square with identifications indicated below; it may also be obtained from the cylinder $[0, 1] \times S^1$ by identifying $(0, x) \in [0, 1] \times S^1$ with $(1, x')$, where x' is the reflection of x through a fixed diameter of the circle. Notice that the

identifications on the square force P_1 , P_2 , P_3 , and P_4 to be identified, so that the set $\{P_1, P_2, P_3, P_4\}$ is a single point of our new space. The dotted lines

below, dividing the sides into thirds, form a single circle, which separates the surface into two parts, one of which is shaded.

Rearrangement of the two parts shows that this surface is precisely two Möbius strips with corresponding points on their boundary identified. The description in terms of $[0, 1] \times S^1$ immediately suggests an immersion of the surface. Turning one end of the cylinder around and pushing it through itself orients the left-hand boundary so that $(0, x)$ is directly opposite $(1, x')$, to which it can then be joined, forming the "Klein bottle".

Examples of higher-dimensional manifolds will not be treated in nearly such detail, but, in addition to the family of n -manifolds S^n , we will mention the related family of “projective spaces”. **Projective n -space** \mathbb{P}^n is defined as the collection of all sets $\{p, -p\}$ for $p \in S^n$. The description of the open sets in \mathbb{P}^n is precisely analogous to the description for \mathbb{P}^2 . Although these spaces seem to form a family as regular as the family S^n , we will see later that the spaces \mathbb{P}^n for even n differ in a very important way from the same spaces for odd n .

One further definition is needed to complete this introduction to manifolds. We have already discussed some spaces which are not manifolds only because they have a “boundary”, for example, the Möbius strip and the disc. Points on these “boundaries” do not have neighborhoods homeomorphic to \mathbb{R}^n , but they do have neighborhoods homeomorphic to an important subset of \mathbb{R}^n . The (closed) **half-space** \mathbb{H}^n is defined by

$$\mathbb{H}^n = \{(x^1, \dots, x^n) \in \mathbb{R}^n : x^n \geq 0\}.$$

A **manifold-with-boundary** is a metric space M with the following property:

If $x \in M$, then there is some neighborhood U of x and some integer $n \geq 0$ such that U is homeomorphic to either \mathbb{R}^n or \mathbb{H}^n .

A point in a manifold-with-boundary cannot have a neighborhood homeomorphic to both \mathbb{R}^n and \mathbb{H}^n (Invariance of Domain again); we can therefore distinguish those points $x \in M$ having a neighborhood homeomorphic to \mathbb{H}^n . The set of all such x is called the **boundary** of M and is denoted by ∂M . If M is actually a manifold, then $\partial M = \emptyset$. Notice that if M is a subset of \mathbb{R}^n , then ∂M is not necessarily the same as the boundary of M in the old sense (defined for any subset of \mathbb{R}^n); indeed, if M is a manifold-with-boundary of dimension $< n$, then all points of M will be boundary points of M .

If manifolds-with-boundary are studied as frequently as manifolds, it becomes bothersome to use this long designation. Often, the word “manifold” is used for “manifold-with-boundary”. A manifold in our sense is then called “non-bounded”; a non-bounded compact manifold is called a “closed manifold”. We will stick to the other terminology, but will sometimes use “bounded manifold” instead of “manifold-with-boundary”.

PROBLEMS

1. Show that if d is a metric on X , then both $\bar{d} = d/(1 + d)$ and $\bar{d} = \min(1, d)$ are also metrics and that they are equivalent to d (i.e., the identity map $1: (X, d) \rightarrow (X, \bar{d})$ is a homeomorphism).
2. If (X_i, d_i) are metric spaces, for $i \in I$, with metrics $d_i < 1$, and $X_i \cap X_j = \emptyset$ for $i \neq j$, then (X, d) is a metric space, where $X = \bigcup_i X_i$, and $d(x, y) = d_i(x, y)$ if $x, y \in X_i$ for some i , while $d(x, y) = 1$ otherwise. Each X_i is an open subset of X , and Y is homeomorphic to X if and only if $Y = \bigcup_i Y_i$ where the Y_i are disjoint open sets and Y_i is homeomorphic to X_i for each i . The space (X, d) (or any space homeomorphic to it) is called the **disjoint union** of the spaces X_i .
3. (a) Every manifold is locally compact.
 (b) Every manifold is locally pathwise connected, and a connected manifold is pathwise connected.
 (c) A connected manifold is arcwise connected. (A path is a continuous image of $[0, 1]$, but an arc is a *one-one* continuous image. A difficult theorem states that every path contains an arc between its end points, but a direct proof of arcwise-connectedness can be given for manifolds.)
4. A space X is called locally connected if for each $x \in X$ it is the case that every neighborhood of x contains a connected neighborhood.
 (a) Connectedness does not imply local connectedness.
 (b) An open subset of a locally connected space is locally connected.
 (c) X is locally connected if and only if components of open sets are open, so every neighborhood of a point in a locally connected space contains an *open* connected neighborhood.
 (d) A locally connected space is homeomorphic to the disjoint union of its components.
 (e) Every manifold is locally connected, and consequently homeomorphic to the disjoint union of its components, which are open submanifolds.
5. (a) The neighborhood U in our definition of a manifold is always open.
 (b) The integer n in our definition is unique for each x .
6. (a) A subset of an n -manifold is an n -manifold if and only if it is open.
 (b) If M is connected, then the dimension of M at x is the same for all $x \in M$.
7. (a) If $U \subset \mathbb{R}$ is an interval and $f: U \rightarrow \mathbb{R}$ is continuous and one-one, then f is either increasing or decreasing.

- (b) The image $f(U)$ is open.
- (c) The map f is a homeomorphism.

8. For this problem, assume

- (1) (The Generalized Jordan Curve Theorem) If $A \subset \mathbb{R}^n$ is homeomorphic to S^{n-1} , then $\mathbb{R}^n - A$ has 2 components, and A is the boundary of each.
- (2) If $B \subset \mathbb{R}^n$ is homeomorphic to $D^n = \{x \in \mathbb{R}^n : d(x, 0) \leq 1\}$, then $\mathbb{R}^n - B$ is connected.

- (a) One component of $\mathbb{R}^n - A$ (the “outside of A ”) is unbounded, and the other (the “inside of A ”) is bounded.
- (b) If $U \subset \mathbb{R}^n$ is open, $A \subset U$ is homeomorphic to S^{n-1} and $f: U \rightarrow \mathbb{R}^n$ is one-one and continuous (so that f is a homeomorphism on A), then $f(\text{inside of } A) = \text{inside of } f(A)$. (First prove \subset .)
- (c) Prove Invariance of Domain.

- 9. (a) Give an elementary proof that \mathbb{R}^1 is not homeomorphic to \mathbb{R}^n for $n > 1$.
- (b) Prove directly from the Generalized Jordan Curve Theorem that \mathbb{R}^m is not homeomorphic to \mathbb{R}^n for $m \neq n$.

10. In the proof of Theorem 2, show that the limit of a convergent subsequence of the z_i is actually in the closed ball of radius $r(y)$ and center y .

11. Every connected manifold (which is a metric space) has a countable base for its topology, and a countable dense subset.

- 12. (a) Compute the composition $f = S^1 - \{(0, 1)\} \xrightarrow{P} \mathbb{R}^1 \times \{-1\} \rightarrow \mathbb{R}^1$ explicitly for the map P on page 7, and show that it is a homeomorphism.
- (b) Do the same for $f: S^{n-1} - \{(0, \dots, 0, 1)\} \rightarrow \mathbb{R}^{n-1}$.

- 13. (a) The text describes the open subsets of \mathbb{P}^2 as sets of the form $f(V)$, where $V \subset S^2$ is open and contains $-p$ whenever it contains p . Show that this last condition is actually unnecessary.
- (b) The analogous condition is necessary for the Möbius strip, which is discussed immediately afterwards. Explain how the two cases differ.

- 14. (a) Check that the metric defined for \mathbb{P}^2 gives the open sets described in the text.
- (b) Check that \mathbb{P}^2 is a surface.

15. (a) Show that \mathbb{P}^1 is homeomorphic to S^1 .

(b) Since we can consider $S^{n-1} \subset S^n$, and since antipodal points in S^{n-1} are still antipodal when considered as points in S^n , we can consider $\mathbb{P}^{n-1} \subset \mathbb{P}^n$ in an obvious way. Show that $\mathbb{P}^n - \mathbb{P}^{n-1}$ is homeomorphic to interior $D^n = \{x \in \mathbb{R}^n : d(x, 0) < 1\}$.

16. A classical theorem of topology states that every compact surface other than S^2 is obtained by gluing together a certain number of tori and projective spaces, and that all compact surfaces-with-boundary are obtained from these by cutting out a finite number of discs. To which of these “standard” surfaces are the following homeomorphic?

17. Let $C \subset \mathbb{R} \subset \mathbb{R}^2$ be the Cantor set. Show that $\mathbb{R}^2 - C$ is homeomorphic to the surface shown at the top of the next page.

18. A locally compact (but non-compact) space X “has one end” if for every compact $C \subset X$ there is a compact K such that $C \subset K \subset X$ and $X - K$ is connected.

(a) \mathbb{R}^n has one end if $n > 1$, but not if $n = 1$.

(b) $\mathbb{R}^n - \{0\}$ does not “have one end” so $\mathbb{R}^n - \{0\}$ is not homeomorphic to \mathbb{R}^m .

19. This problem is a sequel to the previous one; it will be used in Problem 24. An **end** of X is a function ε which assigns to each compact subset $C \subset X$ a non-empty component $\varepsilon(C)$ of $X - C$, in such a way that $C_1 \subset C_2$ implies $\varepsilon(C_2) \subset \varepsilon(C_1)$.

(a) If $C \subset \mathbb{R}$ is compact, then $\mathbb{R} - C$ has exactly 2 unbounded components, the “left” component containing all numbers $<$ some N , the “right” one containing all numbers $>$ some N . If ε is an end of \mathbb{R} , show that $\varepsilon(C)$ is either always the “left” component of $\mathbb{R} - C$, or always the “right” one. Thus \mathbb{R} has 2 ends.

(b) Show that \mathbb{R}^n has only one end ε for $n > 1$. More generally, X has exactly one end ε if and only if X “has one end” in the sense of Problem 18.

(c) This part requires some knowledge of topological spaces. Let $\mathcal{E}(X)$ be the set of all ends of a connected, locally connected, locally compact Hausdorff space X . Define a topology on $X \cup \mathcal{E}(X)$ by choosing as neighborhoods $N_C(\varepsilon_0)$ of an end ε_0 the sets

$$N_C(\varepsilon_0) = \varepsilon_0(C) \cup \{\text{ends } \varepsilon : \varepsilon(C) = \varepsilon_0(C)\},$$

for all compact C . Show that $X \cup \mathcal{E}(X)$ is a compact Hausdorff space. What is $\mathbb{R} \cup \mathcal{E}(\mathbb{R})$, and $\mathbb{R}^n \cup \mathcal{E}(\mathbb{R}^n)$ for $n > 1$?

20. Consider the following three surfaces.

(A) The infinite-holed torus: 

(B) The doubly infinite-holed torus: \cdots  \cdots

(C) The infinite jail cell window:

(a) Surfaces (A) and (C) have one end, while surface (B) does not.

(b) Surfaces (A) and (C) are homeomorphic! *Hint:* The region cut out by the lines in the picture below is a cylinder, which occurs at the left of (A). Now draw in two more lines enclosing more holes, and consider the region between the two pairs.

21. (a) The three open subsets of \mathbb{R}^2 shown below are homeomorphic.

(b) The points *inside* the three surfaces of Problem 20 are homeomorphic.

22. (a) Every open subset of \mathbb{R} is homeomorphic to the disjoint union of intervals.

(b) There are only countably many non-homeomorphic open subsets of \mathbb{R} .

23. For the purposes of this problem we will use a consequence of the Urysohn Metrization Theorem, that for any connected manifold M , there is a homeomorphism f from M to a subset of the countable product $\mathbb{R} \times \mathbb{R} \times \cdots$.

(a) If M is a connected non-compact manifold, then there is a continuous function $f: M \rightarrow \mathbb{R}$ such that f "goes to ∞ at ∞ ", i.e., if $\{x_n\}$ is a sequence which is eventually in the complement of every compact set, then $f(x_n) \rightarrow \infty$. (Compare with Problem 2-30.)

(b) Given a homeomorphism $f: M \rightarrow \mathbb{R} \times \mathbb{R} \times \cdots$ and a $g: M \rightarrow \mathbb{R}$ which goes to ∞ at ∞ , define $\bar{f}: M \rightarrow \mathbb{R} \times (\mathbb{R} \times \mathbb{R} \times \cdots)$ by $\bar{f}(x) = (g(x), f(x))$. Show that $\bar{f}(M)$ is closed.

(c) There are at most c non-homeomorphic connected manifolds (where $c = 2^{\aleph_0}$ is the cardinality of \mathbb{R}).

24. (a) It is possible for $\mathbb{R}^2 - A$ and $\mathbb{R}^2 - B$ to be homeomorphic even though A and B are non-homeomorphic closed subsets.

(b) If $A \subset \mathbb{R}^2$ is closed and totally disconnected (the only components of A are points), then $\mathcal{E}(\mathbb{R}^2 - A)$ is homeomorphic to A . Hence $\mathbb{R}^2 - A$ and $\mathbb{R}^2 - B$ are non-homeomorphic if A and B are non-homeomorphic closed totally disconnected sets.

(c) The derived set A' of A is the set of all non-isolated points. We define $A^{(n)}$ inductively by $A^{(1)} = A'$ and $A^{(n+1)} = (A^{(n)})'$. For each n there is a subset A_n of \mathbb{R} such that $A_n^{(n)}$ consists of one point.

*(d) There are \mathfrak{c} non-homeomorphic closed totally disconnected subsets of \mathbb{R}^2 .

Hint: Let C be the Cantor set, and $c_1 < c_2 < c_3 < \dots$ a sequence of points in C . For each sequence $n_1 < n_2 < \dots$, one can add a set A_{n_i} such that its n_i^{th} derived set is $\{c_i\}$.

(e) There are \mathfrak{c} non-homeomorphic connected open subsets of \mathbb{R}^2 .

25. (a) A manifold-with-boundary could be defined as a metric space M with the property that for each $x \in M$ there is a neighborhood U of x and an integer $n \geq 0$ such that U is homeomorphic to an open subset of \mathbb{H}^n .

(b) If M is a manifold-with-boundary, then ∂M is a closed subset of M and ∂M and $M - \partial M$ are manifolds.

(c) If $C_i, i \in I$ are the components of ∂M , and $I' \subset I$, then $M - \bigcup_{i \in I'} C_i$ is a manifold-with-boundary.

26. If $M \subset \mathbb{R}^n$ is a closed set and an n -dimensional manifold-with-boundary, then the topological boundary of M , as a subset of \mathbb{R}^n , is ∂M . This is not necessarily true if M is not a closed subset.

27. (a) Every point (a, b, c) on Steiner's surface satisfies $b^2c^2 + a^2c^2 + a^2b^2 = abc$.

(b) If (a, b, c) satisfies this equation and $0 \neq D = \sqrt{b^2c^2 + a^2c^2 + a^2b^2}$, then (a, b, c) is on Steiner's surface. *Hint:* Let $x = bc/D$, etc.

(c) The set $\{(a, b, c) \in \mathbb{R}^3 : b^2c^2 + a^2c^2 + a^2b^2 = abc\}$ is the union of the Steiner surface and of the portions $(-\infty, -1/2)$ and $(1/2, \infty)$ of each axis.

CHAPTER 2

DIFFERENTIABLE STRUCTURES

We are now ready to apply analysis to the study of manifolds. The necessary tools of “advanced calculus”, which the reader should bring along freshly sharpened, are contained in Chapters 2 and 3 of *Calculus on Manifolds*. We will use freely the notation and results of these chapters, *including* some problems, notably 2-9, 2-15, 2-25, 2-26, 2-29, 3-32, and 3-35; however, we will denote the identity map from \mathbb{R}^n to \mathbb{R}^n by I , rather than by π (which will be used often enough in other contexts), so that $I^i(x) = x^i$.

On a general manifold M the notion of a continuous function $f: M \rightarrow \mathbb{R}$ makes sense, but the notion of a differentiable function $f: M \rightarrow \mathbb{R}$ does not. This is the case despite the fact that M is locally like \mathbb{R}^n , where differentiability of functions can be defined. If $U \subset M$ is an open set and we choose a homeomorphism $\phi: U \rightarrow \mathbb{R}^n$, it would seem reasonable to define f to be differentiable on U if $f \circ \phi^{-1}: \mathbb{R}^n \rightarrow \mathbb{R}$ is differentiable. Unfortunately, if $\psi: V \rightarrow \mathbb{R}^n$ is another homeomorphism, and $U \cap V \neq \emptyset$, then it is not necessarily true that $f \circ \psi^{-1}: \mathbb{R}^n \rightarrow \mathbb{R}$ is also differentiable. Indeed, since

$$f \circ \psi^{-1} = f \circ \phi^{-1} \circ (\phi \circ \psi^{-1}),$$

we can expect $f \circ \psi^{-1}$ to be differentiable for all f which make $f \circ \phi^{-1}$ differentiable only if $\phi \circ \psi^{-1}: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is differentiable. This is certainly not always

the case; for example, one need merely choose ϕ to be $h \circ \psi$, where $h: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a homeomorphism that is not differentiable.

If we insist on defining differentiable functions on any manifold, there is no way out of this impasse. It is necessary to adorn our manifolds with a little additional structure, the precise nature of which is suggested by the previous discussion.

Among all possible homeomorphisms from $U \subset M$ onto \mathbb{R}^n , we wish to select a certain collection with the property that $\phi \circ \psi^{-1}$ is differentiable whenever ϕ, ψ are in the collection. This is precisely what we shall do, but a few refinements will be introduced along the way.

First of all, we will be interested almost exclusively in functions $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ which are C^∞ (that is, each component function f^i possesses continuous partial derivatives of all orders); sometimes we will use the words “differentiable” or “smooth” to mean C^∞ .

Moreover, instead of considering homeomorphisms from open subsets U of M onto \mathbb{R}^n , it will suffice to consider homeomorphisms $x: U \rightarrow x(U) \subset \mathbb{R}^n$ onto open subsets of \mathbb{R}^n .

The use of the letters x, y , etc., for these homeomorphisms, henceforth adhered to almost religiously, is meant to encourage the casual confusion of a point $p \in M$ with $x(p) \in \mathbb{R}^n$, which has “coordinates” $x^1(p), \dots, x^n(p)$. The only time this notation will be confusing (and it will be) is when we are referring to the manifold \mathbb{R}^n , where it is hard not to lapse back into the practice of denoting points by x and y . We will often mention the pair (x, U) , instead of x alone, just to provide a convenient name for the domain of x .

If U and V are open subsets of M , two homeomorphisms $x: U \rightarrow x(U) \subset \mathbb{R}^n$ and $y: V \rightarrow y(V) \subset \mathbb{R}^n$ are called C^∞ -related if the maps

$$\begin{aligned} y \circ x^{-1}: x(U \cap V) &\rightarrow y(U \cap V) \\ x \circ y^{-1}: y(U \cap V) &\rightarrow x(U \cap V) \end{aligned}$$

are C^∞ . This makes sense, since $x(U \cap V)$ and $y(U \cap V)$ are open subsets of \mathbb{R}^n . Also, it makes sense, and is automatically true, if $U \cap V = \emptyset$.

A family of mutually C^∞ -related homeomorphisms whose domains cover M is called an atlas for M . A particular member (x, U) of an atlas \mathcal{A} is called a chart (for the atlas \mathcal{A}), or a coordinate system on U , for the obvious reason that it provides a way of assigning “coordinates” to points on U , namely, the coordinates $x^1(p), \dots, x^n(p)$ to the point $p \in U$.

We can even imagine a mesh of coordinate lines on U , by considering the

inverse images under x of lines in \mathbb{R}^n parallel to one of the axes.

The simplest example of a manifold together with an atlas consists of \mathbb{R}^n with an atlas \mathcal{A} of only one map, the identity $I: \mathbb{R}^n \rightarrow \mathbb{R}^n$. We can easily make the atlas bigger; if U and V are homeomorphic open subsets of \mathbb{R}^n , we can adjoin any homeomorphism $x: U \rightarrow V$ with the property that x and x^{-1} are C^∞ . Indeed, we can adjoin as many such x 's as we like—it is easy to check that they are all C^∞ -related to each other. The advantage of this bigger atlas \mathcal{U} is that the single word “chart”, when applied to this atlas, denotes something which must be described in cumbersome language if one can refer only to \mathcal{A} . Aside from this, \mathcal{U} differs only superficially from \mathcal{A} ; one can easily construct \mathcal{U} from \mathcal{A} (and one would be foolish not to do so once and for all). What has just been said for the atlas $\{I\}$ applies to any atlas:

1. LEMMA. If \mathcal{A} is an atlas of C^∞ -related charts on M , then \mathcal{A} is contained in a unique maximal atlas \mathcal{A}' for M .

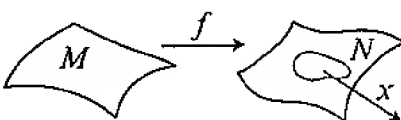

PROOF. Let \mathcal{A}' be the set of all charts y which are C^∞ -related to all charts $x \in \mathcal{A}$. It is easy to check that all charts in \mathcal{A}' are C^∞ -related, so \mathcal{A}' is an atlas, and it is clearly the unique maximal atlas containing \mathcal{A} . ♦

We now define a C^∞ manifold (or differentiable manifold, or smooth manifold) to be a pair (M, \mathcal{A}) , where \mathcal{A} is a maximal atlas for M . Thus, about the simplest example of a C^∞ manifold is $(\mathbb{R}^n, \mathcal{U})$, where \mathcal{U} (the “usual C^∞ -structure for \mathbb{R}^n ”) is the maximal atlas containing $\{I\}$. Another example is $(\mathbb{R}, \mathcal{V})$ where \mathcal{V} contains the homeomorphism $x \mapsto x^3$, whose inverse is *not* C^∞ , together with all charts C^∞ -related to it. Although $(\mathbb{R}, \mathcal{U})$ and $(\mathbb{R}, \mathcal{V})$ are not the same, there is a one-one onto function $f: \mathbb{R} \rightarrow \mathbb{R}$ such that

$$x \in \mathcal{U} \text{ if and only if } x \circ f \in \mathcal{V},$$

namely, the obvious map $f(x) = x^3$. Thus $(\mathbb{R}, \mathcal{U})$ and $(\mathbb{R}, \mathcal{V})$ are the sort of structures one would want to call “isomorphic”. The term actually used is

“diffeomorphic”: two C^∞ manifolds (M, \mathcal{A}) and (N, \mathcal{B}) are **diffeomorphic** if there is a one-one onto function $f: M \rightarrow N$ such that

$$x \in \mathcal{B} \text{ if and only if } x \circ f \in \mathcal{A}.$$

The map f is called a **diffeomorphism**, and f^{-1} is clearly a diffeomorphism also. If we had not required our atlases to be maximal, the definition of diffeomorphism would have had to be more complicated.

Normally, of course, we will suppress mention of the atlas for a differentiable manifold, and speak elliptically of “the differentiable manifold M ”; the atlas for M is sometimes referred to as the *differentiable structure* for M . It will always be understood that \mathbb{R}^n refers to the pair $(\mathbb{R}^n, \mathcal{U})$.

It is easy to see that a diffeomorphism must be continuous. Consequently, its inverse must also be continuous, so that a diffeomorphism is automatically a homeomorphism. This raises the natural question whether, conversely, two homeomorphic manifolds are necessarily diffeomorphic. Later (Problem 9-24) we will be able to prove easily that \mathbb{R} with any atlas is diffeomorphic to $(\mathbb{R}, \mathcal{U})$. A proof of the corresponding assertion for \mathbb{R}^2 is much harder, the proof for \mathbb{R}^3 would certainly be too difficult for inclusion here, and the proof of the essential uniqueness of C^∞ structures on \mathbb{R}^n for $n \geq 5$ requires very difficult techniques from topology.

In the case of spheres, the projections P_1 and P_2 from the points $(0, \dots, 0, 1)$ and $(0, \dots, 0, -1)$ of S^{n-1} are easily seen to be C^∞ -related. They therefore determine an atlas—the “usual C^∞ structure for S^{n-1} ”. This atlas may also be described in terms of the $2n$ homeomorphisms

$$\begin{aligned} f_i: S^{n-1} \cap \{x \in \mathbb{R}^n : x^i > 0\} &\rightarrow \mathbb{R}^{n-1} \\ g_i: S^{n-1} \cap \{x \in \mathbb{R}^n : x^i < 0\} &\rightarrow \mathbb{R}^{n-1} \end{aligned}$$

defined by $f_i(x) = g_i(x) = (x^1, \dots, x^{i-1}, x^{i+1}, \dots, x^n)$, which are C^∞ -related to P_1 and P_2 . There are, up to diffeomorphism, unique differentiable structures on S^n for $n \leq 6$. But there are 28 diffeomorphism classes of differentiable structures on S^7 , and over 16 million on S^{31} . However, we shall not come close to proving these assertions, which are part of the field called “differential topology”, rather than differential geometry. (Perhaps most astonishing of all is the quite recent discovery that \mathbb{R}^4 has a differentiable structure that is not diffeomorphic to the usual differentiable structure!)

Other examples of differentiable manifolds will be given soon, but we can already describe a differentiable structure \mathcal{A}' on any open submanifold N of

a differentiable manifold (M, \mathcal{A}) ; the atlas \mathcal{A}' consists of all (x, U) in \mathcal{A} with $U \subset N$.

Just as diffeomorphisms are analogues for C^∞ manifolds of homeomorphisms, there are analogues of continuous maps. A function $f: M \rightarrow N$ is called **differentiable** if for every coordinate system (x, U) for M and (y, V) for N , the map $y \circ f \circ x^{-1}: \mathbb{R}^n \rightarrow \mathbb{R}^m$ is differentiable. More particularly, f

is called **differentiable at $p \in M$** if $y \circ f \circ x^{-1}$ is differentiable at $x(p)$ for coordinate systems (x, U) and (y, V) with $p \in U$ and $f(p) \in V$. If this is true for one pair of coordinate systems, it is easily seen to be true for any other pair. We can thus define differentiability of f on any open subset $M' \subset M$; as one would suspect, this coincides with differentiability of the restricted map $f|_{M'}: M' \rightarrow N$. Clearly, a differentiable map is continuous.

A differentiable function $f: M \rightarrow \mathbb{R}$ refers, of course, to the usual differentiable structure on \mathbb{R} , and hence f is differentiable if and only if $f \circ x^{-1}$ is differentiable for each chart x . It is easy to see that

- (1) a function $f: \mathbb{R}^n \rightarrow \mathbb{R}^m$ is differentiable as a map between C^∞ manifolds if and only if it is differentiable in the usual sense;
- (2) a function $f: M \rightarrow \mathbb{R}^m$ is differentiable if and only if each $f^i: M \rightarrow \mathbb{R}^m$ is differentiable;
- (3) a coordinate system (x, U) is a diffeomorphism from U to $x(U)$;
- (4) a function $f: M \rightarrow N$ is differentiable if and only if each $y^i \circ f$ is differentiable for each coordinate system y of N ;
- (5) a differentiable function $f: M \rightarrow N$ is a diffeomorphism if and only if f is one-one onto and $f^{-1}: N \rightarrow M$ is differentiable.

The differentiable structures on many manifolds are designed to make certain functions differentiable. Consider first the product $M_1 \times M_2$ of two differen-

tiabile manifolds M_i , and the two “projections” $\pi_i: M_1 \times M_2 \rightarrow M_i$ defined by $\pi_i(p_1, p_2) = p_i$. It is easy to define a differentiable structure on $M_1 \times M_2$ which makes each π_i differentiable. For each pair (x_i, U_i) of coordinate systems on M_i , we construct the homeomorphism

$$x_1 \times x_2: U_1 \times U_2 \rightarrow \mathbb{R}^{n_1+n_2}$$

defined by

$$x_1 \times x_2(p_1, p_2) = (x_1(p_1), x_2(p_2)), \quad \text{i.e.,} \quad x_1 \times x_2 = (x_1 \circ \pi_1, x_2 \circ \pi_2).$$

Then we extend this atlas to a maximal one.

Similarly, there is a differentiable structure on \mathbb{P}^n which makes the map $f: S^n \rightarrow \mathbb{P}^n$ (defined by $f(p) = [p] = \{p, -p\}$) differentiable. Consider any coordinate system (x, U) for S^n , where U does *not* contain $-p$ if it contains p , so that $f|U$ is one-one. The map $x \circ (f|U)^{-1}$ is a homeomorphism on $f(U) \subset \mathbb{P}^n$, and any two such are C^∞ -related. The collection of these homeomorphisms can then be extended to a maximal atlas.

To obtain differentiable structures on other surfaces, we first note that a C^∞ manifold-with-boundary can be defined in an obvious way. It is only necessary to know when a map $f: \mathbb{H}^n \rightarrow \mathbb{R}^n$ is to be considered differentiable; we call f **differentiable** when it can be extended to a differentiable function on an open neighborhood of \mathbb{H}^n . A “handle” is then a C^∞ manifold-with-boundary.

A differentiable structure on the 2-holed torus can be obtained by “matching” the differentiable structure on two handles. The details involved in this process are reserved for Problem 14.

To deal with C^∞ functions effectively, one needs to know that there are lots of them. The existence of C^∞ functions on a manifold depends on the existence of C^∞ functions on \mathbb{R}^n which are 0 outside of a compact set. We briefly recall here the necessary facts about such C^∞ functions (c.f. *Calculus on Manifolds*, pg. 29).

(1) The function $h: \mathbb{R} \rightarrow \mathbb{R}$ defined by

$$h(x) = \begin{cases} e^{-1/x^2} & x \neq 0 \\ 0 & x = 0 \end{cases}$$

is C^∞ , and $h^{(n)}(0) = 0$ for all n .

(2) The function $j: \mathbb{R} \rightarrow \mathbb{R}$ defined by

$$j(x) = \begin{cases} e^{-(x-1)^{-2}} \cdot e^{-(x+1)^{-2}} & x \in (-1, 1) \\ 0 & x \notin (-1, 1) \end{cases}$$

is C^∞ .

Similarly, there is a C^∞ function $k: \mathbb{R} \rightarrow \mathbb{R}$ which is positive on $(0, \delta)$ and 0 elsewhere.

(3) The function $l: \mathbb{R} \rightarrow \mathbb{R}$ defined by

$$l(x) = \left(\int_0^x k \right) / \left(\int_0^\delta k \right)$$

is C^∞ ; it is 0 for $x \leq 0$, increasing on $(0, \delta)$, and 1 for $x \geq \delta$.

(4) The function $g: \mathbb{R}^n \rightarrow \mathbb{R}$ defined by

$$g(x) = j(x^1/\varepsilon) \cdots j(x^n/\varepsilon)$$

is C^∞ ; it is positive on $(-\varepsilon, \varepsilon) \times \cdots \times (-\varepsilon, \varepsilon)$ and 0 elsewhere.

On a C^∞ manifold M we can now produce many non-constant C^∞ functions. The closure $\overline{\{x : f(x) \neq 0\}}$ is called the **support** of f , and denoted simply by **support** f (or sometimes $\text{supp } f$).

2. LEMMA. Let $C \subset U \subset M$ with C compact and U open. Then there is a C^∞ function $f: M \rightarrow [0, 1]$ such that $f = 1$ on C and $\text{support } f \subset U$. (Compare *Case 2* of the proof of Theorem 15.)

PROOF. For each $p \in C$, choose a coordinate system (x, V) with $\bar{V} \subset U$ and $x(p) = 0$. Then $x(V) \supset (-\varepsilon, \varepsilon) \times \cdots \times (-\varepsilon, \varepsilon)$ for some $\varepsilon > 0$. The function $g \circ x$ (where g is defined in (4)) is C^∞ on V . Clearly it remains C^∞ if we extend

it to be 0 outside of V . Let f_p be the extended function. The function f_p can be constructed for each p , and is positive on a neighborhood of p whose closure is contained in U . Since C is compact, finitely many such neighborhoods cover C , and the sum, $f_{p_1} + \cdots + f_{p_n}$, of the corresponding functions has support $\subset U$. On C it is positive, so on C it is $\geq \delta$ for some $\delta > 0$. Let $f = l \circ (f_{p_1} + \cdots + f_{p_n})$, where l is defined in (3). ♦

By the way, we could have defined C^r manifolds for each $r \geq 1$, not just for “ $r = \infty$ ”. (A function $f: \mathbb{R}^n \rightarrow \mathbb{R}$ is C^r if it has continuous partial derivatives up to order r). A “ C^0 function” is just a continuous function, so a C^0 manifold is just a manifold in the sense of Chapter 1. We can also define *analytic* manifolds (a function $f: \mathbb{R}^n \rightarrow \mathbb{R}$ is analytic at $a \in \mathbb{R}^n$ if f can be expressed as a power series in the $(x^i - a^i)$ which converges in some neighborhood of a). The symbol C^ω stands for analytic, and it is convenient to agree that $r < \infty < \omega$ for each integer $r \geq 0$. If $\alpha < \beta$, then the charts of a maximal C^β atlas are all C^α -related, but this atlas can always be extended to a *bigger* atlas of C^α -related charts, as in Lemma 1. Thus, a C^β structure on M can always be extended to a C^α structure in a unique way; the smaller structure is the “stronger” one, the C^0 structure (consisting of all homeomorphisms $x: U \rightarrow \mathbb{R}^n$) being the largest. The converse of this trivial remark is a hard theorem: For $\alpha \geq 1$, every C^α structure contains a C^β structure for each $\beta > \alpha$; it is not unique, of course, but it is unique up to diffeomorphism. This will not be proved here.* In fact, C^α manifolds for $\alpha \neq \infty$ will hardly ever be mentioned again. One remark is in order now; the proof of Lemma 2 produces an appropriate C^α function f on a C^α manifold, for $0 \leq \alpha \leq \infty$. Of course, for $\alpha = \omega$ the proof

* For a proof see Munkres, *Elementary Differential Topology*.

fails completely (and the result is false—an analytic function which is 0 on an open set is 0 everywhere).

With differentiable functions now at our disposal, it is fitting that we begin differentiating them. What we shall define are the partial derivatives of a differentiable function $f: M \rightarrow \mathbb{R}$, with respect to a coordinate system (x, U) . At this point classical notation for partial derivatives is systematically introduced, so it is worth recalling a logical notation for the partial derivatives of a function $f: \mathbb{R}^n \rightarrow \mathbb{R}$. We denote by $D_i f(a)$ the number

$$\lim_{h \rightarrow 0} \frac{f(a^1, \dots, a^i + h, \dots, a^n) - f(a)}{h}.$$

The Chain Rule states that if $g: \mathbb{R}^m \rightarrow \mathbb{R}^n$ and $f: \mathbb{R}^n \rightarrow \mathbb{R}$, then

$$D_j(f \circ g)(a) = \sum_{i=1}^n D_i f(g(a)) \cdot D_j g^i(a).$$

Now, for a function $f: M \rightarrow \mathbb{R}$ and a coordinate system (x, U) we define

$$\frac{\partial f}{\partial x^i}(p) = \left. \frac{\partial f}{\partial x^i} \right|_p = D_i(f \circ x^{-1})(x(p)),$$

(or simply $\frac{\partial f}{\partial x^i} = D_i(f \circ x^{-1}) \circ x$, as an equation between functions). If we define the curve $c_i: (-\varepsilon, \varepsilon) \rightarrow M$ by

$$c_i(h) = x^{-1}(x(p) + (0, \dots, h, \dots, 0)),$$

then this partial derivative is just

$$\lim_{h \rightarrow 0} \frac{f(c_i(h)) - f(p)}{h},$$

so it measures the rate change of f along the curve c_i ; in fact it is just $(f \circ c_i)'(0)$. Notice that

$$\frac{\partial x^i}{\partial x^j}(p) = \delta_j^i = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j. \end{cases}$$

If x happens to be the identity map of \mathbb{R}^n , then $D_i f(p) = \partial f / \partial x^i(p)$, which is the classical symbol for this partial derivative.

Another classical instance of this notation, often not completely clarified, is the use of the symbols $\partial/\partial r$ and $\partial/\partial\theta$ in connection with “polar coordinates”. On the subset A of \mathbb{R}^2 defined by

$$\begin{aligned} A &= \mathbb{R}^2 - \{(x, y) \in \mathbb{R}^2 : y = 0 \text{ and } x \geq 0\} \\ &= \mathbb{R}^2 - L \end{aligned}$$

we can introduce a “coordinate system” $P: A \rightarrow \mathbb{R}^2$ by

$$P(x, y) = (r(x, y), \theta(x, y)),$$

where $r(x, y) = \sqrt{x^2 + y^2}$ and $\theta(x, y)$ is the unique number in $(0, 2\pi)$ with

$$\begin{aligned} x &= r(x, y) \cos \theta(x, y) \\ y &= r(x, y) \sin \theta(x, y). \end{aligned}$$

This really is a coordinate system on A in our sense, with its image being the set $\{r : r > 0\} \times (0, 2\pi)$. (Of course, the polar coordinate system is often

not restricted to the set A . One can delete any ray other than L if $\theta(x, y)$ is restricted to lie in the appropriate interval $(\theta_0, \theta_0 + 2\pi)$; many results are essentially independent of which line is deleted, and this sometimes justifies the sloppiness involved in the definition of the polar coordinate system.)

We have really defined P as an inverse function, whose inverse P^{-1} is defined simply by

$$P^{-1}(r, \theta) = (r \cos \theta, r \sin \theta).$$

From this formula we can compute $\partial f / \partial r$ explicitly:

$$(f \circ P^{-1})(r, \theta) = f(r \cos \theta, r \sin \theta),$$

so

$$\begin{aligned} \frac{\partial f}{\partial r}(x, y) &= D_1(f \circ P^{-1})(P(x, y)) \\ &= D_1 f(P^{-1}(P(x, y))) \cdot D_1[P^{-1}]^1(P(x, y)) \\ &\quad + D_2 f(P^{-1}(P(x, y))) \cdot D_1[P^{-1}]^2(P(x, y)) \\ &\quad \text{by the Chain Rule} \\ &= D_1 f(x, y) \cdot \cos \theta(x, y) + D_2 f(x, y) \cdot \sin \theta(x, y). \end{aligned}$$

This formula just gives the value of the directional derivative of f at (x, y) , along a unit vector $v = (\cos \theta(x, y), \sin \theta(x, y))$ pointing outwards from the origin to (x, y) . This is to be expected, because c_1 , the inverse image under P

of a curve along the “ r -axis”, is just a line in this direction.

A similar computation gives

$$\frac{\partial f}{\partial \theta}(x, y) = D_1 f(x, y)[-r(x, y) \sin \theta(x, y)] + D_2 f(x, y)[r(x, y) \cos \theta(x, y)].$$

The vector $w = (-\sin \theta(x, y), \cos \theta(x, y))$ is perpendicular to v , and thus the direction, at the point (x, y) , of the curve c_2 which is the inverse image under P of a curve along the “ θ -axis”. The factor $r(x, y)$ appears because this curve

goes around a circle of that radius as θ goes from 0 to 2π , so it is going $r(x, y)$ times as fast as it should go in order to be used to compute the directional derivative of f in the direction w . Note that $\partial f/\partial\theta$ is independent of which line is deleted from the plane in order to define the function θ unambiguously.

Using the notation $\partial f/\partial x$ for $D_1 f$, etc., and suppressing the argument (x, y) everywhere (thus writing an equation about functions), we can write the above equations as

$$\begin{aligned}\frac{\partial f}{\partial r} &= \frac{\partial f}{\partial x} \cos \theta + \frac{\partial f}{\partial y} \sin \theta \\ \frac{\partial f}{\partial \theta} &= \frac{\partial f}{\partial x} (-r \sin \theta) + \frac{\partial f}{\partial y} r \cos \theta.\end{aligned}$$

In particular, these formulas also tell us what $\partial x/\partial r$ etc., are, where (x, y) denotes the identity coordinate system of \mathbb{R}^2 . We have $\partial x/\partial r = \cos \theta$, etc., so our formulas can be put in the form

$$\begin{aligned}\frac{\partial f}{\partial r} &= \frac{\partial f}{\partial x} \frac{\partial x}{\partial r} + \frac{\partial f}{\partial y} \frac{\partial y}{\partial r} \\ \frac{\partial f}{\partial \theta} &= \frac{\partial f}{\partial x} \frac{\partial x}{\partial \theta} + \frac{\partial f}{\partial y} \frac{\partial y}{\partial \theta}.\end{aligned}$$

In classical notation, the Chain Rule would always be written in this way. It is a pleasure to report that henceforth this may always be done:

3. PROPOSITION. If (x, U) and (y, V) are coordinate systems on M , and $f: M \rightarrow \mathbb{R}$ is differentiable, then on $U \cap V$ we have

$$(I) \quad \frac{\partial f}{\partial y^i} = \sum_{j=1}^n \frac{\partial f}{\partial x^j} \frac{\partial x^j}{\partial y^i}.$$

PROOF. It's the Chain Rule, of course, if you just keep your cool:

$$\begin{aligned}\frac{\partial f}{\partial y^i}(p) &= D_i(f \circ y^{-1})(y(p)) \\ &= D_i([f \circ x^{-1}] \circ [x \circ y^{-1}])(y(p)) \\ &= \sum_{j=1}^n D_j(f \circ x^{-1})([x \circ y^{-1}](y(p))) \cdot D_i[x \circ y^{-1}]^j(y(p))\end{aligned}$$

$$\begin{aligned}
&= \sum_{j=1}^n D_j(f \circ x^{-1})(x(p)) \cdot D_i[x^j \circ y^{-1}](y(p)) \\
&= \sum_{j=1}^n \frac{\partial f}{\partial x^j}(p) \cdot \frac{\partial x^j}{\partial y^i}(p). \quad \blacklozenge
\end{aligned}$$

At this point we could introduce the “Einstein summation convention”. Notice that the summation in this formula occurs for the index j , which appears both “above” (in $\partial x^j / \partial y^i$) and “below” (in $\partial f / \partial x^j$). There are scads of formulas in which this happens, often with hoards of indices being summed over, and the convention is to omit the \sum sign completely—double indices (which by luck, the nature of things, and felicitous choice of notation, almost always occur above and below) being summed over. I won’t use this notation because whenever I do, I soon forget I’m supposed to be summing, and because by doing things “right”, one can avoid what Élie Cartan has called the “debauch of indices”.

We will often write formula (1) in the form

$$\frac{\partial}{\partial y^i} = \sum_{j=1}^n \frac{\partial x^j}{\partial y^i} \frac{\partial}{\partial x^j};$$

here $\partial / \partial y^i$ is considered as an operator taking the function f to $\partial f / \partial y^i$. The operator taking f to $\partial f / \partial y^i(p)$ is denoted by

$$\left. \frac{\partial}{\partial y^i} \right|_p; \quad \text{thus} \quad \left. \frac{\partial}{\partial y^i} \right|_p = \sum_{j=1}^n \left. \frac{\partial x^j}{\partial y^i}(p) \frac{\partial}{\partial x^j} \right|_p.$$

For later use we record a property of $\ell = \partial / \partial x^i|_p$: it is a “point-derivation”.

4. PROPOSITION. For any differentiable $f, g: M \rightarrow \mathbb{R}$, and any coordinate system (x, U) with $p \in U$, the operator $\ell = \partial / \partial x^i|_p$ satisfies

$$\ell(fg) = f(p)\ell(g) + \ell(f)g(p).$$

PROOF. Left to the reader. \blacklozenge

If (x, U) and (x', U') are two coordinate systems on M , the $n \times n$ matrix

$$\left(\frac{\partial x'^i}{\partial x^j}(p) \right)$$

is just the Jacobian matrix of $x' \circ x^{-1}$ at $x(p)$. It is non-singular; in fact, its inverse is clearly

$$\left(\frac{\partial x^i}{\partial x'^j}(p) \right).$$

Now if $f: M^n \rightarrow N^m$ is C^∞ and (y, V) is a coordinate system around $f(p)$, the rank of the $m \times n$ matrix

$$\left(\frac{\partial(y^i \circ f)}{\partial x^j}(p) \right)$$

clearly does not depend on the coordinate system (x, U) or (y, V) . It is called the **rank of f at p** . The point p is called a **critical point** of f if the rank of f at p is $< m$ (the dimension of the image N); if p is not a critical point of f , it is called a **regular point** of f . If p is a critical point of f , the value $f(p)$ is called a **critical value** of f . Other points in N are **regular values**; thus $q \in N$ is a regular value if and only if p is a regular point of f for every $p \in f^{-1}(q)$. This is true, in particular, if $q \notin f(M)$ —a non-value of f is still a “regular value”.

If $f: \mathbb{R} \rightarrow \mathbb{R}$, then x is a critical point of f if and only if $f'(x) = 0$. It is possible for all points of the interval $[a, b]$ to be critical points, although this can happen only if f is constant on $[a, b]$. If $f: \mathbb{R}^2 \rightarrow \mathbb{R}$ has all points as critical values, then $D_1 f = D_2 f = 0$ everywhere, so f is again constant. On the other hand, a function $f: \mathbb{R}^2 \rightarrow \mathbb{R}^2$ may have all points as critical points without being constant, for example, $f(x, y) = x$. In this case, however, the image $f(\mathbb{R}^2) = \mathbb{R} \times \{0\} \subset \mathbb{R}^2$ is still a “small” subset of \mathbb{R}^2 . The most important theorem about critical points generalizes this fact. To state it, we will need some terminology.

Recall that a set $A \subset \mathbb{R}^n$ has “measure zero” if for every $\varepsilon > 0$ there is a sequence B_1, B_2, B_3, \dots of (closed or open) rectangles with

$$A \subset \bigcup_{n=1}^{\infty} B_n$$

and

$$\sum_{n=1}^{\infty} v(B_n) < \varepsilon,$$

where $v(B_n)$ is the volume of B_n . We want to define the same concept for a subset of a manifold. To do this we need a lemma, which in turn depends on a lemma from *Calculus on Manifolds*, which we merely state.

5. LEMMA. Let $A \subset \mathbb{R}^n$ be a rectangle and let $f: A \rightarrow \mathbb{R}^n$ be a function such that $|D_j f^i| \leq K$ on A for $i, j = 1, \dots, n$. Then

$$|f(x) - f(y)| \leq n^2 K |x - y|$$

for all $x, y \in A$.

6. LEMMA. If $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is C^1 and $A \subset \mathbb{R}^n$ has measure 0, then $f(A)$ has measure 0.

PROOF. We can assume that A is contained in a compact set C (since \mathbb{R}^n is a countable union of compact sets). Lemma 5 implies that there is some K such that

$$|f(x) - f(y)| \leq n^2 K |x - y|$$

for all $x, y \in C$. Thus f takes rectangles of diameter d into sets of diameter $\leq n^2 K d$. This clearly implies that $f(A)$ has measure 0 if A does. ♦

A subset A of a C^∞ n -manifold M has **measure zero** if there is a sequence of charts (x_i, U_i) , with $A \subset \bigcup_i U_i$, such that each set $x_i(A \cap U_i) \subset \mathbb{R}^n$ has measure 0. Using Lemma 6, it is easy to see that if $A \subset M$ has measure 0, then $x(A \cap U) \subset \mathbb{R}^n$ has measure 0 for any coordinate system (x, U) . Conversely, if this condition is satisfied and M is connected, or has only countably many components, then it follows easily from Theorem 1-2 that A has measure 0. (But if M is the disjoint union of uncountably many copies of \mathbb{R} , and A consists of one point from each component, then A does not have measure 0). Lemma 6 thus implies another result:

7. COROLLARY. If $f: M \rightarrow N$ is a C^1 function between two n -manifolds and $A \subset M$ has measure 0, then $f(A) \subset N$ has measure 0.

PROOF. There is a sequence of charts (x_i, U_i) with $A \subset \bigcup_i U_i$ and each set $x_i(A \cap U_i)$ of measure 0. If (y, V) is a chart on N , then $f(A) \cap V = \bigcup_i f(A \cap U_i) \cap V$. Each set

$$y(f(A \cap U_i) \cap V) = y \circ f \circ x^{-1}(x(A \cap U_i))$$

has measure 0, by Lemma 6. Thus $y(f(A) \cap V)$ has measure 0. Since $f(\bigcup_i U_i)$ is contained in the union of at most countably many components of N , it follows that $f(A)$ has measure 0. ♦

8. THEOREM (SARD'S THEOREM). If $f: M \rightarrow N$ is a C^1 map between n -manifolds, and M has at most countably many components, then the critical values of f form a set of measure 0 in N .

PROOF. It clearly suffices to consider the case where M and N are \mathbb{R}^n . But this case is just Theorem 3.14 of *Calculus on Manifolds*. ♦

The stronger version of Sard's Theorem, which we will never use (except once, in Problem 8-24), states* that the critical values of a C^k map $f: M^n \rightarrow N^m$ are a set of measure 0 if $k \geq 1 + \max(n - m, 0)$. Theorem 8 is the easy case, and the case $m > n$ is the trivial case (Problem 20). Although Theorem 8 will be very important later on, for the present we are more interested in knowing what the image of $f: M \rightarrow N$ looks like locally, in terms of the rank k of f at $p \in M$. More exact information can be given when f actually has rank k in a neighborhood of p . It should be noted that f must have rank $\geq k$ in some neighborhood of p , because some $k \times k$ submatrix of $(\partial(y^i \circ f)/\partial x^i)$ has non-zero determinant at p , and hence in a neighborhood of p .

9. THEOREM. (1) If $f: M^n \rightarrow N^m$ has rank k at p , then there is some coordinate system (x, U) around p and some coordinate system (y, V) around $f(p)$ with $y \circ f \circ x^{-1}$ in the form

$$y \circ f \circ x^{-1}(a^1, \dots, a^n) = (a^1, \dots, a^k, \psi^{k+1}(a), \dots, \psi^m(a)).$$

Moreover, given any coordinate system y , the appropriate coordinate system on N can be obtained merely by permuting the component functions of y .

(2) If f has rank k in a neighborhood of p , then there are coordinate systems (x, U) and (y, V) such that

$$y \circ f \circ x^{-1}(a^1, \dots, a^n) = (a^1, \dots, a^k, 0, \dots, 0).$$

Remark: The special case $M = \mathbb{R}^n$, $N = \mathbb{R}^m$ is equivalent to the general theorem, which gives only local results. If y is the identity of \mathbb{R}^m , part (1) says that by first performing a diffeomorphism on \mathbb{R}^n , and then permuting the coordinates in \mathbb{R}^m , we can insure that f keeps the first k components of a point fixed. These diffeomorphisms on \mathbb{R}^n and \mathbb{R}^m are clearly necessary, since f may not even be one-one on $\mathbb{R}^k \times \{0\} \subset \mathbb{R}^n$, and its image could, for example, contain only points with first coordinate 0.

*For a proof, see Milnor, *Topology From the Differentiable Viewpoint* or Sternberg, *Lectures on Differential Geometry*.

In part (2) we must clearly allow more leeway in the choice of y , since $f(\mathbb{R}^n)$ may not be contained in any k -dimensional subspace of \mathbb{R}^n .

PROOF. (1) Choose some coordinate system u around p . By a permutation of the coordinate functions u^i and y^i we can arrange that

$$(1) \quad \det \left(\frac{\partial(y^\alpha \circ f)}{\partial u^\beta}(p) \right) \neq 0 \quad \alpha, \beta = 1, \dots, k.$$

Define

$$\begin{aligned} x^\alpha &= y^\alpha \circ f & \alpha &= 1, \dots, k \\ x^r &= u^r & r &= k+1, \dots, n. \end{aligned}$$

Condition (1) implies that

$$(2) \quad \det \left(\frac{\partial x^i}{\partial u^j}(p) \right) = \det \left(\begin{array}{c|c} \frac{\partial(y^\alpha \circ f)}{\partial u^\beta} & \begin{matrix} \times \\ \times \\ \times \end{matrix} \\ \hline 0 & \begin{matrix} 1 & & \\ & \ddots & \\ & & 1 \end{matrix} \end{array} \right) \neq 0.$$

This shows that $x = (x \circ u^{-1}) \circ u$ is a coordinate system in some neighborhood of p , since (2) and the Inverse Function Theorem show that $x \circ u^{-1}$ is a diffeomorphism in a neighborhood of $u(p)$. Now

$$\begin{aligned} q = x^{-1}(a^1, \dots, a^n) & \text{ means } x(q) = (a^1, \dots, a^n), \\ \text{hence } x^i(q) &= a^i, \\ \text{hence } \begin{cases} y^\alpha \circ f(q) = a^\alpha & \alpha = 1, \dots, k \\ u^r(q) = a^r & r = k+1, \dots, n, \end{cases} \end{aligned}$$

so

$$\begin{aligned} y \circ f \circ x^{-1}(a^1, \dots, a^n) &= y \circ f(q) \quad \text{for } q = x^{-1}(a^1, \dots, a^n) \\ &= (a^1, \dots, a^k, \underline{\quad}). \end{aligned}$$

(2) Choose coordinate systems x and v so that $v \circ f \circ x^{-1}$ has the form in (1). Since $\text{rank } f = k$ in a neighborhood of p , the lower square in the matrix

$$\left(\frac{\partial(v^i \circ f)}{\partial x^j} \right) = \left(\begin{array}{c|c} \begin{matrix} 1 & & \\ & \ddots & \\ & & 1 \end{matrix} & 0 \\ \hline \begin{matrix} \times \\ \times \\ \times \end{matrix} & \begin{matrix} D_{k+1}\psi^{k+1} & & \\ & \ddots & \\ & & D_m\psi^m \end{matrix} \end{array} \right)$$

must vanish in a neighborhood of p . Thus we can write

$$\psi^r(a) = \tilde{\psi}^r(a^1, \dots, a^k) \quad r = k+1, \dots, m.$$

Define

$$\begin{aligned} y^\alpha &= v^\alpha \\ y^r &= v^r - \tilde{\psi}^r \circ (v^1, \dots, v^k). \end{aligned}$$

Since

$$\begin{aligned} (3) \quad y \circ v^{-1}(b^1, \dots, b^m) &= y(q) \quad \text{for } v(q) = (b^1, \dots, b^m) \\ &= (b^1, \dots, b^k, b^{k+1} - \tilde{\psi}^{k+1}(b^1, \dots, b^k), \dots, b^m - \tilde{\psi}^m(b^1, \dots, b^k)), \end{aligned}$$

the Jacobian matrix

$$\left(\frac{\partial y^i}{\partial v^j} \right) = \begin{pmatrix} \boxed{\begin{matrix} 1 & & \\ & \ddots & \\ & & 1 \end{matrix}} & 0 \\ \text{X} & \boxed{\begin{matrix} 1 & & \\ & \ddots & \\ & & 1 \end{matrix}} \end{pmatrix}$$

has non-zero determinant, so y is a coordinate system in a neighborhood of $f(p)$. Moreover,

$$\begin{aligned} y \circ f \circ x^{-1}(a^1, \dots, a^n) &= y \circ v^{-1} \circ v \circ f \circ x^{-1}(a^1, \dots, a^n) \\ &= y \circ v^{-1}(a^1, \dots, a^k, \psi^{k+1}(a), \dots, \psi^m(a)) \\ &= (a^1, \dots, a^k, \psi^{k+1}(a) - \tilde{\psi}^{k+1}(a^1, \dots, a^k), \dots, \psi^m(a) - \tilde{\psi}^m(a^1, \dots, a^k)) \\ &\quad \text{by (3)} \\ &= (a^1, \dots, a^k, 0, \dots, 0). \quad \spadesuit \end{aligned}$$

Theorem 9 acquires a special form when the rank of f is n or m :

10. THEOREM. (1) If $m \leq n$ and $f: M^n \rightarrow N^m$ has rank m at p , then for any coordinate system (y, V) around $f(p)$, there is some coordinate system (x, U) around p with

$$y \circ f \circ x^{-1}(a^1, \dots, a^n) = (a^1, \dots, a^m).$$

(2) If $n \leq m$ and $f: M^n \rightarrow N^m$ has rank n at p , then for any coordinate system (x, U) around p , there is a coordinate system (y, V) around $f(p)$ with

$$y \circ f \circ x^{-1}(a^1, \dots, a^n) = (a^1, \dots, a^n, 0, \dots, 0).$$

PROOF. (1) This is practically a special case of (1) in Theorem 9; it is only necessary to observe that when $k = m$, it is clearly unnecessary, in the proof of this case, to permute the y^i in order to arrange that

$$\det \left(\frac{\partial (y^\alpha \circ f)}{\partial u^\beta} (p) \right) \neq 0 \quad \alpha, \beta = 1, \dots, m;$$

only the u^i need be permuted.

(2) Since the rank of f at any point must be $\leq n$, the rank of f equals n in some neighborhood of p . It is convenient to think of the case $M = \mathbb{R}^n$ and $N = \mathbb{R}^m$ and produce the coordinate system y for \mathbb{R}^m when we are given the identity coordinate system for \mathbb{R}^n . Part (2) of Theorem 9 yields coordinate systems ϕ for \mathbb{R}^n and ψ for \mathbb{R}^m such that

$$\psi \circ f \circ \phi^{-1}(a^1, \dots, a^n) = (a^1, \dots, a^n, 0, \dots, 0).$$

Even if we do not perform ϕ^{-1} first, the map f still takes \mathbb{R}^n into the subset

$f(\mathbb{R}^n)$ which ψ takes to $\mathbb{R}^n \times \{0\} \subset \mathbb{R}^m$ —the points of \mathbb{R}^n just get moved to the wrong place in $\mathbb{R}^n \times \{0\}$. This can be corrected by another map on \mathbb{R}^m . Define λ by

$$\lambda(b^1, \dots, b^m) = (\phi^{-1}(b^1, \dots, b^n), b^{n+1}, \dots, b^m).$$

Then

$$\begin{aligned} \lambda \circ \psi \circ f(a^1, \dots, a^n) &= \lambda \circ \psi \circ f \circ \phi^{-1}(b^1, \dots, b^n) \\ &\quad \text{for } (b^1, \dots, b^n) = \phi(a) \\ &= \lambda(b^1, \dots, b^n, 0, \dots, 0) \\ &= (\phi^{-1}(b^1, \dots, b^n), 0, \dots, 0) \\ &= (a^1, \dots, a^n, 0, \dots, 0), \end{aligned}$$

so $\lambda \circ \psi$ is the desired y . If we are given a coordinate system x on \mathbb{R}^n other than the identity, we just define

$$\lambda(b^1, \dots, b^m) = (x(\phi^{-1}(b^1, \dots, b^n)), b^{n+1}, \dots, b^m);$$

it is easily checked that $y = \lambda \circ \psi$ is now the desired y . ♦

Although p is a regular point of f in case (1) of Theorem 10 and a critical point in case (2) (if $n < m$), it is case (2) which most interests us. A differentiable function $f: M^n \rightarrow N^m$ is called an **immersion** if the rank of f is n , the dimension of the domain M , at all points of M . Of course, it is necessary that $m \geq n$, and it is clear from Theorem 10(2) that an immersion is locally one-one (so it is a topological immersion, as defined in Chapter 1). On the other hand, a differentiable map f need not be an immersion even if it is globally one-one. The simplest example is the function $f: \mathbb{R} \rightarrow \mathbb{R}$ defined by $f(x) = x^3$, with $f'(0) = 0$. Another example is

A more illuminating example is the function $h: \mathbb{R} \rightarrow \mathbb{R}^2$ defined by

$$h(x) = (g(x), |g(x)|);$$

although its image is the graph of a non-differentiable function, the curve itself manages to be differentiable by slowing down to velocity 0 at the point $(0,0)$. One can easily define a similar curve whose image looks like the picture below.

Three immersions of \mathbb{R} in \mathbb{R}^2 are shown below. Although the second and third immersions β_1 and β_2 are one-one, their images are not homeomorphic

to \mathbb{R} . Of course, even if the one-one immersion $f: P \rightarrow M$ is not a homeomorphism onto its image, there is certainly some metric and some differentiable structure on $f(P)$ which makes the inclusion map $i: f(P) \rightarrow M$ an immersion. In general, a subset $M_1 \subset M$, with a differentiable structure (not necessarily compatible with the metric M_1 inherits as a subset of M), is called an **immersed submanifold** of M if the inclusion map $i: M_1 \rightarrow M$ is an immersion. The following picture, indicating the image of an immersion $\beta_3: \mathbb{R} \rightarrow S^1 \times S^1$,

shows that M_1 may even be a dense subset of M .

Despite these complications, if M_1 is a k -dimensional immersed submanifold of M^n and U_1 is a neighborhood in M_1 of a point $p \in M_1$, then there is a coordinate system (y, V) of M around p , such that

$$U_1 \cap V = \{q \in M : y^{k+1}(q) = \dots = y^n(q) = 0\};$$

this is an immediate consequence of Theorem 10(2), with $f = i$. Thus, if $g: M_1 \rightarrow N$ is C^∞ (considered as a function on the manifold M_1) in a neighborhood of a point $p \in M_1$, then there is a C^∞ function \bar{g} on a neighborhood $V \subset M$ of p such that $g = \bar{g} \circ i$ on $V \cap M_1$ —we can define

$$\bar{g}(q) = g(q'), \quad \text{where} \quad \begin{cases} y^\alpha(q') = y^\alpha(q) & \alpha = 1, \dots, k \\ y^r(q') = 0 & r = k+1, \dots, n. \end{cases}$$

On the other hand, even if g is C^∞ on all of M_1 we may not be able to define \tilde{g} on M . For example, this cannot be done if g is one of the functions $\beta_i^{-1}: \beta_i(M) \rightarrow \mathbb{R}$.

One other complication arises with immersed submanifolds. If $M_1 \subset M$ is an immersed submanifold, and $f: P \rightarrow M$ is a C^∞ function with $f(P) \subset M_1$, it is not necessarily true that f is C^∞ when considered as a map into M_1 , with its C^∞ structure. The following figure shows that f might not even be continuous

as a map into M_1 . Actually, this is the only thing that can go wrong:

11. PROPOSITION. If $M_1 \subset M$ is an immersed manifold, $f: P \rightarrow M$ is a C^∞ function with $f(P) \subset M_1$, and f is continuous considered as a map into M_1 , then f is also C^∞ considered as a map into M_1 .

PROOF. Let $i: M_1 \rightarrow M$ be the inclusion map. We want to show that $i^{-1} \circ f$ is C^∞ if it is continuous. Given $p \in P$, choose a coordinate system (y, V) for M around $f(p)$ such that

$$U_1 = \{q \in V : y^{k+1}(q) = \cdots = y^n(q) = 0\}$$

is a neighborhood of $f(p)$ in M_1 and $(y^1|_{U_1}, \dots, y^k|_{U_1})$ is a coordinate system of M_1 on U_1 .

By assumption, $i^{-1} \circ f$ is continuous, so

$$f^{-1} \circ i(\text{open set}) \text{ is an open set.}$$

Since U_1 is open in M_1 , this means that $f^{-1}(U_1) \subset P$ is open. Thus f takes some neighborhood of $p \in P$ into U_1 . Since all $y^j \circ f$ are C^∞ , and y^1, \dots, y^k are a coordinate system on U_1 , the function f is C^∞ considered as a map into M_1 . ♦

Most of these difficulties disappear when we consider one-one immersions $f: P \rightarrow M$ which are homeomorphisms onto their image. Such an immersion is called an *imbedding* ("embedding" for the English). An immersed submanifold $M_1 \subset M$ is called simply a (C^∞) *submanifold* of M if the inclusion map $i: M_1 \rightarrow M$ is an imbedding; it is called a *closed submanifold* of M if M_1 is also a closed subset of M .

There is one way of getting submanifolds which is very important, and gives the sphere $S^{n-1} \subset \mathbb{R}^n - \{0\} \subset \mathbb{R}^n$, defined as $\{x : |x|^2 = 1\}$, as a special case.

12. PROPOSITION. If $f: M^n \rightarrow N$ has constant rank k on a neighborhood of $f^{-1}(y)$, then $f^{-1}(y)$ is a closed submanifold of M of dimension $n - k$ (or is empty). In particular, if y is a regular value of $f: M^n \rightarrow N^m$, then $f^{-1}(y)$ is an $(n - m)$ -dimensional submanifold of M (or is empty).

PROOF. Left to the reader. ♦

It is to be hoped that however abstract the notion of C^∞ manifolds may appear, submanifolds of \mathbb{R}^N will seem like fairly concrete objects. Now it turns out that *every* (connected) C^∞ manifold can be imbedded in some \mathbb{R}^N , so that manifolds can be pictured as subsets of Euclidean space (though this picture is not always the most useful one). We will prove this fact only for compact manifolds, but we first develop some of the machinery which would be used in

the general case, since we will need it later on anyway. Unfortunately, there are many definitions and theorems involved.

If \mathcal{O} is a cover of a space M , a cover \mathcal{O}' of M is a **refinement** of \mathcal{O} (or “refines \mathcal{O} ”) if for every U in \mathcal{O}' there is some V in \mathcal{O} with $U \subset V$ (the sets of \mathcal{O}' are “smaller” than those of \mathcal{O})—a subcover is a very special case of a refining cover. A cover \mathcal{O} is called **locally finite** if every $p \in M$ has a neighborhood W which intersects only finitely many sets in \mathcal{O} .

13. THEOREM. If \mathcal{O} is an open cover of a manifold M , then there is an open cover \mathcal{O}' of M which is locally finite and which refines \mathcal{O} . Moreover, we can choose all members of \mathcal{O}' to be open sets diffeomorphic to \mathbb{R}^n .

PROOF. We can obviously assume that M is connected. By Theorem 1.2, there are compact sets C_1, C_2, C_3, \dots with $M = C_1 \cup C_2 \cup C_3 \cup \dots$. Clearly C_1 has an open neighborhood U_1 with compact closure. Then $\overline{U_1} \cup C_2$ has an open neighborhood U_2 with compact closure. Continuing in this way, we obtain open sets U_i , with $\overline{U_i}$ compact and $\overline{U_i} \subset U_{i+1}$, whose union contains all C_i , and hence is M . Let $U_{-1} = U_0 = \emptyset$.

Now M is the union for $i > 1$ of the “annular” regions $A_i = \overline{U_i} - U_{i-1}$. Since each A_i is compact, we can obviously cover A_i by a finite number of open sets, each contained in some member of \mathcal{O} , and each contained in $V_i = U_{i+1} - U_{i-2}$. We can also choose these open sets to be diffeomorphic to \mathbb{R}^n . In this way we obtain a cover \mathcal{O}' which refines \mathcal{O} and which is locally finite, since a point in U_i is not in V_j for $j \geq 2 + i$. ♦

Notice that if \mathcal{O} is an open locally finite cover of a space M and $C \subset M$ is compact, then C intersects only finitely many members of \mathcal{O} . This shows that an open locally finite cover of a connected manifold must be countable (like the cover constructed in the proof of Theorem 13).

14. THEOREM (THE SHRINKING LEMMA). Let \mathcal{O} be an open locally finite cover of a manifold M . Then it is possible to choose, for each U in \mathcal{O} , an open set U' with $\overline{U'} \subset U$ in such a way that the collection of all U' is also an open cover of M .

PROOF. We can clearly assume that M is connected. Let $\mathcal{O} = \{U_1, U_2, U_3, \dots\}$. Then

$$C_1 = U_1 - (U_2 \cup U_3 \cup \dots)$$

is a closed set contained in U_1 , and $M = C_1 \cup U_2 \cup U_3 \cup \dots$. Let U'_1 be an open set with $C_1 \subset U'_1 \subset \overline{U'_1} \subset U_1$. Now

$$C_2 = U_2 - (U'_1 \cup U_3 \cup \dots)$$

is a closed set contained in U_2 , and $M = U'_1 \cup C_2 \cup U_3 \cup \dots$. Let U'_2 be an open set with $C_2 \subset U'_2 \subset \overline{U'_2} \subset U_2$. Continue in this way.

For any $p \in M$ there is a largest n with $p \in U_n$, because \mathcal{O} is locally finite. Now

$$p \in U'_1 \cup U'_2 \cup \dots \cup U'_n \cup (U_{n+1} \cup U_{n+2} \cup \dots);$$

it follows that

$$p \in U'_1 \cup U'_2 \cup \dots,$$

since replacing U_{n+i} by U'_{n+i} cannot possibly eliminate p . ♦

15. THEOREM. Let \mathcal{O} be an open locally finite cover of a manifold M . Then there is a collection of C^∞ functions $\phi_U: M \rightarrow [0, 1]$, one for each U in \mathcal{O} , such that

- (1) support $\phi_U \subset U$ for each U ,
- (2) $\sum_U \phi_U(p) = 1$ for all $p \in M$ (this sum is really a finite sum in some neighborhood of p , by (1)).

PROOF. Case 1. Each U in \mathcal{O} has compact closure. Choose the U' as in Theorem 14. Apply Lemma 2 to $\overline{U'} \subset U \subset M$ to obtain a C^∞ function $\psi_U: M \rightarrow [0, 1]$ which is 1 on $\overline{U'}$ and has support $\subset U$. Since the U' cover M , clearly

$$\sum_{U \in \mathcal{O}} \psi_U > 0 \quad \text{everywhere.}$$

Define

$$\phi_U = \frac{\psi_U}{\sum_{U \in \mathcal{O}} \psi_U}.$$

Case 2. General case. This case can be proved in the same way, provided that Lemma 2 is true for $C \subset U \subset M$ with C closed (but not necessarily compact) and U open. But this is a consequence of *Case 1*:

For each $p \in C$ choose an open set $U_p \subset U$ with compact closure. Cover $M - C$ with open sets V_α having compact closure and contained in $M - C$. The open cover $\{U_p, V_\alpha\}$ has an open locally finite refinement \mathcal{O} to which *Case 1* applies. Let

$$f = \sum_{U \in \mathcal{O}'} \phi_U, \quad \text{where } \mathcal{O}' = \{U \in \mathcal{O} : U \subset U_p \text{ for some } p\}.$$

This sum is C^∞ , since it is a finite sum in a neighborhood of each point. Since $\sum_U \phi_U(p) = 1$ for all p , and $\phi_U(p) = 0$ when $U \subset V_\alpha$, clearly $f(p) = 1$ for all $p \in C$. Using the fact that \mathcal{O} is locally finite, it is easy to see that support $f \subset U$. ♦

16. COROLLARY. If \mathcal{O} is any open cover of a manifold M , then there is a collection of C^∞ functions $\phi_i: M \rightarrow [0, 1]$ such that

- (1) the collection of sets $\{p: \phi_i(p) \neq 0\}$ is locally finite,
- (2) $\sum_i \phi_i(p) = 1$ for all $p \in M$,
- (3) for each i there is a $U \in \mathcal{O}$ such that support $\phi_i \subset U$.

(A collection $\{\phi_i: M \rightarrow [0, 1]\}$ satisfying (1) and (2) is called a **partition of unity**; if it satisfies (3), it is called **subordinate to \mathcal{O}** .)

It is now fairly easy to prove the last theorem of this chapter.

17. THEOREM. If M^n is a compact C^∞ manifold, then there is an imbedding $f: M \rightarrow \mathbb{R}^N$ for some N .

PROOF. There are a finite number of coordinate systems $(x_1, U_1), \dots, (x_k, U_k)$ with $M = U_1 \cup \dots \cup U_k$. Choose U'_i as in Theorem 14, and functions $\psi_i: M \rightarrow [0, 1]$ which are 1 on $\overline{U'_i}$ and have support $\subset U_i$. Define $f: M \rightarrow \mathbb{R}^N$, where $N = nk + k$, by

$$f = (\psi_1 \cdot x_1, \dots, \psi_k \cdot x_k, \psi_1, \dots, \psi_k).$$

This is an immersion, because any point p is in U'_i for some i , and on U'_i , where $\psi_i = 1$, the $N \times n$ Jacobian matrix

$$\left(\frac{\partial f^\alpha}{\partial x_i^\beta} \right) \text{ contains the } n \times n \text{ matrix } \left(\frac{\partial x_i^\alpha}{\partial x_i^\beta} \right) = I.$$

It is also one-one. For suppose that $f(p) = f(q)$. There is some i such that $p \in U'_i$. Then $\psi_i(p) = 1$, so also $\psi_i(q) = 1$. This shows that we must have $q \in U_i$. Moreover,

$$\psi_i \cdot x_i(p) = \psi_i \cdot x_i(q),$$

so $p = q$, since x_i is one-one on U_i . ♦

Problem 3-33 shows that, in fact, we can always choose $N = 2n + 1$.

PROBLEMS

1. (a) Show that being C^∞ -related is *not* an equivalence relation.
 (b) In the proof of Lemma 1, show that all charts in \mathcal{A}' are C^∞ -related, as claimed.
2. (a) If M is a metric space together with a collection of homeomorphisms $x: U \rightarrow \mathbb{R}^n$ whose domains cover M and which are C^∞ -related, show that the n at each point is unique *without* using Invariance of Domain.
 (b) Show similarly that ∂M is well-defined for a C^∞ manifold-with-boundary M .
3. (a) All C^∞ functions are continuous, and the composition of C^∞ functions is C^∞ .
 (b) A function $f: M \rightarrow N$ is C^∞ if and only if $g \circ f$ is C^∞ for every C^∞ function $g: N \rightarrow \mathbb{R}$.
4. How many distinct C^∞ structures are there on \mathbb{R} ? (There is only one up to diffeomorphism; that is not the question being asked.)

5. (a) If $N \subset M$ is open and \mathcal{A}' consists of all (x, U) in \mathcal{A} with $U \subset N$, show that \mathcal{A}' is maximal for N if \mathcal{A} is maximal for M .
 (b) Show that \mathcal{A}' can also be described as the set of all $(x|V \cap N, V \cap N)$ for (x, V) in \mathcal{A} .
 (c) Show that the inclusion $i: N \rightarrow M$ is C^∞ , and that \mathcal{A}' is the unique atlas with this property.
6. Check that the two projections P_1 and P_2 on S^{n-1} are C^∞ related to the $2n$ homeomorphisms f_i and g_i .
7. (a) If M is a connected C^∞ manifold and $p, q \in M$, then there is a C^∞ curve $c: [0, 1] \rightarrow M$ with $c(0) = p$ and $c(1) = q$.
 (b) It is even possible to choose c to be one-one.
8. (a) Show that $(M_1 \times M_2) \times M_3$ is diffeomorphic to $M_1 \times (M_2 \times M_3)$ and that $M_1 \times M_2$ is diffeomorphic to $M_2 \times M_1$.
 (b) The differentiable structure on $M_1 \times M_2$ makes the “slice” maps

$$\begin{aligned} p_1 &\mapsto (p_1, \bar{p}_2) \\ p_2 &\mapsto (\bar{p}_1, p_2) \end{aligned}$$

of $M_1, M_2 \rightarrow M_1 \times M_2$ differentiable for all $\bar{p}_1 \in M_1, \bar{p}_2 \in M_2$.

- (c) More generally, a map $f: N \rightarrow M_1 \times M_2$ is C^∞ if and only if the compositions $\pi_1 \circ f: N \rightarrow M_1$ and $\pi_2 \circ f: N \rightarrow M_2$ are C^∞ . Moreover, the C^∞ structure we have defined for $M_1 \times M_2$ is the only one with this property.
- (d) If $f_i: N \rightarrow M_i$ are C^∞ ($i = 1, 2$), can one determine the rank of $(f_1, f_2): N \rightarrow M_1 \times M_2$ at p in terms of the ranks of f_i at p ? For $f_i: N_i \rightarrow M_i$, show that $f_1 \times f_2: N_1 \times N_2 \rightarrow M_1 \times M_2$, defined by $f_1 \times f_2(p_1, p_2) = (f_1(p_1), f_2(p_2))$, is C^∞ and determine its rank in terms of the ranks of f_i .
9. Let $g: S^n \rightarrow \mathbb{P}^n$ be the map $p \mapsto [p]$. Show that $f: \mathbb{P}^n \rightarrow M$ is C^∞ if and only if $f \circ g: S^n \rightarrow M$ is C^∞ . Compare the rank of f and the rank of $f \circ g$.
10. (a) If $U \subset \mathbb{R}^n$ is open and $f: U \rightarrow \mathbb{R}$ is locally C^∞ (every point has a neighborhood on which f is C^∞), then f is C^∞ . (Obvious.)
 (b) If $f: \mathbb{H}^n \rightarrow \mathbb{R}$ is locally C^∞ , then f is C^∞ , i.e., f can be extended to a C^∞ function on a neighborhood of \mathbb{H}^n . (Not so obvious.)
11. If $f: \mathbb{H}^n \rightarrow \mathbb{R}$ has two extensions g, h to C^∞ functions in a neighborhood of \mathbb{H}^n , then $D_j g$ and $D_j h$ are the same at points of $\mathbb{R}^{n-1} \times \{0\}$ (so we can speak of $D_j f$ at these points).
12. If M is a C^∞ manifold-with-boundary, then there is a unique C^∞ structure on ∂M such that the inclusion map $i: \partial M \rightarrow M$ is an imbedding.

13. (a) Let $U \subset M^n$ be an open set such that boundary U is an $(n-1)$ -dimensional (differentiable) submanifold. Show that \bar{U} is an n -dimensional manifold-with-boundary. (It is well to bear in mind the following example: if $U = \{x \in \mathbb{R}^n : d(x, 0) < 1 \text{ or } 1 < d(x, 0) < 2\}$, then \bar{U} is a manifold-with-boundary, but $\partial \bar{U} \neq \text{boundary } U$.)
- (b) Consider the figure shown below. This figure may be extended by putting

smaller copies of the two parts of S' into the regions indicated by arrows, and then repeating this construction indefinitely. The closure S of the final resulting figure is known as *Alexander's Horned Sphere*. Show that S is homeomorphic to S^2 . (*Hint:* The additional points in the closure are homeomorphic to the Cantor set.) If U is the unbounded component of $\mathbb{R}^3 - S$, then $S = \text{boundary } U$, but \bar{U} is not a 2-dimensional manifold-with-boundary, so part (a) is true only for differentiable submanifolds.

14. (a) There is a map $f: \mathbb{R}^2 \rightarrow \mathbb{R}^2$ such that

- (1) $f(x, 0) = (x, 0)$ for all x ,
- (2) $f(x, y) \in \mathbb{H}^2$ for $y \geq 0$,
- (3) $f(x, y) \in \mathbb{R}^2 - \mathbb{H}^2$ for $y < 0$,

- (4) f restricted to the upper half-plane or the lower half-plane is C^∞ , but f itself is not C^∞ .

(b) Suppose M and N are C^∞ manifolds-with-boundary and $f: \partial M \rightarrow \partial N$ is a diffeomorphism. Let $P = M \cup_f N$ be obtained from the disjoint union of M and N by identifying $x \in \partial M$ with $f(x) \in \partial N$. If (x, U) is a coordinate system around $p \in \partial M$ and (y, V) a coordinate system around $f(p)$, with $f(U \cap \partial M) = V \cap \partial N$, and $(y \circ f)|_{U \cap \partial M} = x|_{U \cap \partial M}$, we can define a homeomorphism from $U \cup V \subset P$ to \mathbb{R}^n by sending U to \mathbb{H}^n by x and V to the lower half-plane by the reflection of y . Show that this procedure does *not*

define a C^∞ structure on P .

(c) Now suppose that there is a neighborhood U of ∂M in M and a diffeomorphism $\alpha: U \rightarrow \partial M \times [0, 1)$, such that $\alpha(p) = (p, 0)$ for all $p \in \partial M$, and a similar diffeomorphism $\beta: V \rightarrow \partial N \times [0, 1)$. (We will be able to prove later that such diffeomorphisms always exist). Show that there is a unique C^∞ structure

on P such that the inclusions of M and N are C^∞ and such that the map from $U \cup V$ to $\partial M \times (-1, 1)$ induced by α and β is a diffeomorphism.

(d) By using two different pairs (α, β) , define two different C^∞ structures on \mathbb{R}^2 , considered as the union of two copies of \mathbb{H}^2 with corresponding points on $\partial \mathbb{H}^2$ identified. Show that the resulting C^∞ manifolds are diffeomorphic, but that the diffeomorphism *cannot* be chosen arbitrarily close to the identity map.

15. (a) Find a C^∞ structure on $\mathbb{H}^1 \times \mathbb{H}^1$ which makes the inclusion into \mathbb{R}^2 a C^∞ map. Can the inclusion be an imbedding? Are the projections on each factor C^∞ maps?

(b) If M and N are manifolds-with-boundary, construct a C^∞ structure on $M \times N$ such that all the "slice maps" (defined in Problem 8) are C^∞ .

16. Show that the function $f: \mathbb{R} \rightarrow \mathbb{R}$ defined by

$$f(x) = \begin{cases} e^{-1/x} & x > 0 \\ 0 & x \leq 0 \end{cases}$$

is C^∞ (the formula e^{-1/x^2} is used just to get a function which is > 0 for $x < 0$, and $e^{-1/|x|}$ could be used just as well).

17. Lemma 2 (as addended by the proof of Theorem 15) shows that if C_1 and C_2 are disjoint closed subsets of M , then there is a C^∞ function $f: M \rightarrow [0, 1]$ such that $C_1 \subset f^{-1}(0)$ and $C_2 \subset f^{-1}(1)$. Actually, we can even find f with $C_1 = f^{-1}(0)$ and $C_2 = f^{-1}(1)$. The proof turns out to be quite easy, once you know the trick.

(a) It suffices to find, for any closed $C \subset M$, a C^∞ function f with $C = f^{-1}(0)$.

(b) Let $\{U_i\}$ be a countable cover of $M - C$, where each U_i is of the form

$$U_i = x^{-1}(\{a \in \mathbb{R}^n : |a| < 1\})$$

for some coordinate system x taking an open subset of $M - C$ onto \mathbb{R}^n . Let $f_i: M \rightarrow [0, 1]$ be a C^∞ function with $f_i > 0$ on U_i and $f_i = 0$ on $M - U_i$. Functions like

$$\frac{\partial f_i}{\partial x^j}, \frac{\partial^2 f_i}{\partial x^j \partial x^k}, \dots$$

will be called mixed partials of f_i , of order $1, 2, \dots$. Let

$$\alpha_i = \sup \text{ of all mixed partials of } f_i, \dots, f_i \text{ of all orders } \leq i.$$

Show that

$$f = \sum_{i=1}^{\infty} \frac{f_i}{\alpha_i 2^i}$$

is C^∞ , and $C = f^{-1}(0)$.

18. Consider the coordinate system (y^1, y^2) for \mathbb{R}^2 defined by

$$\begin{aligned} y^1(a, b) &= a \\ y^2(a, b) &= a + b. \end{aligned}$$

- (a) Compute $\partial f / \partial y^1(a, b)$ from the definition.
 (b) Also compute it from Proposition 3 (to find $\partial I^i / \partial y^j$, write each I^i in terms of y^1 and y^2).

Notice that $\partial f / \partial y^1 \neq \partial f / \partial I^1$ even though $y^1 = I^1$; the operator $\partial / \partial y^i$ depends on y and i , not just on y^i .

19. Compute the “Laplacian”

$$\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$$

in terms of polar coordinates. (First compute $\partial / \partial x$ in terms of $\partial / \partial r$ and $\partial / \partial \theta$; then compute $\partial^2 / \partial x^2$ from this). *Answer:* $\frac{1}{r} \left[\frac{\partial}{\partial r} \left(r \frac{\partial}{\partial r} \right) + \frac{\partial}{\partial \theta} \left(\frac{1}{r} \frac{\partial}{\partial \theta} \right) \right]$.

20. If $f: M^n \rightarrow N^m$ is C^1 and $m > n$, then $f(M)$ has measure 0 (provided that M has only countably many components).

21. The following pictures show, for $n = 1, 2$, and 3, a subdivision of $[0, 1] \times [0, 1]$ into 2^{2n} squares, $A_{n,1}, \dots, A_{n,2^{2n}}$; square $A_{n,k}$ is labeled simply k . The numbering is determined by the following conditions:

- (a) The lower left square is $A_{n,1}$.
- (b) The upper left square is $A_{n,2^{2n}}$.
- (c) Squares $A_{n,k}$ and $A_{n,k+1}$ have a common side.
- (d) Squares $A_{n,4l+1}, A_{n,4l+2}, A_{n,4l+3}, A_{n,4l+4}$ are contained in $A_{n-1,l+1}$.

1	2						

Define $f: [0, 1] \rightarrow [0, 1] \times [0, 1]$ by the condition

$$f(t) \in A_{n,k} \quad \text{for all} \quad \frac{k-1}{2^{2n}} \leq t \leq \frac{k}{2^{2n}}.$$

Show that f is continuous, onto $[0, 1] \times [0, 1]$, and not one-one.

22. For $p/2^n \in [0, 1]$, define $f(p/2^n) \in \mathbb{R}^2$ as shown below.

(a) Show that f is uniformly continuous, so that it has a continuous extension $g: [0, 1] \rightarrow \mathbb{R}^2$. Show that g is one-one, and that its image will not have measure 0 if the shaded triangles are chosen correctly.

(b) Consider the homeomorphic image of S^1 obtained by adding, below the image of g , a semi-circle with diameter the line segment AB . What does the inside of this curve look like?

23. Let $c: [0, 1] \rightarrow \mathbb{R}^n$ be continuous. For each partition $P = \{t_0, \dots, t_k\}$ of $[0, 1]$, define

$$\ell(c, P) = \sum_{i=1}^k d(c(t_i), c(t_{i-1})).$$

The curve c is rectifiable if $\{\ell(c, P)\}$ is bounded above (with length equal to $\sup\{\ell(c, P)\}$). Show that the image of a rectifiable curve has measure 0.

24. (a) If M is a C^∞ manifold, a set $M_1 \subset M$ can be made into a k -dimensional submanifold of M if and only if around each point in M_1 there is a coordinate system (x, U) on M such that $M_1 \cap U = \{p: x^{k+1}(p) = \dots = x^n(p) = 0\}$.

(b) The subset M_1 can be made into a closed submanifold if and only if such coordinate systems exist around every point of M .

25. The set $\{(x, |x|): x \in \mathbb{R}\}$ is not the image of any immersion of \mathbb{R} into \mathbb{R}^2 .

26. (a) If $U \subset \mathbb{R}^k$ is open and $f: U \rightarrow \mathbb{R}^{n-k}$ is C^∞ , then the graph of $f = \{(p, f(p)) \in \mathbb{R}^n: p \in U\}$ is a submanifold of \mathbb{R}^n .

(b) Every submanifold of \mathbb{R}^n is locally of this form, after renumbering coordinates. (Neither Theorem 9 nor 10 is quite strong enough. You will need

the implicit function theorem (*Calculus on Manifolds*, pg. 41). Theorem 10 is essentially Theorem 2-13 of *Calculus on Manifolds*; comparison with the implicit function theorem will show how some information has been allowed to escape.)

27. (a) An immersion from one n -manifold to another is an open map (the image of an open set is open).

(b) If M and N are n -manifolds with M compact and N connected, and $f: M \rightarrow N$ is an immersion, then f is onto.

28. Prove Proposition 12: If $f: M^n \rightarrow N$ has constant rank k on a neighborhood of $f^{-1}(y)$, then $f^{-1}(y)$ is a (closed) submanifold of M of dimension $n - k$ (or is empty).

29. Let $f: \mathbb{P}^2 \rightarrow \mathbb{R}^3$ be the map

$$g([x, y, z]) = (yz, xz, xy)$$

defined in Chapter 1, whose image is the Steiner surface. Show that g fails to be an immersion at 6 points (the image points are the points at distance $\pm 1/2$ on each axis). There is a way of immersing \mathbb{P}^2 in \mathbb{R}^3 , known as Boy's Surface. See Hilbert and Cohn-Vossen, *Geometry and the Imagination*, pp. 317–321.

30. A continuous function $f: X \rightarrow Y$ is proper if $f^{-1}(C)$ is compact for every compact $C \subset Y$. The limit set $L(f)$ of f is the set of all $y \in Y$ such that $y = \lim f(x_n)$ for some sequence $x_1, x_2, x_3, \dots \in X$ with no convergent subsequence.

(a) $L(f) = \emptyset$ if and only if f is proper.

(b) $f(X) \subset Y$ is closed if and only if $L(f) \subset f(X)$.

(c) There is a continuous $f: \mathbb{R} \rightarrow \mathbb{R}^2$ with $f(\mathbb{R})$ closed, but $L(f) \neq \emptyset$.

(d) A one-one continuous function $f: X \rightarrow Y$ is a homeomorphism (onto its image) if and only if $L(f) \cap f(Y) = \emptyset$.

(e) A submanifold $M_1 \subset M$ is a closed submanifold if and only if the inclusion map $i: M_1 \rightarrow M$ is proper.

(f) If M is a manifold, there is a proper map $f: M \rightarrow \mathbb{R}$; the function f can be made C^∞ if M is a C^∞ manifold.

31. (a) Find a cover of $[0, 1]$ which is not locally finite but which is “point-finite”: every point of $[0, 1]$ is in only finitely many members of the cover.

(b) Prove the Shrinking Lemma when the cover \mathcal{O} is point-finite and countable (notice that local-finiteness is not really used).

(c) Prove the Shrinking Lemma when \mathcal{O} is a (not necessarily countable) point-finite cover of any space. (You will need Zorn's Lemma; consider collections \mathcal{C}

of pairs (U, U') where $U \in \mathcal{O}$, $U' \subset U$, and the union of all U' for $(U, U') \in \mathcal{C}$, together with all other $U \in \mathcal{O}$ covers the space.)

32. (a) If $M_1 \subset M$ is a closed submanifold, $U \supset M_1$ is any neighborhood, and $f: M_1 \rightarrow \mathbb{R}$ is C^∞ , then there is a C^∞ function $\tilde{f}: M \rightarrow \mathbb{R}$ with $\tilde{f} = f$ on M_1 , and with support $\tilde{f} \subset U$.
 (b) This is false if $M = \mathbb{R}$ and $M_1 = (0, 1)$.
 (c) This is false if \mathbb{R} is replaced by a disconnected manifold N .

Remark: It is also false if $M = \mathbb{R}^2$, $M_1 = N = S^1$, and $f = \text{identity}$; in fact, in this case, f has no continuous extension to a map from \mathbb{R}^2 to S^1 , but the proof requires some topology. However, f can always be extended to a C^∞ function in a neighborhood of M_1 (extend locally, and use partitions of unity).

33. (a) The set of all non-singular $n \times n$ matrices with real entries is called $GL(n, \mathbb{R})$, the **general linear group**. It is a C^∞ manifold, since it is an open subset of \mathbb{R}^{n^2} . The **special linear group** $SL(n, \mathbb{R})$, or **unimodular group**, is the subgroup of all matrices with $\det = 1$. Using the formula for $D(\det)$ in *Calculus on Manifolds*, pg. 24, show that $SL(n, \mathbb{R})$ is a closed submanifold of $GL(n, \mathbb{R})$ of dimension $n^2 - 1$.
 (b) The symmetric $n \times n$ matrices may be thought of as $\mathbb{R}^{n(n+1)/2}$. Define $\psi: GL(n, \mathbb{R}) \rightarrow (\text{symmetric matrices})$ by $\psi(A) = A \cdot A^t$, where A^t is the transpose of A . The subgroup $\psi^{-1}(I)$ of $GL(n, \mathbb{R})$ is called the **orthogonal group** $O(n)$. Show that $A \in O(n)$ if and only if the rows [or columns] of A are orthonormal.
 (c) Show that $O(n)$ is compact.
 (d) For any $A \in GL(n, \mathbb{R})$, define $R_A: GL(n, \mathbb{R}) \rightarrow GL(n, \mathbb{R})$ by $R_A(B) = BA$. Show that R_A is a diffeomorphism, and that $\psi \circ R_A = \psi$ for all $A \in O(n)$. By applying the chain rule, show that for $A \in O(n)$ the matrix

$$\left(\frac{\partial \psi^{ij}}{\partial x^{kl}}(A) \right) \text{ has the same rank as } \left(\frac{\partial \psi^{ij}}{\partial x^{kl}}(I) \right).$$

(Here x^{kl} are the coordinate functions in \mathbb{R}^{n^2} , and ψ^{ij} the $n(n+1)/2$ component functions of ψ .) Conclude from Proposition 12 that $O(n)$ is a submanifold of $GL(n, \mathbb{R})$.

- (e) Using the formula

$$\psi^{ij}(A) = \sum_k a_{ik} a_{jk} \quad (A = (a_{ij})),$$

show that

$$\frac{\partial \psi^{ij}}{\partial x^{kl}}(A) = \begin{cases} a_{jl} & k = i \neq j \\ a_{il} & k = j \neq i \\ 2a_{il} & k = i = j \\ 0 & \text{otherwise.} \end{cases}$$

Show that the rank of this matrix is $n(n+1)/2$ at I (and hence at A for all $A \in O(n)$.) Conclude that $O(n)$ has dimension $n(n-1)/2$.

(f) Show that $\det A = \pm 1$ for all $A \in O(n)$. The group $O(n) \cap SL(n, \mathbb{R})$ is called the **special orthogonal group** $SO(n)$, or the **rotation group** $R(n)$.

34. Let $M(m, n)$ denote the set of all $m \times n$ matrices, and $M(m, n; k)$ the set of all $m \times n$ matrices of rank k .

(a) For every $X_0 \in M(m, n; k)$ there are permutation matrices P and Q such that

$$PX_0Q = \begin{pmatrix} A_0 & B_0 \\ C_0 & D_0 \end{pmatrix}, \quad \text{where } A_0 \text{ is } k \times k \text{ and non-singular.}$$

(b) There is some $\varepsilon > 0$ such that A is non-singular whenever all entries of $A - A_0$ are $< \varepsilon$.

(c) If

$$PXQ = \begin{pmatrix} A & B \\ C & D \end{pmatrix}$$

where the entries of $A - A_0$ are $< \varepsilon$, then X has rank k if and only if $D = CA^{-1}B$. *Hint:* If I_k denotes the $k \times k$ identity matrix, then

$$\begin{pmatrix} I_k & 0 \\ X & I_{p-k} \end{pmatrix} \begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} A & B \\ XA + C & XB + D \end{pmatrix}.$$

(d) $M(m, n; k) \subset M(m, n)$ is a submanifold of dimension $k(m+n-k)$ for all $k \leq m, n$.

CHAPTER 3

THE TANGENT BUNDLE

A point $v \in \mathbb{R}^n$ is frequently pictured as an arrow from 0 to v . But there are many situations where we would like to picture this same arrow as starting

at a different point $p \in \mathbb{R}^n$:

For example, suppose $c: \mathbb{R} \rightarrow \mathbb{R}^n$ is a differentiable curve. Then $c'(t) = (c^1(t), \dots, c^n(t))$ is just a point of \mathbb{R}^n , but the line between $c(t)$ and $c(t) + c'(t)$ is tangent to the curve, and the “velocity vector” or “tangent vector” $c'(t)$ of the curve c is customarily pictured as the arrow from $c(t)$ to $c(t) + c'(t)$.

To give this picture mathematical substance, we simply describe the “arrow” from p to $p + v$ by the pair (p, v) . The set of all such pairs is just $\mathbb{R}^n \times \mathbb{R}^n$, which we will also denote by $T\mathbb{R}^n$, the “tangent space of \mathbb{R}^n ”; elements of $T\mathbb{R}^n$ are called “tangent vectors” of \mathbb{R}^n . We will often denote $(p, v) \in T\mathbb{R}^n$ by v_p (“the vector v at p ”); in conformity with this notation, we will denote the set of all (p, v) for $v \in \mathbb{R}^n$ by \mathbb{R}^n_p . At times, it is more convenient to denote a member of $T\mathbb{R}^n$ by a single letter, like v . To recover the first member of a pair $v \in T\mathbb{R}^n$, we define the “projection” map $\pi: \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ by $\pi(a, b) = a$. For any tangent vector v , the point $\pi(v)$ is “where it’s at”.

The set $\pi^{-1}(p)$ may be pictured as all arrows starting at p . Alternately,

it can be pictured more geometrically as a particular subset of $\mathbb{R}^n \times \mathbb{R}^n$, the one visualizable case occurring when $n = 1$. This picture gives rise to some

terminology—we call $\pi^{-1}(p)$ the fibre over p . This fibre can be made into a

vector space in an obvious way: we define

$$(p, v) \oplus (p, w) = (p, v + w) \\ a \bullet (p, v) = (p, a \cdot v).$$

(The operations \oplus and \bullet should really be thought of as defined on

$$\bigcup_{p \in \mathbb{R}^n} \pi^{-1}(p) \times \pi^{-1}(p), \quad \text{and} \quad \mathbb{R} \times T\mathbb{R}^n, \quad \text{respectively.}$$

Usually we will just use ordinary $+$ and \cdot instead of \oplus and \bullet .)

If $f: \mathbb{R}^n \rightarrow \mathbb{R}^m$ is a differentiable map, and $p \in \mathbb{R}^n$, then the linear transformation $Df(p): \mathbb{R}^n \rightarrow \mathbb{R}^m$ may be used to produce a linear map from $\mathbb{R}^n_p \rightarrow \mathbb{R}^m_{f(p)}$ defined by

$$v_p \mapsto [Df(p)(v)]_{f(p)}.$$

This map, whose apparently anomalous features will soon be justified, is denoted by f_{*p} ; the symbol f_* denotes the map $f_*: T\mathbb{R}^n \rightarrow T\mathbb{R}^m$ which is the union of all f_{*p} . Since $f_{*p}(v)$ is defined to be a vector $\in \mathbb{R}^m_{f(p)}$, the following diagram “commutes” (the two possible compositions from $T\mathbb{R}^n$ to \mathbb{R}^m are equal),

$$\begin{array}{ccc} T\mathbb{R}^n & \xrightarrow{f_*} & T\mathbb{R}^m \\ \pi \downarrow & & \downarrow \pi \\ \mathbb{R}^n & \xrightarrow{f} & \mathbb{R}^m \end{array} \quad \pi \circ f_* = f \circ \pi.$$

Thus, f_* has the map f , as well as all maps $Df(p)$, built into it.

This is not the only reason for defining f_* in this particular way, however. Suppose that $g: \mathbb{R}^m \rightarrow \mathbb{R}^k$ is another differentiable function, so that, by the chain rule,

$$(1) \quad D(g \circ f)(p) = Dg(f(p)) \circ Df(p).$$

By our definition,

$$g_*([Df(p)(v)]_{f(p)}) = (Dg(f(p))(Df(p)(v)))_{g(f(p))}.$$

This looks horribly complicated, but, using (1), it can be written

$$g_*(f_*(v_p)) = (g \circ f)_*(v_p);$$

thus we have

$$g_* \circ f_* = (g \circ f)_*.$$

This relation would clearly fall apart completely if $f_*(v_p)$ were not in $\mathbb{R}^m_{f(p)}$; with our present definition of f_* , it is merely an elegant restatement of the chain rule.

Henceforth, we will state almost all concepts about Jacobian matrices, like rank or singularity, in terms of f_* , rather than Df . The “tangent vector” of a curve $c: \mathbb{R} \rightarrow \mathbb{R}^n$ can be defined in terms of this concept, also. The tangent vector of c at t may be defined as

$$c'(t)_{c(t)} \in \mathbb{R}^n_{c(t)}.$$

[If c happens to be of the form

$$c(t) = (t, f(t)) \text{ for } f: \mathbb{R} \rightarrow \mathbb{R}$$

then

$$c'(t)_{c(t)} = (1, f'(t))_{c(t)};$$

this vector lies along the tangent line to the graph of f at $(t, f(t))$.] Notice that the tangent vector of c at t is the same as

$$c_*(1_t) = [Dc(t)(1)]_{c(t)} = (c^{1'}(t), \dots, c^{n'}(t))_{c(t)},$$

where $1_t = (t, 1)$ is the “unit” tangent vector of \mathbb{R} at t .

If $g: \mathbb{R}^n \rightarrow \mathbb{R}^m$ is differentiable, then $g \circ c$ is a curve in \mathbb{R}^m . The tangent

vector of $g \circ c$ at t is

$$\begin{aligned} (g \circ c)_*(l_t) &= g_*(c_*(l_t)) \\ &= g_*(\text{tangent vector of } c \text{ at } t). \end{aligned}$$

Consider now an n -dimensional manifold M and an imbedding $i: M \rightarrow \mathbb{R}^N$. Suppose we take a coordinate system (x, U) around p . Then $i \circ x^{-1}$ is a map from \mathbb{R}^n to \mathbb{R}^N with rank n . Consequently, $(i \circ x^{-1})_*(\mathbb{R}^n_{x(p)})$ is an n -dimensional subspace of $\mathbb{R}^N_{i(p)}$. This subspace doesn't depend on the coordinate

system x , for if y is another coordinate system, then

$$\begin{aligned} (i \circ y^{-1})_* &= (i \circ x^{-1} \circ x \circ y^{-1})_* \\ &= (i \circ x^{-1})_* \circ (x \circ y^{-1})_* \end{aligned}$$

and

$$(x \circ y^{-1})_{*y(p)}: \mathbb{R}^n_{y(p)} \rightarrow \mathbb{R}^n_{x(p)}$$

is an isomorphism (with inverse $(y \circ x^{-1})_{*x(p)}$).

There is another way to see this, which justifies the picture we have drawn. If $c: (-\varepsilon, \varepsilon) \rightarrow \mathbb{R}^n$ is a curve with $c(0) = x(p)$, then $\alpha = i \circ x^{-1} \circ c$ is a curve in \mathbb{R}^N which lies in $i(M)$, and every differentiable curve in $i(M)$ is of this

form (Proof?). Now

$$\alpha_*(1_0) = (i \circ x^{-1})_* \circ c_*(1_0),$$

so the tangent vector of every α is in $(i \circ x^{-1})_*(\mathbb{R}^n_{x(p)})$. Moreover, every vector in this subspace is the tangent vector of some α , since every vector in $\mathbb{R}^n_{x(p)}$ is the tangent vector of some curve c . Thus, our n -dimensional subspace is just the set of all tangent vectors at $i(p)$ to differentiable curves in $i(M)$. We will denote this n -dimensional subspace by $(M, i)_p$.

We now want to look at the (disjoint) union

$$T(M, i) = \bigcup_{p \in M} (M, i)_p \subset i(M) \times \mathbb{R}^N \subset T\mathbb{R}^N.$$

We can define a “projection” map

$$\pi: T(M, i) \rightarrow M$$

by

$$\pi(v) = p \quad \text{if} \quad v \in (M, i)_p.$$

As in the case of $T\mathbb{R}^n$, each “fibre” $\pi^{-1}(p)$ has a vector space structure also. Beyond this we have to look a little more carefully at some specific examples.

Consider first the manifold $M = S^1$ and the inclusion $i: S^1 \rightarrow \mathbb{R}^2$. The curve $c(\theta) = (\cos \theta, \sin \theta)$ passes through every point of S^1 , and

$$c'(\theta) = (-\sin \theta, \cos \theta) \neq 0.$$

For each $p = (\cos \theta, \sin \theta) \in S^1$, let $u_p = (-\sin \theta, \cos \theta)_p$ (it clearly doesn't matter which of the infinitely many possible θ 's we choose). Then $(S^1, i)_p$ con-

sists of all multiples of the vector u_p . We can therefore define a homeomorphism

$f_1: T(S^1, i) \rightarrow S^1 \times \mathbb{R}^1$ by $f_1(\lambda u_p) = (p, \lambda)$, which makes the following diagram commute.

$$\begin{array}{ccc}
 T(S^1, i) & \xrightarrow{f_1} & S^1 \times \mathbb{R}^1 \\
 \searrow \pi & & \swarrow \pi' \\
 & S^1 &
 \end{array}
 \quad [\pi'(a, b) = a]$$

If we define the “fibres” of π' to be the sets $\pi'^{-1}(p)$, then each fibre has a vector space structure in a natural way. Commutativity of the diagram means that f_1 takes fibres into fibres; clearly f_1 restricted to a fibre is a linear isomorphism onto the image.

Now consider the manifold $M = S^2$ and the inclusion $i: S^2 \subset \mathbb{R}^3$. In this case there is no map $f_2: T(S^2, i) \rightarrow S^2 \times \mathbb{R}^2$ with the properties of the map f_1 . If there were, then, for a fixed vector $v \neq 0$ in \mathbb{R}^2 , the set of vectors

$$\{f_2^{-1}(v_p) : p \in S^2\}$$

would be a collection of non-zero tangent vectors, one at each point of S^2 , which varied continuously. It is a well-known (hard) theorem of topology that this is impossible (you can't comb the hair on a sphere).

There is another example where we can prove that no appropriate homeomorphism $T(M, i) \rightarrow M \times \mathbb{R}^2$ exists, without appealing to a hard theorem of topology. The map i will just be the inclusion $M \rightarrow \mathbb{R}^3$ where M is a Möbius strip, to be precise, the particular subset of \mathbb{R}^3 defined in Chapter 1— M is the image of the map $f: [0, 2\pi] \times (-1, 1) \rightarrow \mathbb{R}^3$ defined by

$$f(\theta, t) = \left(2 \cos \theta + t \cos \frac{\theta}{2} \cos \theta, 2 \sin \theta + t \cos \frac{\theta}{2} \sin \theta, t \sin \frac{\theta}{2} \right).$$

At each point $p = (2 \cos \theta, 2 \sin \theta, 0)$ of M , the vector

$$v_p = (-2 \sin \theta, 2 \cos \theta, 0)_p = f_*((1, 0)_{(\theta, 0)})$$

is a tangent vector. The same is true for all multiples of $f_*((0, 1)_{(\theta, 0)})$, shown as dashed arrows in the picture. Notice that

$$\begin{aligned} f_*((0, 1)_{(0, 0)}) &= [Df(0, 0)(0, 1)]_{(2, 0, 0)} \\ &= \left[\frac{\partial f}{\partial t}(0, 0) \right]_{(2, 0, 0)} = (1, 0, 0)_{(2, 0, 0)}, \end{aligned}$$

while

$$f_*((0, 1)_{(2\pi, 0)}) = \left[\frac{\partial f}{\partial t}(2\pi, 0) \right]_{(2, 0, 0)} = (-1, 0, 0)_{(2, 0, 0)}.$$

This means that we can never pick non-zero dashed vectors *continuously* on the set of all points $(2 \cos \theta, 2 \sin \theta, 0)$: If we could, then each vector would be

$$f_*((0, \lambda(\theta))_{(\theta, 0)})$$

for some continuous function $\lambda: [0, 2\pi] \rightarrow \mathbb{R}$. This function would have to be non-zero everywhere and also satisfy $\lambda(2\pi) = -\lambda(0)$, which it can't (by an easy theorem of topology). The impossibility of choosing non-zero dashed vectors continuously clearly shows that there is no way to map $T(M, i)$, fibre by fibre,

homeomorphically onto $M \times \mathbb{R}^2$. We thus have another case where $T(M, i)$ does not “look like” a product $M \times \mathbb{R}^n$.

For any imbedding $i: M \rightarrow \mathbb{R}^N$, however, the structure of $T(M, i)$ is always simple *locally*: if (x, U) is a coordinate system on M , then $\pi^{-1}(U)$, the part of $T(M, i)$ over U , can always be mapped, fibre by fibre, homeomorphically onto $U \times \mathbb{R}^n$. In fact, for each $p \in U$, the fibre

$$(M, i)_p \text{ equals } (i \circ x^{-1})_{*x(p)} (\mathbb{R}^n_{x(p)}) = m_p (\mathbb{R}^n_{x(p)}),$$

where the abbreviation m_p has been introduced temporarily; we can therefore define

$$f: \pi^{-1}(U) \rightarrow U \times \mathbb{R}^n$$

by

$$f(m_p(v_{x(p)})) = (p, v).$$

In standard jargon, $T(M, i)$ is “locally trivial”. This additional feature qualifies $T(M, i)$ to be included among an extremely important class of structures:

An n -dimensional vector bundle (or n -plane bundle) is a five-tuple

$$\xi = (E, \pi, B, \oplus, \odot),$$

where

- (1) E and B are spaces (the “total space” and “base space” of ξ , respectively),
- (2) $\pi: E \rightarrow B$ is a continuous map *onto* B ,
- (3) \oplus and \odot are maps

$$\oplus: \bigcup_{p \in B} \pi^{-1}(p) \times \pi^{-1}(p) \rightarrow E, \quad \odot: \mathbb{R} \times E \rightarrow E,$$

with $\oplus(\pi^{-1}(p) \times \pi^{-1}(p)) \subset \pi^{-1}(p)$ and $\odot(\mathbb{R} \times \pi^{-1}(p)) \subset \pi^{-1}(p)$, which make each fibre $\pi^{-1}(p)$ into an n -dimensional vector space over \mathbb{R} ,

such that the following “local triviality” condition is satisfied:

For each $p \in B$, there is a neighborhood U of p and a homeomorphism $t: \pi^{-1}(U) \rightarrow U \times \mathbb{R}^n$ which is a vector space isomorphism from each $\pi^{-1}(q)$ onto $q \times \mathbb{R}^n$, for all $q \in U$.

Because this local triviality condition really is a local condition, each bundle $\xi = (E, \pi, B, \oplus, \odot)$ automatically gives rise to a bundle $\xi|A$ over any subset $A \subset B$; to be precise,

$$\xi|A = \left(\pi^{-1}(A), \pi|_{\pi^{-1}(A)}, A, \oplus|_{\bigcup_{p \in A} \pi^{-1}(p) \times \pi^{-1}(p)}, \odot|_{\mathbb{R} \times \pi^{-1}(A)} \right).$$

Notation as cumbersome as all this invites abuse, and we shall usually refer simply to a bundle $\pi: E \rightarrow B$, or even denote the bundle by E alone. For vectors $v, w \in \pi^{-1}(p)$ and $a \in \mathbb{R}$, we will denote $\oplus(v, w)$ and $\odot(a, v)$ by $v + w$, and $a \cdot v$ or av , respectively.

The simplest example of an n -plane bundle is just $X \times \mathbb{R}^n$ with $\pi: X \times \mathbb{R}^n \rightarrow X$ the projection on the first factor, and the obvious vector space structure on each fibre. This is called the trivial n -plane bundle over X and will be denoted by $\varepsilon^n(X)$. The “tangent bundle” $T\mathbb{R}^n$ is just $\varepsilon^n(\mathbb{R}^n)$.

The bundle $T(S^1, i)$ considered before is equivalent to $\varepsilon^1(S^1)$. Equivalence is here a technical term: Two vector bundles $\xi_1 = \pi_1: E_1 \rightarrow B$ and $\xi_2 = \pi_2: E_2 \rightarrow B$ are equivalent ($\xi_1 \simeq \xi_2$) if there is a homeomorphism $h: E_1 \rightarrow E_2$ which takes each fibre $\pi_1^{-1}(p)$ isomorphically onto $\pi_2^{-1}(p)$. The map h is called an equivalence. A bundle equivalent to $\varepsilon^n(B)$ is called **trivial**. (The local triviality condition for a bundle ξ just says that $\xi|U$ is trivial for some neighborhood U of p .)

The bundles $T(S^2, i)$ and $T(M, i)$ are not trivial, but there is an even simpler example of a non-trivial bundle. The Möbius strip *itself* (not $T(M, i)$) can be considered as a 1-dimensional vector bundle over S^1 , for M can be obtained from $[0, 1] \times \mathbb{R}$ by identifying $(0, a)$ with $(1, -a)$, while S^1 can be obtained from

$[0, 1]$ by identifying 0 with 1; the map π is defined by $\pi(t, a) = t$ for $0 < t < 1$ and $\pi(\{(0, a), (1, -a)\}) = \{0, 1\}$. The diagram above illustrates local triviality near the point $\{0, 1\}$ of S^1 . Suppose that $s: S^1 \rightarrow M$ is a continuous function with $\pi \circ s = \text{identity of } M$ (such a function is called a section). Such a map

corresponds to a continuous function $\bar{s}: [0, 1] \rightarrow \mathbb{R}$ with $\bar{s}(0) = -\bar{s}(1)$. Since \bar{s} must be 0 somewhere, the section s must be 0 somewhere (that is, $s(\theta) \in \pi^{-1}(\theta)$ must be the 0 vector for some $\theta \in S^1$). This surely shows that M is not a trivial bundle.

An equivalence is obviously the analogue of an isomorphism. The analogue of a homomorphism is the following.* A bundle map from ξ_1 to ξ_2 is a pair of continuous maps (\tilde{f}, f) , with $\tilde{f}: E_1 \rightarrow E_2$ and $f: B_1 \rightarrow B_2$, such that

(1) the following diagram commutes

$$\begin{array}{ccc} E_1 & \xrightarrow{\tilde{f}} & E_2 \\ \pi_1 \downarrow & & \downarrow \pi_2 \\ B_1 & \xrightarrow{f} & B_2 \end{array},$$

(2) $\tilde{f}: \pi_1^{-1}(p) \rightarrow \pi_2^{-1}(f(p))$ is a linear map.

The pair (f_*, f) is a bundle map from $T\mathbb{R}^k$ to $T\mathbb{R}^l$ for any differentiable $f: \mathbb{R}^k \rightarrow \mathbb{R}^l$. If $M^n \subset \mathbb{R}^k$ and $N^m \subset \mathbb{R}^l$ are submanifolds, $i: M \rightarrow \mathbb{R}^k$ and $j: N \rightarrow \mathbb{R}^l$ are the inclusions, and the map f satisfies $f(M) \subset N$, then f_*

*There are actually several possible choices, depending on whether one is considering all bundles at once, fixed bundles over various spaces, or a fixed base space with varying bundles. Thus f may be restricted to be an isomorphism on fibres and f to be the identity, or a homeomorphism. The relations between some of these cases are considered in the problems.

takes $T(M, i)$ to $T(N, j)$; to see this, just remember that $v \in T(M, i)_p$ is the tangent vector of a curve c in M , so $f_*(v)$ is the tangent vector of the curve $f \circ c$ in N , and consequently $f_*(v) \in T(N, j)$. In this way we obtain a bundle map from $T(M, i)$ to $T(N, j)$. Actually, it would have sufficed to begin with a C^∞ function $f: M \rightarrow N$, since f can be extended to \mathbb{R}^k locally. In fact, this construction could be generalized much further, to the case where i and j are merely imbeddings of two abstract manifolds M and N , and $f: M \rightarrow N$ is C^∞ ; we just consider the function $j \circ f \circ i^{-1}: i(M) \rightarrow i(N)$ and extend it locally to \mathbb{R}^k . The case which we want to examine most carefully is the simplest: where $M = N$ and f is the identity, while i and j are two imbeddings of M in \mathbb{R}^k and \mathbb{R}^l , respectively. Elements of $T(M, i)_p$ are of the form $(i \circ x^{-1})_*(w)$

for $w \in \mathbb{R}^n_{x(p)}$, while elements of $T(M, j)_p$ are of the form $(j \circ x^{-1})_*(w)$ for $w \in \mathbb{R}^n_{x(p)}$. If we map

$$(i \circ x^{-1})_*(w) \mapsto (j \circ x^{-1})_*(w)$$

we obtain a bundle map from $T(M, i)|U$ to $T(M, j)|U$, which is obviously an equivalence. The map $(M, i)_p \rightarrow (M, j)_p$ induced on fibres is independent of the coordinate system x , for if (y, V) is another coordinate system, then

$$\begin{array}{ccc} (i \circ y^{-1})_*(w) & = & (i \circ x^{-1})_*((x \circ y^{-1})_*(w)) \\ \downarrow & & \downarrow \\ (j \circ y^{-1})_*(w) & = & (j \circ x^{-1})_*((x \circ y^{-1})_*(w)). \end{array}$$

We can therefore put all these maps together, and obtain an *equivalence* from $T(M, i)$ to $T(M, j)$. In other words, the dependence of $T(M, i)$ on i is almost illusory; we could abbreviate $T(M, i)$ to TM , if we agreed that TM really denotes an equivalence class of bundles, rather than one bundle. That is the

sort of thing an algebraist might do, and it is undoubtedly ugly. What we would like to do is to get a single bundle for each M , in some natural way, which has all the properties any one of these particular bundles $T(M, i)$ has. Can we do this? Yes, we can. When we do, $T\mathbb{R}^n$ will be different from our old definition (namely, $\varepsilon^n(\mathbb{R}^n)$), and so will f_* for $f: \mathbb{R}^n \rightarrow \mathbb{R}^m$, so in stating our result precisely we will write “old f_* ” when necessary.

1. THEOREM. It is possible to assign to each n -manifold M an n -plane bundle TM over M , and to each C^∞ map $f: M \rightarrow N$ a bundle map (f_*, f) , such that:

- (1) If $1: M \rightarrow M$ is the identity, then $1_*: TM \rightarrow TM$ is the identity. If $g: N \rightarrow P$, then $(g \circ f)_* = g_* \circ f_*$.
- (2) There are equivalences $t^n: T\mathbb{R}^n \rightarrow \varepsilon^n(\mathbb{R}^n)$ such that for every C^∞ function $f: \mathbb{R}^n \rightarrow \mathbb{R}^m$ the following commutes.

$$\begin{array}{ccc} T\mathbb{R}^n & \xrightarrow{f_*} & T\mathbb{R}^m \\ t^n \downarrow & & \downarrow t^m \\ \varepsilon^n(\mathbb{R}^n) & \xrightarrow{\text{old } f_*} & \varepsilon^m(\mathbb{R}^m) \end{array}$$

- (3) If $U \subset M$ is an open submanifold, then TU is equivalent to $(TM)|U$, and for $f: M \rightarrow N$ the map $(f|U)_*: TU \rightarrow TN$ is just the restriction of f_* . More precisely, there is an equivalence $TU \simeq (TM)|U$ such that the following diagrams commute, where $i: U \rightarrow M$ is the inclusion.*

$$\begin{array}{ccc} TU & \xrightarrow{i_*} & TM \\ \simeq \searrow & & \nearrow \subset \\ & (TM)|U & \end{array} \qquad \begin{array}{ccc} TU & \xrightarrow{(f|U)_*} & TN \\ i_* \searrow & & \nearrow f_* \\ & TM & \end{array}$$

PROOF. The construction of TM is an ingenious, though quite natural, subterfuge. We will obtain a single bundle for TM , but the *elements* of TM will each be large equivalence classes.

* When using the notation f_* , it must be understood that the symbol “ f ” really refers to a triple (f, M, N) where $f: M \rightarrow N$. The identity map 1 of U to itself and the inclusion map $i: U \rightarrow M$ have to be considered as different, since the maps $1_*: TU \rightarrow TU$ and $i_*: TU \rightarrow TM$ are certainly different (they map TU into two different sets).

The construction is much easier to understand if we first imagine that we *already had* our bundles TM . Then if (x, U) is a coordinate system, we would have a map $x_*: TU \rightarrow T(x(U))$, and this would be an equivalence (with inverse $(x^{-1})_*$). Since TU should be essentially $(TM)|_U$, and $T(x(U))$ should essentially be $x(U) \times \mathbb{R}^n$, a point $e \in \pi^{-1}(p)$ would be taken by x_* to some $(x(p), v)$. Here v is just an element of \mathbb{R}^n (and every v would occur, since x_* maps $\pi^{-1}(p)$ isomorphically onto $\{p\} \times \mathbb{R}^n$). If y is another coordinate system, then $y_*(e)$ would be $(y(p), w)$ for some $w \in \mathbb{R}^n$. We can easily figure out what the relationship between v and w would be; since $(x(p), v)$ is taken to $(y(p), w)$ by $y_* \circ x_*^{-1} = (y \circ x^{-1})_*$, and $(y \circ x^{-1})_*$ is supposed to be the old $(y \circ x^{-1})_*$, we would have

$$(a) \quad w = D(y \circ x^{-1})(x(p))(v).$$

This condition makes perfect sense without any mention of bundles. It is the clue which enables us to now define TM .

If x and y are coordinate systems whose domains contain p , and $v, w \in \mathbb{R}^n$, we *define*

$$(x, v) \sim_p (y, w) \quad \text{if (a) is satisfied.}$$

It is easy to check (using the chain rule) that \sim_p is an equivalence relation; the equivalence class of (x, v) will be denoted by $[x, v]_p$. These equivalence classes will be called tangent vectors at p , and TM is defined to be the set of all tangent vectors at all points $p \in M$; the map π takes \sim_p equivalence classes to p . We define a vector space structure on $\pi^{-1}(p)$ by the formulas

$$\begin{aligned} [x, v]_p + [x, w]_p &= [x, v + w]_p \\ a \cdot [x, v]_p &= [x, a \cdot v]_p; \end{aligned}$$

this definition is independent of the particular coordinate system x or y , because $D(y \circ x^{-1})(x(p))$ is an isomorphism from \mathbb{R}^n to \mathbb{R}^n .

Our definition of TM provides a one-one onto map

$$(b) \quad t_x: \pi^{-1}(U) \rightarrow U \times \mathbb{R}^n, \quad \text{namely} \quad [x, v]_q \mapsto (q, v).$$

We want this to be a homeomorphism, so we want $t_x^{-1}(A)$ to be open for every open $A \subset U \times \mathbb{R}^n$, and thus we want any union of such sets to be open. There is a metric with exactly these sets as open sets, but it is a little ticklish to produce, so we leave this one part of the proof to Problem 1.

We now have a bundle $\pi: TM \rightarrow M$. We will denote the fibre $\pi^{-1}(p)$ by M_p , in conformity with the notation \mathbb{R}^n_p , though TM_p might be better. If

$f: M \rightarrow N$, and (x, U) and (y, V) are coordinate systems around p and $f(p)$, respectively, we define

$$(c) \quad f_*([x, v]_p) = [y, D(y \circ f \circ x^{-1})(x(p))(v)]_{f(p)}.$$

Of course, it must be checked that this definition is independent of x and y (the chain rule again).

Condition (1) of our theorem is obvious.

To prove (2), we define t^n to be t_I , where I is the identity map of \mathbb{R}^n and t_x is defined in (b); it is trivial, though perhaps confusing to the novice, to prove commutativity of the diagram.

Condition (3) is practically obvious also. In fact, the fibre of TU over $p \in U$ is almost exactly the same as the fibre of TM over p ; the only difference is that each equivalence class for M contains some extra members, since in M there are more coordinate systems around p than there are in $U \subset M$. ♦

Henceforth, the bundle $\pi: TM \rightarrow M$ will be called the **tangent bundle** of M . If $i: M \rightarrow \mathbb{R}^k$ is an imbedding, then TM is equivalent to $T(M, i)$. In fact, if (x, U) is a coordinate system around p , and I is the identity coordinate system of \mathbb{R}^k , then

$$\begin{aligned} i_*([x, v]_p) &= [I, D(i \circ x^{-1})(x(p))(v)]_{i(p)} && \text{by (c)} \\ t^n &= t_I \quad \downarrow \\ (i(p), D(i \circ x^{-1})(x(p))(v)) &\in (M, i)_p; \end{aligned}$$

the composition $t^n i_*$ is easily seen to be an equivalence. But $T(M, i)$ will play no further role in this story—the abstract substitute TM will always be used instead.

Having succeeded in producing a bundle over each M , which is equivalent to $T(M, i)$, we next ask how fortuitous this was. Can one find other bundles with the same properties? The answer is yes, and we proceed to define two different such bundles.

For the first example, we consider curves $c: (-\varepsilon, \varepsilon) \rightarrow M$, each defined on some interval around 0, with $c(0) = p$. If (x, U) is a coordinate system around p , we define

$$c_1 \underset{p}{\approx} c_2 \quad \text{if and only if:} \quad \begin{array}{l} x \circ c_1 \text{ and } x \circ c_2, \text{ mapping } \mathbb{R} \text{ to } \mathbb{R}^n, \\ \text{have the same derivative at 0.} \end{array}$$

The equivalence classes, for all $p \in M$, will be the elements of our new bundle, $T'M$. For $f: M \rightarrow N$ there is a map $f_\#$ taking the $\underset{p}{\approx}$ equivalence class

of c to the $\widetilde{f(p)}$ equivalence class of $f \circ c$. Without bothering to check details, we can already see that this example is “really the same” as TM —

$[x, v]_p$ corresponds to: the \approx_p equivalence class of $x^{-1} \circ \gamma$,
where γ is a curve in \mathbb{R}^n with $\gamma'(0) = v$;

under this correspondence, $f_\#$ corresponds to f_* .

In the second example, things are not so simple. We define a tangent vector at p to be a linear operator ℓ which operates on all C^∞ functions f and which is a “derivation at p ”:

$$\ell(fg) = f(p)\ell(g) + g(p)\ell(f).$$

We have already seen that the operators $\ell = \partial/\partial x^i|_p$ have this property. For these operators, clearly $\ell(f) = \ell(g)$ if $f = g$ in a neighborhood of p . This condition is actually true for any derivation ℓ . For, suppose that $f = 0$ in a neighborhood of p . There is a C^∞ function $h: M \rightarrow \mathbb{R}$ with $h(p) = 1$ and support $h \subset f^{-1}(0)$. Then

$$0 = \ell(0) = \ell(fh) = f(0)\ell(h) + h(0)\ell(f) = 0 + \ell(f).$$

Thus, if $f = g$ in a neighborhood of 0, then $0 = \ell(f - g) = \ell(f) - \ell(g)$. If f is defined only in a neighborhood of p , we may use this trick to define $\ell(f)$: choose h to be 1 on a neighborhood of p , with support $h \subset f^{-1}(0)$, and define $\ell(f)$ as $\ell(fh)$.

The set of all such operators is a vector space, but it is not *a priori* clear what its dimension is. This comes out of the following.

2. LEMMA. Let f be a C^∞ function in a convex open neighborhood U of 0 in \mathbb{R}^n , with $f(0) = 0$. Then there are C^∞ functions $g_i: U \rightarrow \mathbb{R}$ with

$$(1) \quad f(x^1, \dots, x^n) = \sum_{i=1}^n x^i g_i(x^1, \dots, x^n) \quad \text{for } x \in U,$$

$$(2) \quad g_i(0) = D_i f(0).$$

(The second condition actually follows from the first.)

PROOF. For $x \in U$, let $h_x(t) = f(tx)$; this is defined for $0 \leq t \leq 1$, since U is convex. Then

$$f(x) = f(x) - f(0) = \int_0^1 h_x'(t) dt = \int_0^1 \sum_{i=1}^n D_i f(tx) \cdot x^i dt.$$

Therefore we can let $g(x) = \int_0^1 D_i f(tx) dt$. ♦

3. THEOREM. The set of all linear derivations at $p \in M^n$ is an n -dimensional vector space. In fact, if (x, U) is a coordinate system around p , then

$$\left. \frac{\partial}{\partial x^1} \right|_p, \dots, \left. \frac{\partial}{\partial x^n} \right|_p$$

span this vector space, and any derivation ℓ can be written

$$\ell = \sum_{i=1}^n \ell(x^i) \cdot \left. \frac{\partial}{\partial x^i} \right|_p,$$

(so ℓ is determined by the numbers $\ell(x^i)$).

PROOF. Notice that

$$\ell(1) = \ell(1 \cdot 1) = 1 \cdot \ell(1) + 1 \cdot \ell(1),$$

so $\ell(1) = 0$. Hence $\ell(c) = c \cdot \ell(1) = 0$ for any constant function c on U . Consider the case where $M = \mathbb{R}^n$ and $p = 0$. Assume U is convex. Given f on U , choose g_i as in Lemma 2, for the function $f - f(0)$. Then

$$\begin{aligned} \ell(f) &= \ell(f - f(0)) = \ell\left(\sum_{i=1}^n I^i g_i\right) \quad (I^i \text{ denotes the } i^{\text{th}} \\ &\quad \text{coordinate function}) \\ &= \sum_{i=1}^n [\ell(I^i)g_i(0) + I^i(0)\ell(g_i)] \\ &= \sum_{i=1}^n \ell(I^i) \frac{\partial f}{\partial I^i}(0) + 0. \end{aligned}$$

This shows that $\partial/\partial I^i|_0$ span the vector space; they are clearly linearly independent. It is a simple exercise to use the coordinate system x to transfer this result from \mathbb{R}^n to M . ♦

From Theorem 3 we can see that, once again, a bundle constructed from all derivations at all points of M is “really the same” as TM . We can let

$$\ell = \sum_{i=1}^n a^i \left. \frac{\partial}{\partial x^i} \right|_p \quad \text{correspond to} \quad [x, a]_p;$$

the formula

$$\left. \frac{\partial}{\partial x^i} \right|_p = \sum_{j=1}^n \frac{\partial y^j}{\partial x^i}(p) \left. \frac{\partial}{\partial y^j} \right|_p,$$

derived in Chapter 2, shows that

$$\sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_p = \sum_{i=1}^n b^i \frac{\partial}{\partial y^i} \Big|_p \quad \text{if and only if} \quad b^j = \sum_{i=1}^n a^i \frac{\partial y^j}{\partial x^i}(p),$$

and this is precisely the equation which says that $(x, a) \underset{p}{\sim} (y, b)$. It is easily checked that under this correspondence, the map which corresponds to f_* can be defined as follows:

$$[f_*(\ell)](g) = \ell(g \circ f).$$

Notice that if x denotes the identity coordinate system on \mathbb{R}^n , then $\sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_p$ corresponds to a_p when we identify $T\mathbb{R}^n$ with $\varepsilon^n(\mathbb{R}^n)$.

We will usually make no distinction whatsoever between a tangent vector $v \in M_p$ and the linear derivation it corresponds to, that is, between $[x, a]_p$ and

$$\sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_p;$$

consequently, we will not hesitate to write $v(f)$ for a differentiable function f defined in a neighborhood of p . In fact, a tangent vector is often most easily described by telling what derivation it corresponds to, and the map f_* is often most easily analyzed from the relation

$$(f_*v)(g) = v(g \circ f).$$

It is customary to denote the identity coordinate system on \mathbb{R}^1 by t , and to write

$$\frac{d}{dt} \Big|_{t_0} \quad \text{for} \quad \frac{\partial}{\partial t} \Big|_{t_0};$$

this is a basis for \mathbb{R}_{t_0} . If $c: \mathbb{R} \rightarrow M$ is a differentiable curve, then

$$c_* \left(\frac{d}{dt} \Big|_{t_0} \right) \in M_{c(t_0)}$$

is called the *tangent vector to c at t_0* . We will denote it by the suggestive symbol

$$\frac{dc}{dt} \Big|_{t_0}.$$

This symbol will be subjected to the standard abuses one finds (unexplained) in calculus textbooks: the symbol

$$\frac{dc}{dt} \quad \text{will often stand for} \quad \left. \frac{dc}{dt} \right|_t,$$

the subscript “ t ” now denoting a particular number $t \in \mathbb{R}$, as well as the identity coordinate system.

As you might well expect, it is no accident that our second and third examples turned out to be “really the same” as TM . There is a general theorem that all “reasonable” examples will have this property, but it is a little delicate to state, and quite a mess to prove, so it has been quarantined in an Addendum to this chapter.

The tangent bundle TM of a C^∞ manifold has a little more structure than an arbitrary n -plane bundle. Since TM locally looks like $U \times \mathbb{R}^n$, clearly TM is itself a manifold; there is, moreover, a natural way to put a C^∞ structure on TM . If $x: U \rightarrow \mathbb{R}^n$ is a chart on M , then every element $v \in (TM)|_U$ is uniquely of the form

$$v = \sum_{i=1}^n a^i \left. \frac{\partial}{\partial x^i} \right|_p, \quad p = \pi(v).$$

Let us denote a^i by $\dot{x}^i(v)$. Then the map

$$v \mapsto (x^1(\pi(v)), \dots, x^n(\pi(v)), \dot{x}^1(v), \dots, \dot{x}^n(v)) \in \mathbb{R}^{2n}$$

is a homeomorphism from $(TM)|_U$ to $x(U) \times \mathbb{R}^n$. This map, $(x \circ \pi, \dot{x})$, is simply the map x_* when we identify TU with $U \times \mathbb{R}^n$ in the standard way. If (y, V) is another coordinate system, and

$$v = \sum_{j=1}^n b^j \left. \frac{\partial}{\partial y^j} \right|_p,$$

then, as we have already seen,

$$b^j = \sum_{i=1}^n a^i \frac{\partial y^j}{\partial x^i}(p) = \sum_{i=1}^n a^i D_i(y^j \circ x^{-1})(x(p)).$$

This shows that if $(t, a) = (t^1, \dots, t^n, a^1, \dots, a^n) \in \mathbb{R}^{2n}$, then

$$\begin{aligned} y_* \circ (x_*)^{-1}(t, a) \\ = (y \circ x^{-1}(t), \sum_{i=1}^n a^i D_i(y^1 \circ x^{-1})(t), \dots, \sum_{i=1}^n a^i D_i(y^n \circ x^{-1})(t)). \end{aligned}$$

This expression shows that $y_* \circ (x_*)^{-1}$ is C^∞ .

We thus have a collection of C^∞ -related charts on TM , which can be extended to a maximal atlas.

With this C^∞ structure, the local trivializations x_* are C^∞ . In general, a vector bundle $\pi: E \rightarrow B$ is called a C^∞ vector bundle if E and B are C^∞ manifolds and there are C^∞ local trivializations in a neighborhood of each point. It follows that $\pi: E \rightarrow B$ is C^∞ .

Recall that a section of a bundle $\pi: E \rightarrow B$ is a continuous function $s: B \rightarrow E$ such that $\pi \circ s = \text{identity of } B$; for C^∞ vector bundles we can also speak of C^∞ sections. A section of TM is called a vector field on M ; for submanifolds M of \mathbb{R}^n , a vector field may be pictured as a continuous selection of arrows tangent to M . The theorem that you can't comb the hair on a sphere just states that

there is no vector field on S^2 which is everywhere non-zero. We have shown that there do not exist two vector fields on the Möbius strip which are everywhere linearly independent.

Vector fields are customarily denoted by symbols like X , Y , or Z , and the vector $X(p)$ is often denoted by X_p (sometimes X may be used to denote a single vector, in some M_p). If we think of TM as the set of derivations, then for any coordinate system (x, U) , we have

$$X(p) = \sum_{i=1}^n a^i(p) \left. \frac{\partial}{\partial x^i} \right|_p \quad \text{for all } p \in U.$$

The functions a^i are continuous or C^∞ if and only if $X: U \rightarrow TM$ is continuous or C^∞ .

If X and Y are two vector fields, we define a new vector field $X + Y$ by

$$(X + Y)(p) = X(p) + Y(p).$$

Similarly, if $f: M \rightarrow \mathbb{R}$, we define the vector field fX by

$$(fX)(p) = f(p)X(p).$$

Clearly $X + Y$ and fX are C^∞ if X , Y , and f are C^∞ . On U we can write

$$X = \sum_{i=1}^n a^i \frac{\partial}{\partial x^i},$$

the symbol $\partial/\partial x^i$ now denoting the vector field

$$p \mapsto \left. \frac{\partial}{\partial x^i} \right|_p.$$

If $f: M \rightarrow \mathbb{R}$ is a C^∞ function, and X is a vector field, then we can define a new function $\bar{X}(f): M \rightarrow \mathbb{R}$ by letting X operate on f at each point:

$$\bar{X}(f)(p) = X_p(f).$$

It is not hard to check that if X is a C^∞ vector field, then $\bar{X}(f)$ is C^∞ for every C^∞ function f ; indeed, if locally

$$X(p) = \sum_{i=1}^n a^i(p) \left. \frac{\partial}{\partial x^i} \right|_p,$$

then

$$\bar{X}(f) = \sum_{i=1}^n a^i \frac{\partial f}{\partial x^i},$$

which is a sum of products of C^∞ functions. Conversely, if $\bar{X}(f)$ is C^∞ for every C^∞ function f , then X is a C^∞ vector field (since $\bar{X}(x^i) = a^i$).

Let \mathcal{F} denote the set of all C^∞ functions on M . We have just seen that a C^∞ vector field X gives rise to a function $\bar{X}: \mathcal{F} \rightarrow \mathcal{F}$. Clearly,

$$\begin{aligned} \bar{X}(f + g) &= \bar{X}(f) + \bar{X}(g) \\ \bar{X}(fg) &= f\bar{X}(g) + g\bar{X}(f); \end{aligned}$$

thus \bar{X} is a "derivation" of the ring \mathcal{F} . Often, a C^∞ vector field X is identified with the derivation \bar{X} . The reason for this is that if $A: \mathcal{F} \rightarrow \mathcal{F}$ is any derivation, then $A = \bar{X}$ for a unique C^∞ vector field X . In fact, we clearly must define

$$X_p(f) = A(f)(p),$$

and the operator X_p thus defined is a derivation at p .

The tangent bundle is the true beginning of the study of differentiable manifolds, and you should not read further until you grok it.* The next few chapters constitute a detailed study of this bundle. One basic theme in all these chapters is that any structure one can put on a vector space leads to a structure on any vector bundle, in particular on the tangent bundle of a manifold. For the present, we will discuss just one new concept about manifolds, which arises in this very way from the notion of “orientation” in a vector space.

The non-singular linear maps $f: V \rightarrow V$ from a finite dimensional vector space to itself fall into two groups, those with $\det f > 0$, and those with $\det f < 0$; linear transformations in the first group are called **orientation preserving** and the others are called **orientation reversing**. A simple example of the latter is the map $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ defined by $f(x) = (x^1, \dots, x^{n-1}, -x^n)$ (reflection in the hyperplane $x^n = 0$). There is no way to pass continuously between these two groups: if we identify linear maps $\mathbb{R}^n \rightarrow \mathbb{R}^n$ with $n \times n$ matrices, and thus with \mathbb{R}^{n^2} , then the orientation preserving and orientation reversing maps are disjoint open subsets of the set of all non-singular maps (those with $\det \neq 0$). The terminology “orientation preserving” is a bit strange, since we have not yet defined anything called “orientation”, which is being preserved. The problem becomes more acute if we want to define orientation preserving isomorphisms between two different (but isomorphic) vector spaces V and W ; this clearly makes no sense unless we supply V and W with more structure.

To provide this extra structure, we note that two ordered bases (v_1, \dots, v_n) and (v'_1, \dots, v'_n) for V determine an isomorphism $f: V \rightarrow V$ with $f(v_i) = v'_i$; the matrix $A = (a_{ij})$ of f is given by the equations

$$v'_i = \sum_{j=1}^n a_{ji} v_j.$$

We call (v_1, \dots, v_n) and (v'_1, \dots, v'_n) **equally oriented** if $\det A > 0$ (i.e., if f is orientation preserving) and **oppositely oriented** if $\det A < 0$.

The relation of being equally oriented is clearly an equivalence relation, dividing the collection of all ordered bases into just two equivalence classes. Either of these two equivalence classes is called an **orientation** for V . The class to which (v_1, \dots, v_n) belongs will be denoted by $[v_1, \dots, v_n]$, so that if μ is an orientation of V , then $(v_1, \dots, v_n) \in \mu$ if and only if $[v_1, \dots, v_n] = \mu$. If μ denotes one

* A cult word of the sixties, “grok” was coined, purportedly as a word from the Martian language, by Robert A. Heinlein in his pop science fiction novel *Stranger in a Strange Land*. Its sense is nicely conveyed by the definition in *The American Heritage Dictionary*: “To understand profoundly through intuition or empathy”.

Examples of equally oriented ordered bases in \mathbb{R} , \mathbb{R}^2 , and \mathbb{R}^3 .

orientation of V , the other will be denoted by $-\mu$, and the orientation $[e_1, \dots, e_n]$ for \mathbb{R}^n will be called the “standard orientation”.

Now if (V, μ) and (W, ν) are two n -dimensional vector spaces, together with orientations, an isomorphism $f: V \rightarrow W$ is called **orientation preserving** (with respect to μ and ν) if $[f(v_1), \dots, f(v_n)] = \nu$ whenever $[v_1, \dots, v_n] = \mu$; if this holds for any one (v_1, \dots, v_n) , it clearly holds for all.

For the trivial bundle $\varepsilon^n(X) = X \times \mathbb{R}^n$ we can put the “standard orientation” $[(x, e_1), \dots, (x, e_n)]$ on each fibre $\{x\} \times \mathbb{R}^n$. If $f: \varepsilon^n(X) \rightarrow \varepsilon^n(X)$ is an equivalence, and X is connected, then f is either orientation preserving or orientation reversing on each fibre, for if we define the functions $a_{ij}: X \rightarrow \mathbb{R}$ by

$$f(x, e_i) = \sum_{j=1}^n a_{ji}(x) \cdot (x, e_j),$$

then $\det(a_{ij}): X \rightarrow \mathbb{R}$ is continuous and never 0. If $\pi: E \rightarrow B$ is a non-trivial n -plane bundle, an **orientation** μ of E is defined to be a collection of orientations μ_p for $\pi^{-1}(p)$ which satisfy the following “compatibility condition” for any open connected set $U \subset B$:

If $t: \pi^{-1}(U) \rightarrow U \times \mathbb{R}^n$ is an equivalence, and the fibres of $U \times \mathbb{R}^n$ are given the standard orientation, then t is either orientation preserving or orientation reversing on all fibres.

Notice that if this condition is satisfied for a certain t , and $t': \pi^{-1}(U) \rightarrow U \times \mathbb{R}^n$ is another equivalence, then t' automatically satisfies the same condition, since

$t' \circ t^{-1}: U \times \mathbb{R}^n \rightarrow U \times \mathbb{R}^n$ is an equivalence. This shows that the orientations μ_p define an orientation of E if the compatibility condition holds for a collection of sets U which cover B .

If a bundle E has orientation $\mu = \{\mu_p\}$, it has another orientation $-\mu = \{-\mu_p\}$, but not every bundle has an orientation. For example, the Möbius strip, considered as a 1-dimensional bundle over S^1 , has no orientation. For, although the Möbius strip has no non-zero section, we can pick two vectors from each fibre so that the totality A looks like two sections. For example, we can let A be $[0, 1] \times \{-1, 1\}$ with $(0, a)$ identified with $(1, -a)$; then A just looks like the boundary of the Möbius strip obtained from $[0, 1] \times [-1, 1]$. If

we had compatible orientations μ_p , we could define a section $s: S^1 \rightarrow M$ by choosing $s(p)$ to be the unique vector $s(p) \in A \cap \pi^{-1}(p)$ with $[s(p)] = \mu_p$.

A bundle is called **orientable** if it has an orientation, and **non-orientable** otherwise; an **oriented bundle** is just a pair (ξ, μ) where μ is an orientation for ξ . This definition can be applied, in particular, to the tangent bundle TM of a C^∞ manifold M . In this case, we call M itself **orientable** or **non-orientable** depending on whether TM is orientable or non-orientable; an orientation of TM is also called an **orientation** of M , and an **oriented manifold** is a pair (M, μ) where μ is an orientation for TM .

The manifold \mathbb{R}^n is orientable, since $T\mathbb{R}^n \simeq \varepsilon^n(\mathbb{R}^n)$, on which we have the standard orientation. The sphere $S^{n-1} \subset \mathbb{R}^n$ is also orientable. To see this we

note that for each $p \in S^{n-1}$ the vector $w = p_p \in \varepsilon^n(\mathbb{R}^n) \simeq T\mathbb{R}^n$ is *not* in $i_*(S^{n-1}_p) \in T\mathbb{R}^n_p$ (Problem 21), so for $v_1, \dots, v_{n-1} \in S^{n-1}_p$ we can define $(v_1, \dots, v_{n-1}) \in \mu_p$ if and only if $(w, i_*(v_1), \dots, i_*(v_{n-1}))$ is in the standard orientation of \mathbb{R}^n_p . The orientation $\mu = \{\mu_p : p \in S^{n-1}\}$ thus defined is called the “standard orientation” of S^{n-1} .

The torus $S^1 \times S^1$ is another example of an orientable manifold. This can be seen by noting that for any two manifolds M_1 and M_2 the fibre $(M_1 \times M_2)_p$ of $T(M_1 \times M_2)$ can be written as $V_{1p} \oplus V_{2p}$ where $(\pi_i)_*: V_{ip} \rightarrow (M_i)_p$ is an isomorphism and the subspaces V_{ip} vary continuously (Problem 26). Since TS^1 is trivial, this shows that $T(S^1 \times S^1)$ is also trivial, and consequently orientable. Any n -holed torus is also orientable—the proof is presented in Problem 16, which also discusses the tangent bundle of a manifold-with-boundary.

The Möbius strip M is the simplest example of a non-orientable 2-manifold. For the imbedding of M considered previously we have already seen that on the

subset $S = \{(2 \cos \theta, 2 \sin \theta, 0)\} \subset M$ there are continuously varying vectors v_p , but that it is impossible to choose continuously from among the dashed vectors $w_p = f_*(0, 1)_{(\theta, 0)}$ and their negatives. If we had orientations μ_p for $p \in S$, then we could simply choose w_p if $[v_p, w_p] = \mu_p$ and $-w_p$ otherwise.

The projective plane \mathbb{P}^2 must be non-orientable also, since it contains the Möbius strip (for any orientable bundle $\xi = \pi: E \rightarrow B$, the restriction $\xi|_{B'}$ to any subset $B' \subset B$ is also orientable). Non-orientability of \mathbb{P}^2 can be seen in another way, by considering the “antipodal map” $A: S^2 \rightarrow S^2$ defined by $A(p) = -p$. This map is just the restriction of a linear map $\bar{A}: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ defined by the same formula. The map $A_*: S^2_p \rightarrow S^2_{A(p)}$ is just $(p, v) \mapsto (\bar{A}(p), \bar{A}(v))$, when S^2_p is identified with a subspace of $\{p\} \times \mathbb{R}^3$. The map \bar{A} is orientation reversing, so if $v_i = (p, u_i) \in S^2_p$, the bases

$$(u_1, u_2, p) \quad \text{and} \quad (\bar{A}(u_1), \bar{A}(u_2), \bar{A}(p))$$

are oppositely oriented. This shows that if μ is the standard orientation of S^2 and $[v_1, v_2] \in \mu_p$, then $[A_*v_1, A_*v_2] \in -\mu_{A(p)}$. Thus the map $A: S^2 \rightarrow S^2$ is

“orientation reversing” (the notion of an **orientation preserving** or **orientation reversing** map $f: M \rightarrow N$ makes sense for any imbedding f of one oriented manifold into another oriented manifold of the same dimension). From this fact it follows easily that \mathbb{P}^2 is not orientable: If \mathbb{P}^2 had an orientation $\nu = \{\nu_{[p]}\}$ and $g: S^2 \rightarrow \mathbb{P}^2$ is the map $p \mapsto [p]$, then we could define an orientation $\{\bar{\mu}_p\}$ on S^2 by requiring g to be orientation preserving; the map A would then be orientation preserving with respect to $\bar{\mu}$, which is impossible, since $\bar{\mu} = \mu$ or $-\mu$.

For projective 3-space \mathbb{P}^3 the situation is just the opposite. In this case, the antipodal map $A: S^3 \rightarrow S^3$ is orientation preserving. If $g: S^3 \rightarrow \mathbb{P}^3$ is the map $p \mapsto [p]$, we obviously can define orientations ν_p for \mathbb{P}^3 by requiring g to be orientation preserving. In general, these same arguments show that \mathbb{P}^n is orientable for n odd and non-orientable for n even.

There is a more “elementary” definition of orientability, which does not use the tangent bundle of M at all. According to this definition, M is orientable if there is a subset \mathcal{A}' of the atlas \mathcal{A} for M such that

- (1) the domains of all $(x, U) \in \mathcal{A}'$ cover M ,
- (2) for all (x, U) and $(y, V) \in \mathcal{A}'$,

$$\det \left(\frac{\partial y^i}{\partial x^j} \right) > 0 \quad \text{on} \quad U \cap V.$$

An orientation μ of TM allows us to distinguish the subset \mathcal{A}' as the collection of all (x, U) for which $x_*: TM|U \rightarrow T(x(U)) \simeq x(U) \times \mathbb{R}^n$ is orientation preserving (when $x(U) \times \mathbb{R}^n$ is given the standard orientation). Condition (2) holds, because it is just the condition that $(y \circ x^{-1})_*: T(x(U)) \rightarrow T(y(V))$ is orientation preserving. Conversely, given \mathcal{A}' we can orient the fibres of $TM|U$ in such a way that x_* is orientation preserving, and obtain an orientation of TM . Although our original definition is easier to picture geometrically, the determinant condition will be very important later on.

ADDENDUM

EQUIVALENCE OF TANGENT BUNDLES

The fact that all reasonable candidates for the tangent bundle of M turn out to be essentially the same is stated precisely as follows.

4. THEOREM*. If we have a bundle $T'M$ over M for each M , and a bundle map (f_{\sharp}, f) for each C^{∞} map $f: M \rightarrow N$ satisfying

- (1) of Theorem 1,
- (2) of Theorem 1, for certain equivalences t'^n ,
- (3) of Theorem 1, for certain equivalences $T'U \simeq (T'M)|U$,

then there are equivalences

$$e_M: TM \rightarrow T'M$$

such that the following diagram commutes for every C^{∞} map $f: M \rightarrow N$.

$$\begin{array}{ccc} TM & \xrightarrow{f_*} & TN \\ e_M \downarrow & & \downarrow e_N \\ T'M & \xrightarrow{f_{\sharp}} & T'N \end{array}$$

PROOF. The details of this proof are so horrible that you should probably skip it (and you should definitely quit when you get bogged down); the welcome symbol \diamond occurs quite a ways on. Nevertheless, the idea behind the proof is simple enough. If (x, U) is a chart on M , then both $(TM)|U$ and $(T'M)|U$ “look like” $x(U) \times \mathbb{R}^n$, so there ought to be a map taking the fibres of one to the fibres of the other. What we have to hope is that our conditions on TM and $T'M$ make them “look alike” in a sufficiently strong way for this idea to really work out. Those who have been through this sort of rigamarole before know (i.e., have faith) that it’s going to work out; those for whom this sort of proof is a new experience should find it painful and instructive.

Functorites will notice that Theorems 1 and 4 say that there is, up to natural equivalence, a unique functor from the category of C^{∞} manifolds and C^{∞} maps to the category of bundles and bundle maps which is naturally equivalent to $(\varepsilon^n, \text{old } f_)$ on Euclidean spaces, and to the restriction of the functor on open submanifolds.

Let (x, U) be a coordinate system on M . Then we have the following string of equivalences. Two of them, which are denoted by the same symbol \simeq , are the equivalences mentioned in condition (3). Let α_x denote the composition $\alpha_x = (i^n|_{x(U)}) \circ \simeq \circ x_* \circ (\simeq)^{-1}$.

$$(TM)|U \xleftarrow{\simeq} TU \xrightarrow{x_*} T(x(U)) \xrightarrow{\simeq} (T\mathbb{R}^n)|_{x(U)} \xrightarrow{i^n|_{x(U)}} \varepsilon^n(\mathbb{R}^n)|_{x(U)}$$

α_x

Similarly, using equivalence \simeq' for T' , we can define β_x .

$$(T'M)|U \xleftarrow{\simeq'} T'U \xrightarrow{x'_*} T'(x(U)) \xrightarrow{\simeq'} (T'\mathbb{R}^n)|_{x(U)} \xrightarrow{i'^n|_{x(U)}} \varepsilon^n(\mathbb{R}^n)|_{x(U)}$$

β_x

Then

$$\beta_x^{-1} \circ \alpha_x: (TM)|U \rightarrow (T'M)|U$$

is an equivalence, so it takes the fibre of TM over p isomorphically to the fibre of $T'M$ over p for each $p \in U$. Our main task is to show that this isomorphism between the fibres over p is independent of the coordinate system (x, U) . This will be done in three stages.

(I) Suppose $V \subset U$ is open and $y = x|_V$. We will need to name all the inclusion maps

$$i: U \rightarrow M$$

$$\bar{i}: V \rightarrow M$$

$$j: V \rightarrow U$$

$$k: y(V) \rightarrow x(U).$$

To compare α_x and α_y , consider the following diagram.

$$(1) \quad \begin{array}{ccccccc} (TM)|U & \xleftarrow{\simeq} & TU & \xrightarrow{x_*} & T(x(U)) & \xrightarrow{\simeq} & (T\mathbb{R}^n)|_{x(U)} \xrightarrow{i^n|_{x(U)}} \varepsilon^n(\mathbb{R}^n)|_{x(U)} \\ \uparrow \subset & \textcircled{1} & \uparrow j_* & \textcircled{2} & \uparrow k_* & \textcircled{3} & \uparrow \subset \textcircled{4} \uparrow \subset \\ (TM)|V & \xleftarrow{\simeq} & TV & \xrightarrow{y_*} & T(y(V)) & \xrightarrow{\simeq} & (T\mathbb{R}^n)|_{y(V)} \xrightarrow{i^n|_{y(V)}} \varepsilon^n(\mathbb{R}^n)|_{y(V)} \end{array}$$

Each of the four squares in this diagram commutes. To see this for square ①, we enlarge it, as shown below. The two triangles on the left commute by condition (3) for TM , and the one on the right commutes because $i \circ j = \bar{i}$.

$$\begin{array}{ccc}
 (TM)|U & & \\
 \downarrow \subset & \swarrow \cong & \\
 & TU & \\
 & \swarrow i_* & \uparrow j_* \\
 TM & & TV \\
 \uparrow \subset & \swarrow \bar{i}_* & \\
 (TM)|V & &
 \end{array}$$

Square ② commutes because $k \circ y = x \circ j$. Square ③ commutes for the same reason as square ①; the inclusions $x(U) \rightarrow \mathbb{R}^n$ and $y(V) \rightarrow \mathbb{R}^n$ come into play. Square ④ obviously commutes. Chasing through diagram (1) now shows that the following commutes.

$$\begin{array}{ccc}
 (TM)|U & \xrightarrow{\alpha_x} & \varepsilon^n(\mathbb{R}^n)|x(U) \\
 \uparrow \subset & & \uparrow \subset \\
 (TM)|V & \xrightarrow{\alpha_y} & \varepsilon^n(\mathbb{R}^n)|y(V)
 \end{array}$$

This means that for $p \in V$, the isomorphism α_y between the fibres over p is the same as α_x . Clearly the same is true for β_x and β_y , since our proof used only properties (1), (2), and (3), not the explicit construction of TM . Thus $\beta_y^{-1} \circ \alpha_y = \beta_x^{-1} \circ \alpha_x$ on the fibres over p , for every $p \in V$.

(II) We now need a Lemma which applies to both TM and $T'M$. Again, it will be proved for TM (where it is actually obvious), using only properties (1), (2), and (3), so that it is also true for $T'M$.

LEMMA. If $A \subset \mathbb{R}^n$ and $B \subset \mathbb{R}^m$ are open, and $f: A \rightarrow B$ is C^∞ , then the following diagram commutes.

$$\begin{array}{ccccc} TA & \xrightarrow{\simeq} & (T\mathbb{R}^n)|_A & \xrightarrow{i^n|_A} & \varepsilon^n(\mathbb{R}^n)|_A \\ f_* \downarrow & & & & \downarrow \text{old } f_* \\ TB & \xrightarrow{\simeq} & (T\mathbb{R}^m)|_B & \xrightarrow{i^m|_B} & \varepsilon^m(\mathbb{R}^m)|_B \end{array}$$

PROOF. Case 1. There is a map $\bar{f}: \mathbb{R}^n \rightarrow \mathbb{R}^m$ with $\bar{f} = f$ on A . Consider the following diagram, where $i: A \rightarrow \mathbb{R}^n$ and $j: B \rightarrow \mathbb{R}^m$ are the inclusion maps.

$$\begin{array}{ccccccc} & & & (T\mathbb{R}^n)|_A & \xrightarrow{i^n|_A} & \varepsilon^n(\mathbb{R}^n)|_A & \\ & \nearrow \simeq & & \downarrow \subset & & \downarrow \subset & \\ TA & \xrightarrow{i_*} & T\mathbb{R}^n & \xrightarrow{i^n} & \varepsilon^n(\mathbb{R}^n) & & \\ f_* \downarrow & & \downarrow \bar{f}_* & & \downarrow \text{old } \bar{f}_* & & \\ TB & \xrightarrow{j_*} & T\mathbb{R}^m & \xrightarrow{i^m} & \varepsilon^m(\mathbb{R}^m) & & \\ & \searrow \simeq & & \uparrow \subset & & \uparrow \subset & \\ & & (T\mathbb{R}^m)|_B & \xrightarrow{i^m|_B} & \varepsilon^m(\mathbb{R}^m)|_B & & \end{array}$$

Everything in this diagram obviously commutes. This implies that the two compositions

$$TA \xrightarrow{\simeq} (T\mathbb{R}^n)|_A \xrightarrow{i^n|_A} \varepsilon^n(\mathbb{R}^n)|_A \xrightarrow{\subset} \varepsilon^n(\mathbb{R}^n) \xrightarrow{\text{old } \bar{f}_*} \varepsilon^m(\mathbb{R}^m)$$

and

$$TA \xrightarrow{f_*} TB \xrightarrow{\simeq} (T\mathbb{R}^m)|_B \xrightarrow{i^m|_B} \varepsilon^m(\mathbb{R}^m)|_B \xrightarrow{\subset} \varepsilon^m(\mathbb{R}^m)$$

are equal and this proves the Lemma in Case 1, since the maps “old \bar{f}_* ” and “old f_* ” are equal on A .

Case 2. General case. For each $p \in A$, we want to show that two maps are the same on the fibre over p . Now there is a map $\bar{f}: \mathbb{R}^n \rightarrow \mathbb{R}^m$ with $\bar{f} = f$ on an open set A' , where $p \in A' \subset A$. We then have the following diagram, where every \simeq comes from the fact that some set is an open submanifold of another,

and $i: A' \rightarrow A$ is the inclusion map.

$$\begin{array}{ccccc}
 & TA & \xrightarrow{\quad} & (T\mathbb{R}^n)|_A & \xrightarrow{i^n|_A} & \varepsilon^n(\mathbb{R}^n)|_A \\
 & \uparrow i_* & \nwarrow \subset & \uparrow \subset & & \uparrow \subset \\
 & (TA)|_{A'} & \xrightarrow{\quad} & (T\mathbb{R}^n)|_{A'} & \xrightarrow{i^n|_{A'}} & \varepsilon^n(\mathbb{R}^n)|_{A'} \\
 \textcircled{1} & \uparrow f_* & \nwarrow \cong & \uparrow \subset & & \uparrow \subset \\
 TA' & \xrightarrow{\quad} & (T\mathbb{R}^n)|_{A'} & \xrightarrow{i^n|_{A'}} & \varepsilon^n(\mathbb{R}^n)|_{A'} & \textcircled{5} \\
 \downarrow (f|_{A'})_* & & \downarrow \text{old } (f|_{A'})_* & & \downarrow \text{old } \bar{f}_* & \\
 TB & \xrightarrow{\quad} & (T\mathbb{R}^m)|_B & \xrightarrow{i^m|_B} & \varepsilon^m(\mathbb{R}^m)|_B
 \end{array}$$

$\textcircled{2}$ $\textcircled{3}$ $\textcircled{4}$

Boxes $\textcircled{1}$, $\textcircled{3}$, and $\textcircled{5}$ obviously commute, and $\textcircled{4}$ commutes by *Case 1*. To see that square $\textcircled{2}$ (which has a triangle within it) commutes, we imbed it in a larger diagram, in which $j: A \rightarrow \mathbb{R}^n$ is the inclusion map, and other maps have also been named, for ease of reference.

$$\begin{array}{ccc}
 & T\mathbb{R}^n & \\
 j_* \nearrow & & \nwarrow \subset (\nu) \\
 TA & \xrightarrow{\cong (\lambda)} & (T\mathbb{R}^n)|_A \\
 i_* \uparrow & & \uparrow \subset (\mu) \\
 TA' & \xrightarrow{\cong (\kappa)} & (T\mathbb{R}^n)|_{A'}
 \end{array}$$

To prove that $\lambda \circ i_* = \mu \circ \kappa$, it suffices to prove that

$$\nu \circ \lambda \circ i_* = \nu \circ \mu \circ \kappa,$$

since ν is one-one. Thus it suffices to prove $j_* \circ i_* = \nu \circ \mu \circ \kappa$, which amounts to proving commutativity of the following diagram.

$$\begin{array}{ccc}
 & T\mathbb{R}^n & \\
 (j \circ i)_* \nearrow & & \nwarrow \subset \\
 TA' & \xrightarrow{\cong} & (T\mathbb{R}^n)|_{A'}
 \end{array}$$

Since $j \circ i$ is just the inclusion of A' in \mathbb{R}^n , this does commute.

Commutativity of diagram (2) shows that the composition

$$TA \xrightarrow{f_*} TB \xrightarrow{\cong} (T\mathbb{R}^m)|_B \xrightarrow{t^m|_B} \varepsilon^m(\mathbb{R}^m)|_B$$

coincides, on the subset $(TA)|_{A'}$, with the composition

$$TA \xrightarrow{\cong} (T\mathbb{R}^n)|_A \xrightarrow{t^n|_A} \varepsilon^n(\mathbb{R}^n)|_A \xrightarrow{\text{old } \tilde{f}_*} \varepsilon^m(\mathbb{R}^m)|_B,$$

and on A' we can replace “old \tilde{f}_* ” by “old f_* ”. In other words, the two compositions are equal in a neighborhood of any $p \in A$, and are thus equal, which proves the Lemma.

(III) Now suppose (x, U) and (y, V) are any two coordinate systems with $p \in U \cap V$. To prove that $\beta_y^{-1} \circ \alpha_y$ and $\beta_x^{-1} \circ \alpha_x$ induce the same isomorphism on the fibre of TM at p , we can assume without loss of generality that $U = V$, because part (I) applies to x and $x|_{U \cap V}$, as well as to y and $y|_{U \cap V}$.

Assuming $U = V$, we have the following diagram.

$$(3) \quad \begin{array}{ccccc} & & T(x(U)) & \xrightarrow{\cong} & (T\mathbb{R}^n)|_{x(U)} & \xrightarrow{t^n|_{x(U)}} & \varepsilon^n(\mathbb{R}^n)|_{x(U)} \\ & \nearrow x_* & \downarrow (y \circ x^{-1})_* & & \downarrow \text{old } (y \circ x^{-1})_* & & \downarrow \\ (TM)|_U & \xleftarrow{\cong} & TU & & & & \\ & \searrow y_* & \downarrow & & & & \\ & & T(y(U)) & \xrightarrow{\cong} & (T\mathbb{R}^n)|_{y(U)} & \xrightarrow{t^n|_{y(U)}} & \varepsilon^n(\mathbb{R}^n)|_{y(U)} \end{array}$$

The triangle obviously commutes, and the rectangle commutes by part (II). Diagram (3) thus shows that

$$\alpha_y = \text{old } (y \circ x^{-1})_* \circ \alpha_x.$$

Exactly the same result holds for T' :

$$\beta_y = \text{old } (y \circ x^{-1})_* \circ \beta_x.$$

The desired result $\beta_y^{-1} \circ \alpha_y = \beta_x^{-1} \circ \alpha_x$ follows immediately.

Now that we have a well-defined bundle map $TM \rightarrow T'M$ (the union of all $\beta_x^{-1} \circ \alpha_x$), it is clearly an equivalence e_M . The proof that $e_N \circ f_* = f_{\sharp} \circ e_M$ is left as a masochistic exercise for the reader. ♦

PROBLEMS

1. Let M be any set, and $\{(x_i, U_i)\}$ a sequence of one-one functions $x_i: U_i \rightarrow \mathbb{R}^n$ with $U_i \subset M$ and $x(U_i)$ open in \mathbb{R}^n , such that each

$$x_j \circ x_i^{-1}: x_i(U_i \cap U_j) \rightarrow x_j(U_i \cap U_j)$$

is continuous. It would seem that M ought to have a metric which makes each U_i open and each x_i a homeomorphism. Actually, this is not quite true:

(a) Let $M = \mathbb{R} \cup \{*\}$, where $* \notin \mathbb{R}$. Let $U_1 = \mathbb{R}$ and $x_1: U_1 \rightarrow \mathbb{R}$ be the identity, and let $U_2 = \mathbb{R} - \{0\} \cup \{*\}$, with $x_2: U_2 \rightarrow \mathbb{R}$ defined by

$$\begin{aligned} x_2(a) &= a, & a \neq 0, * \\ x_2(*) &= 0. \end{aligned}$$

Show that there is no metric on M of the required sort, by showing that every neighborhood of 0 would have to intersect every neighborhood of *. Nevertheless, we can find on M a pseudometric ρ (a function $\rho: M \times M \rightarrow \mathbb{R}$ with all properties for a metric except that $\rho(p, q)$ may be 0 for $p \neq q$) such that ρ is a metric on each U_i and each x_i is a homeomorphism:

(b) If $A \subset \mathbb{R}^n$ is open, then there is a sequence A_1, A_2, A_3, \dots of open subsets of A such that every open subset of A is a union of certain A_i 's.

(c) There is a sequence of continuous functions $f_i: A \rightarrow [0, 1]$, with support $f_i \subset A$, which "separates points and closed sets": if C is closed and $p \in A - C$, then there is some f_i with $f_i(p) \notin f_i(A \cap C)$. *Hint:* First arrange in a sequence all pairs (A_i, A_j) of part (b) with $\overline{A_i} \subset A_j$.

(d) Let $f_{i,j}$, $j = 1, 2, 3, \dots$ be such a sequence for each open set $x_i(U_i)$. Define $g_{i,j}: M \rightarrow [0, 1]$ by

$$g_{i,j}(p) = \begin{cases} f_{i,j}(p) & p \in U_i \\ 0 & p \notin U_i. \end{cases}$$

Arrange all $g_{i,j}$ in a single sequence G_1, G_2, G_3, \dots , let d be a bounded metric on \mathbb{R} , and define ρ on M by

$$\rho(p, q) = \sum_{i=1}^{\infty} \frac{1}{2^i} d(G_i(p), G_i(q)).$$

Show that ρ is the required pseudometric.

(e) Suppose that for every $p, q \in M$ there is a U_i and U_j with $p \in U_i$ and $q \in U_j$ and open sets $B_i \subset x_i(U_i)$ and $B_j \subset x_j(U_j)$ so that $p \in x_i^{-1}(B_i)$, $q \in x_j^{-1}(B_j)$, and $x_i^{-1}(B_i) \cap x_j^{-1}(B_j) = \emptyset$. Show that ρ is actually a metric on M .

2. (a) Suppose (x, U) and (y, V) are two coordinate systems, giving rise to two maps on TM ,

$$\begin{aligned} t_x: \pi^{-1}(U) &\rightarrow U \times \mathbb{R}^n, & [x, v]_q &\mapsto (q, v), \\ t_y: \pi^{-1}(V) &\rightarrow V \times \mathbb{R}^n, & [y, w]_q &\mapsto (q, w). \end{aligned}$$

Show that in $\pi^{-1}(U \cap V)$ the sets of the form $t_x^{-1}(A)$ for $A \subset U \times \mathbb{R}^n$ open are exactly the sets of the form $t_y^{-1}(B)$ for $B \subset V \times \mathbb{R}^n$ open.

(b) Show that if there is a metric on TM such that t_{x_i} is a homeomorphism for a collection (x_i, U_i) with $M = \bigcup_i U_i$, then all t_x are homeomorphisms.

(c) Conclude from Problem 1 that there is a metric on TM which makes each t_x a homeomorphism.

3. Show that in the definition of an equivalence it suffices to assume that the map $E_1 \rightarrow E_2$ is continuous. (To prove the inverse continuous, note that locally it is just a map $U \times \mathbb{R}^n \rightarrow U \times \mathbb{R}^n$).

4. Show that in the definition of a bundle map, continuity of $f: B_1 \rightarrow B_2$ follows automatically from continuity of $\tilde{f}: E_1 \rightarrow E_2$.

5. A weak equivalence between two bundles over the same base space B is a bundle map (\tilde{f}, f) where \tilde{f} is an isomorphism on each fibre, and f is a homeomorphism of B onto itself. Find two inequivalent, but weakly equivalent, bundles over the following base spaces:

(i) the disjoint union of two circles,

(ii) a figure eight ,

(iii) the torus.

6. Given a bundle map (\tilde{f}, f) , show that $\tilde{f} = g \circ h$ where g and h are continuous maps such that h takes fibres linearly to fibres, while g is an isomorphism on each fibre.

7. (a) Show that for any bundle $\pi: E \rightarrow B$, the map $s: B \rightarrow E$ with $s(p)$ the 0 vector of $\pi^{-1}(p)$ is a section.

(b) Show that an n -plane bundle ξ is trivial if and only if there are n sections s_1, \dots, s_n which are everywhere linearly independent, i.e., $s_1(p), \dots, s_n(p) \in \pi^{-1}(p)$ are linearly independent for all $p \in B$.

(c) Show that locally every n -plane bundle has n linearly independent sections.

8. (a) Check that \sim_p is an equivalence relation on the set of pairs (x, v) .

(b) Check that the definition of f_* is independent of the coordinate systems x and y which are used.

(c) Check the remaining details in Theorem 1.

9. (a) Show that the correspondence between TM and equivalence classes of curves under which $[x, v]_p$ corresponds to the \approx equivalence class of $x^{-1} \circ \gamma$, for γ a curve in \mathbb{R}^n with $\gamma'(0) = v$, makes f_* correspond to $f_\#$.

(b) Show that under the correspondence $[x, a]_p \mapsto \sum_i a^i \partial/\partial x^i|_p$, the map f_* can be defined by

$$[f_*(\ell)](g) = \ell(g \circ f).$$

10. If V is a finite dimensional vector space over \mathbb{R} , define a C^∞ structure on V and a homeomorphism from $V \times V$ to TV which is independent of choice of bases. As in the case of \mathbb{R}^n , for $v, w \in V$ we will denote by $v_w \in V_w$ the vector corresponding to (w, v) .

11. If $g: \mathbb{R} \rightarrow \mathbb{R}$ is C^∞ show that

$$g(x) = g(0) + g'(0)x + x^2h(x)$$

for some C^∞ function $h: \mathbb{R} \rightarrow \mathbb{R}$.

12. (a) Let \mathcal{F}_p be the set of all C^∞ functions $f: M \rightarrow \mathbb{R}$ with $f(p) = 0$, and let $\ell: \mathcal{F}_p \rightarrow \mathbb{R}$ be a linear operator with $\ell(fg) = 0$ for all $f, g \in \mathcal{F}_p$. Show that ℓ has a unique extension to a derivation.

(b) Let W be the vector subspace of \mathcal{F}_p generated by all products fg for $f, g \in \mathcal{F}_p$. Show that the vector space of all derivations at p is isomorphic to the dual space $(\mathcal{F}_p/W)^*$.

(c) Since $(\mathcal{F}_p/W)^*$ has dimension $n = \text{dimension of } M$, the same must be true of \mathcal{F}_p/W . If x is a coordinate system with $x(p) = 0$, show that $x^1 + W, \dots, x^n + W$ is a basis for \mathcal{F}_p/W (use Lemma 2). The situation is quite different for C^1 functions, as the next problem shows.

13. (a) Let V be the vector space of all C^1 functions $f: \mathbb{R} \rightarrow \mathbb{R}$ with $f(0) = 0$, and let W be the subspace generated by all products. Show that $\lim_{x \rightarrow 0} f(x)/x^2$ exists for all $f \in W$.

(b) For $0 < \varepsilon < 1$, let

$$f_\varepsilon(x) = \begin{cases} x^{1+\varepsilon} & x \geq 0 \\ 0 & x \leq 0. \end{cases}$$

Show that all f_ε are in V , and that they represent linearly independent elements of V/W .

(c) Conclude that $(V/W)^*$ has dimension $c^c = 2^c$.

14. If $f: M \rightarrow N$ and f_* is the 0 map on each fibre, then f is constant on each component of M .

15. (a) A map $f: M \rightarrow N$ is an immersion if and only if f_* is one-one on each fibre of TM . More generally, the rank of f at $p \in M$ is the rank of the linear transformation $f_*: M_p \rightarrow N_{f(p)}$.

(b) If $f \circ g = f$, where g is a diffeomorphism, then the rank of $f \circ g$ at a equals the rank of f at $g(a)$. (Compare with Problem 2-33(d).)

16. (a) If M is a manifold-with-boundary, the tangent bundle TM is defined exactly as for M ; elements of M_p are \sim_p equivalence classes of pairs (x, v) . Although x takes a neighborhood of $p \in \partial M$ onto \mathbb{H}^n , rather than \mathbb{R}^n , the vectors v still run through \mathbb{R}^n , so M_p still has tangent vectors “pointing in all directions”. If $p \in \partial M$ and $x: U \rightarrow \mathbb{H}^n$ is a coordinate system around p , then

$x_*^{-1}(\mathbb{R}^{n-1}_{x(p)}) \subset M_p$ is a subspace. Show that this subspace does not depend on the choice of x ; in fact, it is $i_*(\partial M)_p$, where $i: \partial M \rightarrow M$ is the inclusion.

(b) Let $a \in \mathbb{R}^{n-1} \times \{0\} \subset \mathbb{H}^n$. A tangent vector in \mathbb{H}^n_a is said to point “inward” if, under the identification of $T\mathbb{H}^n$ with $\varepsilon^n(\mathbb{H}^n)$, the vector is (a, v) where $v^n > 0$. A vector $v \in M_p$ which is not in $i_*(\partial M)_p$ is said to point “inward” if

$x_*(v) \in \mathbb{H}^n_{x(p)}$ points inward. Show that this definition does not depend on the coordinate system x .

(c) Show that if M has an orientation μ , then ∂M has a unique orientation $\partial\mu$ such that $[v_1, \dots, v_{n-1}] = (\partial\mu)_p$ if and only if $[w, i_*v_1, \dots, i_*v_{n-1}] = \mu_p$ for every outward pointing $w \in M_p$.

(d) If μ is the usual orientation of \mathbb{H}^n , show that $\partial\mu$ is $(-1)^n$ times the usual orientation of $\mathbb{R}^{n-1} = \partial\mathbb{H}^n$. (The reason for this choice will become clear in Chapter 8.)

(e) Suppose we are in the setup of Problem 2-14. Define $g: \partial M \times [0, 1) \rightarrow \partial N \times [0, 1)$ by $g(p, t) = (f(p), t)$. Show that TP is obtained from $TM \cup TN$

by identifying

$$v \in (\partial M)_p \quad \text{with} \quad (\beta^{-1})_* g_* \alpha_*(v) \in (\partial N)_{f(p)}.$$

(f) If M and N have orientations μ and ν and $f: (\partial M, \partial\mu) \rightarrow (\partial N, \partial\nu)$ is orientation-reversing, show that P has an orientation which agrees with μ and ν on $M \subset P$ and $N \subset P$.

(g) Suppose M is S^2 with two holes cut out, and N is $[0, 1] \times S^1$. Let f be a diffeomorphism from M to N which is orientation preserving on one copy of S^1 and orientation reversing on the other. What is the resulting manifold P ?

17. Show that $T\mathbb{P}^2$ is homeomorphic to the space obtained from $T(S^2, i)$ by identifying $(p, v) \in (S^2, i)_p$ with $(-p, -v) \in (S^2, i)_{-p}$.

18. Although there is no everywhere non-zero vector field on S^2 , there is one on $S^2 - \{(0, 0, 1)\}$, which is diffeomorphic to \mathbb{R}^2 . Show that such a vector field can be picked so that near $(0, 0, 1)$ the vector field looks like the following picture (a “magnetic dipole”):

19. Suppose we have a “multiplication” map $(a, b) \mapsto a \cdot b$ from $\mathbb{R}^n \times \mathbb{R}^n$ to \mathbb{R}^n that makes \mathbb{R}^n into a (non-associative) division algebra. That is,

$$(a_1 + a_2) \cdot b = a_1 \cdot b + a_2 \cdot b$$

$$a \cdot (b_1 + b_2) = a \cdot b_1 + a \cdot b_2$$

$$\lambda(a \cdot b) = (\lambda a) \cdot b = a \cdot (\lambda b) \quad \text{for } \lambda \in \mathbb{R}$$

$$a \cdot (1, 0, \dots, 0) = a$$

and there are no zero divisors:

$$a, b \neq 0 \implies ab \neq 0.$$

(For example, for $n = 1$, we can use ordinary multiplication, and for $n = 2$ we can use “complex multiplication”, $(a, b) \cdot (c, d) = (ac - bd, ad + bc)$.) Let e_1, \dots, e_n be the standard basis of \mathbb{R}^n .

- (a) Every point in S^{n-1} is $a \cdot e_1$ for a unique $a \in \mathbb{R}^n$.
- (b) If $a \neq 0$, then $a \cdot e_1, \dots, a \cdot e_n$ are linearly independent.
- (c) If $p = a \cdot e_1 \in S^{n-1}$, then the projection of $a \cdot e_2, \dots, a \cdot e_n$ on $(S^{n-1}, i)_p$ are linearly independent.
- (d) Multiplication by a is continuous.
- (e) TS^{n-1} is trivial.
- (f) $T\mathbb{P}^{n-1}$ is trivial.

The tangent bundles TS^3 and TS^7 are both trivial. Multiplications with the required properties on \mathbb{R}^4 and \mathbb{R}^8 are provided by the “quaternions” and “Cayley numbers”, respectively; the quaternions are not commutative and the Cayley numbers are not even associative. It is a classical theorem that the reals, complexes, and quaternions are the only associative examples. For a simple proof, see R. S. Palais, *The Classification of Real Division Algebras*, Amer. Math. Monthly 75 (1968), 366–368. J. F. Adams has proved, using methods of algebraic topology, that $n = 1, 2, 4$, or 8 .

[Incidentally, non-existence of zero divisors immediately implies that for $a \neq 0$ there is some b with $ab = (1, 0, \dots, 0)$ and b' with $b'a = (1, 0, \dots, 0)$. If the multiplication is associative it follows easily that $b = b'$, so that we always have multiplicative inverses. Conversely, this condition implies that there are no zero divisors if the multiplication is associative; otherwise it suffices to assume the existence of a *unique* b with $a \cdot b = b \cdot a = (1, 0, \dots, 0)$.]

20. (a) Consider the space obtained from $[0, 1] \times \mathbb{R}^n$ by identifying $(0, v)$ with $(1, Tv)$, where $T: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a vector space isomorphism. Show that this can be made into the total space of a vector bundle over S^1 (a generalized Möbius strip).

(b) Show that the resulting bundle is orientable if and only if T is orientation preserving.

21. Show that for $p \in S^2$, the vector $p_p \in \mathbb{R}^3_p$ is not in $i_*(S^2_p)$ by showing that the inner product $\langle p, c'(t) \rangle = 0$ for all curves c with $c(0) = p$ and $|c(t)| = 1$ for all t . (Recall that

$$\langle f, g \rangle'(t) = (f'(t))^t, g(t) \rangle + \langle f(t), g'(t)^t \rangle,$$

where t denotes the transpose; see *Calculus on Manifolds*, pg. 23.)

22. Let M be a C^∞ manifold. Suppose that $(TM)|_A$ is trivial whenever $A \subset M$ is homeomorphic to S^1 . Show that M is orientable. *Hint:* An arc c from

$p_0 \in M$ to $p \in M$ is contained in some such A so $(TM)|_c$ is trivial. Thus one can “transport” the orientation of M_{p_0} to M_p . It must be checked that this is independent of the choice of c . First consider pairs c, c' which meet only at p_0 and p . The general, possibly quite messy, case can be treated by breaking up c into small pieces contained in coordinate neighborhoods.

Remark: Using results from the Addendum to Chapter 9, together with Problem 29, we can conclude that a neighborhood of some $S^1 \subset M$ is non-orientable if M is non-orientable.

The next two problems deal with important constructions associated with vector bundles.

23. (a) Suppose $\xi = \pi: E \rightarrow X$ is a bundle and $f: Y \rightarrow X$ is a continuous map. Let $E' \subset Y \times E$ be the set of all (y, e) with $f(y) = \pi(e)$, define $\pi': E' \rightarrow Y$ by $\pi'(y, e) = y$, and define $\tilde{f}: E' \rightarrow E$ by $\tilde{f}(y, e) = e$. A vector space structure can be defined on

$$\pi'^{-1}(y) = \{(y, e): e \in \pi^{-1}(f(y))\}$$

by using the vector space structure on $\pi^{-1}(f(y))$. Show that $\pi': E' \rightarrow Y$ is a bundle, and (\tilde{f}, f) a bundle map which is an isomorphism on each fibre. This bundle is denoted by $f^*(\xi)$, and is called the bundle induced (from ξ) by f .

(b) Suppose we have another bundle $\xi'' = \pi'': E'' \rightarrow Y$ and a bundle map (\tilde{f}, f) from ξ'' to ξ which is an isomorphism on each fibre. Show that $\xi'' \simeq \xi' = f^*(\xi)$. *Hint:* Map $e \in E''$ to $(\pi''(e), \tilde{f}(e)) \in E'$.

(c) If $g: Z \rightarrow Y$, then $(f \circ g)^*(\xi) \simeq g^*(f^*(\xi))$.

(d) If $A \subset X$ and $i: A \rightarrow X$ is the inclusion map, then $i^*(\xi) \simeq \xi|_A$.

(e) If ξ is orientable, then $f^*(\xi)$ is also orientable.

(f) Give an example where ξ is non-orientable, but $f^*(\xi)$ is orientable.

(g) Let $\xi = \pi: E \rightarrow B$ be a vector bundle. Since $\pi: E \rightarrow B$ is a continuous map from a space to the base space B of ξ , the symbol $\pi^*(\xi)$ makes sense. Show that if ξ is not orientable, then $\pi^*(\xi)$ is not orientable.

24. (a) Given an n -plane bundle $\xi = \pi: E \rightarrow B$ and an m -plane bundle $\eta = \pi': E' \rightarrow B$, let $E'' \subset E \times E'$ be the set of all pairs (e, e') with $\pi(e) = \pi'(e')$. Let $\pi''(e, e') = \pi(e) = \pi'(e')$. Show that $\pi'': E'' \rightarrow B$ is an $(n + m)$ -plane bundle. It is called the Whitney sum $\xi \oplus \eta$ of ξ and η ; the fibre of $\xi \oplus \eta$ over p is the direct sum $\pi^{-1}(p) \oplus \pi'^{-1}(p)$.

(b) If $f: Y \rightarrow B$, show that $f^*(\xi \oplus \eta) \simeq f^*(\xi) \oplus f^*(\eta)$.

- (c) Given bundles $\xi_i = \pi_i: E_i \rightarrow B_i$, define $\pi: E_1 \times E_2 \rightarrow B_1 \times B_2$ by $\pi(e_1, e_2) = (\pi_1(e_1), \pi_2(e_2))$. Show that this is a bundle $\xi_1 \times \xi_2$ over $B_1 \times B_2$.
- (d) If $\Delta: B \rightarrow B \times B$ is the “diagonal map”, $\Delta(x) = (x, x)$, show that $\xi \oplus \eta \simeq \Delta^*(\xi \times \eta)$.
- (e) If ξ and η are orientable, show that $\xi \oplus \eta$ is orientable.
- (f) If ξ is orientable, and η is non-orientable, show that $\xi \oplus \eta$ is also non-orientable.
- (g) Define a “natural” orientation on $V \oplus V$ for any vector space V , and use this to show that $\xi \oplus \xi$ is always orientable.
- (h) If X is a “figure eight” (c.f. Problem 5), find two non-orientable 1-plane bundles ξ and η over X such that $\xi \oplus \eta$ is also non-orientable.

25. (a) If $\pi: E \rightarrow M$ is a C^∞ vector bundle, then π_* has maximal rank at each point, and each fibre $\pi^{-1}(p)$ is a C^∞ submanifold of E .

(b) The 0-section of E is a submanifold, carried diffeomorphically onto B by π .

26. (a) If M and N are C^∞ manifolds, and π_M [or π_N] : $M \times N \rightarrow M$ [or N] is the projection on M [or N], then $T(M \times N) \simeq \pi_M^*(TM) \oplus \pi_N^*(TN)$.

(b) If M and N are orientable, then $M \times N$ is orientable.

(c) If $M \times N$ is orientable, then both M and N are orientable.

27. Show that the Jacobian matrix of $y_* \circ (x_*)^{-1}$ is of the form

$$\begin{pmatrix} D_j y^i \circ x^{-1} & 0 \\ \times & D_j y^i \circ x^{-1} \end{pmatrix}.$$

This shows that the manifold TM is *always orientable*, i.e., the bundle $T(TM)$ is orientable. (Here is a more conceptual formulation: for $v \in TM$, the orientation for $(TM)_v$ can be defined as

$$\left[\frac{\partial}{\partial(x^1 \circ \pi)} \Big|_v, \dots, \frac{\partial}{\partial(x^n \circ \pi)} \Big|_v, \frac{\partial}{\partial \dot{x}^1} \Big|_v, \dots, \frac{\partial}{\partial \dot{x}^n} \Big|_v \right];$$

the form of $y_* \circ (x_*)^{-1}$ shows that this orientation is independent of the choice of x .) A different proof that TM is orientable is given in Problem 29.

28. (a) Let (x, U) be a coordinate system on M with $x(p) = 0$ and let $v \in M_p$ be $\sum_{i=1}^n a^i \partial/\partial x^i|_p$. Consider the curve c in TM defined by

$$c(t) = v + t \frac{\partial}{\partial x^i} \Big|_p.$$

Show that

$$\frac{dc}{dt}(0) = \frac{\partial}{\partial \dot{x}^i} \Big|_v.$$

(b) Find a curve whose tangent vector at 0 is $\partial/\partial(x^i \circ \pi)|_v$.

29. This problem requires some familiarity with the notion of exact sequences

(c.f. Chapter 11). A sequence of bundle maps $E_1 \xrightarrow{\tilde{f}} E_2 \xrightarrow{\tilde{g}} E_3$ with $f = g =$ identity of B is exact if at each fibre it is exact as a sequence of vector space maps.

(a) If $\xi = \pi: E \rightarrow B$ is a C^∞ vector bundle, show that there is an exact sequence

$$0 \rightarrow \pi^*(\xi) \rightarrow TE \rightarrow \pi^*(TB) \rightarrow 0.$$

Hint: (1) An element of the total space of $\pi^*(\xi)$ is a pair of points in the same fibre, which determines a tangent vector of the fibre. (2) Map $X \in (TE)_e$ to $(e, \pi_* X)$.

(b) If $0 \rightarrow E_1 \rightarrow E_2 \rightarrow E_3 \rightarrow 0$ is exact, then each bundle E_i is orientable if the other two are.

(c) $T(TM)$ is always orientable.

(d) If $\pi: E \rightarrow M$ is not orientable, then the manifold E is not orientable. (This is why the proof that the Möbius strip is a non-orientable manifold is so similar to the proof that the Möbius bundle over S^1 is not orientable.)

The next two Problems contain more information about the groups introduced in Problem 2-33. In addition to being used in Problem 32, this information will all be important in Chapter 10.

30. (a) Let $p_0 \in S^{n-1}$ be the point $(0, \dots, 0, 1)$. For $n \geq 2$ define $f: \text{SO}(n) \rightarrow S^{n-1}$ by $f(A) = A(p_0)$. Show that f is continuous and open. Show that $f^{-1}(p_0)$ is homeomorphic to $\text{SO}(n-1)$, and then show that $f^{-1}(p)$ is homeomorphic to $\text{SO}(n-1)$ for all $p \in S^{n-1}$.

(b) $\text{SO}(1)$ is a point, so it is connected. Using part (a), and induction on n , prove that $\text{SO}(n)$ is connected for all $n \geq 1$.

(c) Show that $\text{O}(n)$ has exactly two components.

31. (a) If $T: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a linear transformation, $T^*: \mathbb{R}^n \rightarrow \mathbb{R}^n$, the adjoint of T , is defined by $(T^*v, w) = (v, Tw)$ (for each v , the map $w \mapsto (v, Tw)$ is linear, so it is $w \mapsto (T^*v, w)$ for a unique T^*v). If A is the matrix of T with respect to the usual basis, show that the matrix of T^* is the transpose A^t .

(b) A linear transformation $T: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is self-adjoint if $T = T^*$, so that $(Tv, w) = (v, Tw)$ for all $v, w \in \mathbb{R}^n$. If A is the matrix of T with respect to the standard basis, then T is self-adjoint if and only if A is symmetric, $A^t = A$. It is a standard theorem that a symmetric A can be written as CDC^{-1} for some diagonal matrix D (for an analytic proof, see *Calculus on Manifolds*, pg. 122). Show that C can be chosen orthogonal, by showing that eigenvectors for distinct eigenvalues are orthogonal.

(c) A self-adjoint T (or the corresponding symmetric A) is called **positive semi-definite** if $(Tv, v) \geq 0$ for all $v \in \mathbb{R}^n$, and **positive definite** if $(Tv, v) > 0$ for all $v \neq 0$. Show that a positive definite A is non-singular. *Hint*: Use the Schwarz inequality.

(d) Show that $A^t \cdot A$ is always positive semi-definite.

(e) Show that a positive semi-definite A can be written as $A = B^2$ for some B . (Remember that A is symmetric.)

(f) Show that every $A \in \text{GL}(n, \mathbb{R})$ can be written uniquely as $A = A_1 \cdot A_2$ where $A_1 \in \text{O}(n)$ and A_2 is positive definite. *Hint*: Consider $A^t \cdot A$, and use part (e).

(g) The matrices A_1 and A_2 are continuous functions of A . *Hint*: If $A^{(n)} \rightarrow A$ and $A^{(n)} = A^{(n)}_1 \cdot A^{(n)}_2$, then some subsequence of $\{A^{(n)}_1\}$ converges.

(h) $\text{GL}(n, \mathbb{R})$ is homeomorphic to $\text{O}(n) \times \mathbb{R}^{n(n+1)/2}$ and has exactly two components, $\{A: \det A > 0\}$ and $\{A: \det A < 0\}$. (Notice that this also gives us another way of finding the dimension of $\text{O}(n)$.)

32. Two continuous functions $f_0, f_1: X \rightarrow Y$ are called **homotopic** if there is a continuous function $H: X \times [0, 1] \rightarrow Y$ such that

$$f_i(x) = H(x, i) \quad i = 0, 1.$$

The functions $H_t: X \rightarrow Y$ defined by $H_t(x) = H(x, t)$ may be thought of as a path of functions from $H_0 = f_0$ to $H_1 = f_1$. The map H is called a **homotopy** between f_0 and f_1 .

The notation $f: (X, A) \rightarrow (Y, B)$, for $A \subset X$ and $B \subset Y$, means that $f: X \rightarrow Y$ and $f(A) \subset B$. We call $f_0, f_1: (X, A) \rightarrow (Y, B)$ **homotopic** (as maps from (X, A) to (Y, B)) if there is an H as above such that each $H_t: (X, A) \rightarrow (Y, B)$.

(a) If $A: [0, 1] \rightarrow \text{GL}(n, \mathbb{R})$ is continuous and $H: \mathbb{R}^n \times [0, 1] \rightarrow \mathbb{R}^n$ is defined by $H(x, t) = A(t)(x)$, show that H is continuous, so that H_0 and H_1 are homotopic as maps from $(\mathbb{R}^n, \mathbb{R}^n - \{0\})$ to $(\mathbb{R}^n, \mathbb{R}^n - \{0\})$. Conclude that a non-singular linear transformation $T: (\mathbb{R}^n, \mathbb{R}^n - \{0\}) \rightarrow (\mathbb{R}^n, \mathbb{R}^n - \{0\})$ with $\det T > 0$ is homotopic to the identity map.

(b) Suppose $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is C^∞ and $f(0) = 0$, while $f(\mathbb{R}^n - \{0\}) \subset \mathbb{R}^n - \{0\}$. If $Df(0)$ is non-singular, show that $f: (\mathbb{R}^n, \mathbb{R}^n - \{0\}) \rightarrow (\mathbb{R}^n, \mathbb{R}^n - \{0\})$ is

homotopic to $Df(0): (\mathbb{R}^n, \mathbb{R}^n - \{0\}) \rightarrow (\mathbb{R}^n, \mathbb{R}^n - \{0\})$. *Hint:* Define $H(x, t) = f(tx)$ for $0 < t \leq 1$ and $H(x, 0) = Df(0)(x)$. To prove continuity at points $(x, 0)$, use Lemma 2.

(c) Let U be a neighborhood of $0 \in \mathbb{R}^n$ and $f: U \rightarrow \mathbb{R}^n$ a homeomorphism with $f(0) = 0$. Let $B_r \subset V$ be the open ball with center 0 and radius r , and let $h: \mathbb{R}^n \rightarrow B_r$ be the homeomorphism

$$h(x) = \left(\frac{2r}{\pi} \arctan |x| \right) x;$$

then

$$f \circ h: (\mathbb{R}^n, \mathbb{R}^n - \{0\}) \rightarrow (\mathbb{R}^n, \mathbb{R}^n - \{0\}).$$

We will say that f is **orientation preserving** at 0 if $f \circ h$ is homotopic to the identity map $1: (\mathbb{R}^n, \mathbb{R}^n - \{0\}) \rightarrow (\mathbb{R}^n, \mathbb{R}^n - \{0\})$. Check that this does not depend on the choice of $B_r \subset V$.

(d) For $p \in \mathbb{R}^n$, let $T_p: \mathbb{R}^n \rightarrow \mathbb{R}^n$ be $T_p(q) = p + q$. If $f: U \rightarrow V$ is a homeomorphism, where $U, V \subset \mathbb{R}^n$ are open, we will say that f is **orientation preserving** at p if $T_{-f(p)} \circ f \circ T_p$ is orientation preserving at 0. Show that if M is orientable, then there is a collection \mathcal{C} of charts whose domains cover M such that for every (x, U) and (y, V) in \mathcal{C} , the map $y \circ x^{-1}$ is orientation preserving at $x(p)$ for all $p \in U \cap V$.

(e) Notice that the condition on $y \circ x^{-1}$ in part (d) makes sense even if $y \circ x^{-1}$ is not differentiable. Thus, if M is any (not necessarily differentiable) manifold, we can define M to be **orientable** if there is a collection \mathcal{C} of homeomorphisms $x: U \rightarrow \mathbb{R}^n$ whose domains cover M , such that \mathcal{C} satisfies the condition in part (d). To prove that this definition agrees with the old one we need a fact from algebraic topology: If $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a homeomorphism with $f(0) = 0$ and $T: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is $T(x^1, \dots, x^n) = (x^1, \dots, x^{n-1}, -x^n)$, then precisely one of f and $T \circ f$ is orientation preserving at 0. Assuming this result, show that if M has such a collection \mathcal{C} of homeomorphisms, then for any C^∞ structure on M the tangent bundle TM is orientable.

33. Let $M^n \subset \mathbb{R}^N$ be a C^∞ n -dimensional submanifold. By a **chord** of M we mean a point of \mathbb{R}^N of the form $p - q$ for $p, q \in M$.

(a) Prove that if $N > 2n + 1$, then there is a vector $v \in S^{N-1}$ such that

- (i) no chord of M is parallel to v ,
- (ii) no tangent plane M_p contains v .

Hint: Consider certain maps from appropriate open subsets of $M \times M$ and TM to S^{N-1} .

(b) Let $\mathbb{R}^{N-1} \subset \mathbb{R}^N$ be the subspace perpendicular to v , and $\pi: \mathbb{R}^N \rightarrow \mathbb{R}^{N-1}$ the corresponding projection. Show that $\pi|_M$ is a one-one immersion. In particular, if M is compact, then $\pi|_M$ is an imbedding.

(c) Every compact C^∞ n -dimensional manifold can be imbedded in \mathbb{R}^{2n+1} .

Note: This is the easy case of Whitney's classical theorem, which gives the same result even for non-compact manifolds (H. Whitney, *Differentiable manifolds*, Ann. of Math. 37 (1935), 645–680). Proofs may be found in Auslander and MacKenzie, *Introduction to Differentiable Manifolds* and Sternberg, *Lectures on Differential Geometry*. In Munkres, *Elementary Differential Topology*, there is a different sort of argument to prove that a not-necessarily-compact n -manifold M can be imbedded in some \mathbb{R}^N (in fact, with $N = (n+1)^2$). Then we may show that M imbeds in \mathbb{R}^{2n+1} using essentially the argument above, together with the existence of a proper map $f: M \rightarrow \mathbb{R}$, given by Problem 2-30 (compare Guillemin and Pollack, *Differential Topology*). A much harder result of Whitney shows that M^n can actually be imbedded in \mathbb{R}^{2n} (H. Whitney, *The self-intersections of a smooth n -manifold in $2n$ -space*, Ann. of Math. 45 (1944), 220–246).

CHAPTER 4

TENSORS

All the constructions on vector bundles carried out in this chapter have a common feature. In each case, we replace each fibre $\pi^{-1}(p)$ by some other vector space, and then fit all these new vector spaces together to form a new vector bundle over the same base space.

The simplest case arises when we replace each fibre V by its dual space V^* . Recall that V^* denotes the vector space of all linear functions $\lambda: V \rightarrow \mathbb{R}$. If $f: V \rightarrow W$ is a linear transformation, then there is a linear transformation $f^*: W^* \rightarrow V^*$ defined by

$$(f^*\lambda)(v) = \lambda(fv).$$

It is clear that if $1_V: V \rightarrow V$ is the identity, then 1_V^* is the identity map of V^* and if $g: U \rightarrow V$, then $(f \circ g)^* = g^* \circ f^*$. These simple remarks already show that f^* is an isomorphism if $f: V \rightarrow W$ is, for $(f^{-1} \circ f)^* = 1_V^*$ and $(f \circ f^{-1})^* = 1_W^*$.

The dimension of V^* is the same as that of V , for finite dimensional V . In fact, if v_1, \dots, v_n is a basis for V , then the elements $v_i^* \in V^*$, defined by

$$v_i^*(v_j) = \delta_j^i,$$

are easily checked to be a basis for V^* . The linear function v_i^* depends on the entire set v_1, \dots, v_n , not just on v_i alone, and the isomorphism from V to V^* obtained by sending v_i to v_i^* is *not* independent of the choice of basis (consider what happens if v_1 is replaced by $2v_1$).

On the other hand, if $v \in V$, we can define $v^{**} \in V^{**} = (V^*)^*$ unambiguously by

$$v^{**}(\lambda) = \lambda(v) \quad \text{for every } \lambda \in V^*.$$

If $v^{**}(\lambda) = 0$ for every $\lambda \in V^*$, then $\lambda(v) = 0$ for all $\lambda \in V^*$, which implies that

$v = 0$. Thus the map $v \mapsto v^{**}$ is an isomorphism from V to V^{**} . It is called the **natural isomorphism** from V to V^{**} .

(Problem 6 gives a precise meaning to the word “natural”, formulated only after the term had long been in use. Once the meaning is made precise, we can prove that there is *no* natural isomorphism from V to V^* .)

Now let $\xi = \pi : E \rightarrow B$ be any vector bundle. Let

$$E' = \bigcup_{p \in B} [\pi^{-1}(p)]^*,$$

and define the function $\pi' : E' \rightarrow B$ to take each $[\pi^{-1}(p)]^*$ to p . If $U \subset B$, and $t : \pi^{-1}(U) \rightarrow U \times \mathbb{R}^n$ is a trivialization, then we can define a function

$$t' : \pi'^{-1}(U) \rightarrow U \times (\mathbb{R}^n)^*$$

in the obvious way: since the map t restricted to a fibre,

$$t_p : \pi^{-1}(p) \rightarrow \{p\} \times \mathbb{R}^n,$$

is an isomorphism, it gives us an isomorphism

$$(t_p^*)^{-1} : [\pi^{-1}(p)]^* \rightarrow \{p\} \times (\mathbb{R}^n)^*.$$

We can make $\pi' : E' \rightarrow B$ into a vector bundle, the **dual bundle** ξ^* of ξ , by requiring that all such t' be local trivializations. (We first pick an isomorphism from $(\mathbb{R}^n)^*$ to \mathbb{R}^n , once and for all.)

At first it might appear that $\xi^* \simeq \xi$, since each $\pi^{-1}(p)$ is isomorphic to $\pi'^{-1}(p)$. However, this is true merely because the two vector spaces have the same dimension. The lack of a natural isomorphism from V to V^* prevents us from constructing an equivalence between ξ^* and ξ . Actually, we will see later that in “most” cases ξ^* is equivalent to ξ ; for the present, readers may ponder this question for themselves. In contrast, the bundle $\xi^{**} = (\xi^*)^*$ is *always* equivalent to ξ . We construct the equivalence by mapping the fibre V of ξ over p to the fibre V^{**} of ξ^{**} over p by the natural isomorphism. If you

think about how ξ^* is constructed, it will appear obvious that this map is indeed an equivalence.

Even if ξ can be pictured geometrically (e.g., if ξ is TM), there is seldom a geometric picture for ξ^* . Rather, ξ^* operates on ξ : If s is a section of ξ and σ is a section of ξ^* , then we can define a function from B to \mathbb{R} by

$$p \mapsto \sigma(p)(s(p)) \quad \begin{array}{l} s(p) \in \pi^{-1}(p) \\ \sigma(p) \in \pi'^{-1}(p) = \pi^{-1}(p)^*. \end{array}$$

This function will be denoted simply by $\sigma(s)$.

When this construction is applied to the tangent bundle TM of M , the resulting bundle, denoted by T^*M , is called the **cotangent bundle** of M ; the fibre of T^*M over p is $(M_p)^*$. Like TM , the cotangent bundle T^*M is actually a C^∞ vector bundle: since two trivializations x_* and y_* of TM are C^∞ -related, the same is clearly true for x_*' and y_*' (in fact, $y_*' \circ (x_*')^{-1} = y_* \circ (x_*)^{-1}$). We can thus define C^∞ , as well as continuous, sections of T^*M . If ω is a C^∞ section of T^*M and X is a C^∞ vector field, then $\omega(X)$ is the C^∞ function $p \mapsto \omega(p)(X(p))$.

If $f: M \rightarrow \mathbb{R}$ is a C^∞ function, then a C^∞ section df of T^*M can be defined by

$$df(p)(X) = X(f) \quad \text{for } X \in M_p.$$

The section df is called the **differential** of f . Suppose, in particular, that X is $dc/dt|_{t_0}$, where $c(t_0) = p$. Recall that

$$\left. \frac{dc}{dt} \right|_{t_0} = c_* \left(\left. \frac{d}{dt} \right|_{t_0} \right).$$

This means that

$$\begin{aligned} df \left(\left. \frac{dc}{dt} \right|_{t_0} \right) &= c_* \left(\left. \frac{d}{dt} \right|_{t_0} \right) (f) \\ &= \left. \frac{d}{dt} \right|_{t_0} (f \circ c) \\ &= (f \circ c)'(t_0) \quad \text{or} \quad \left. \frac{d(f(c(t)))}{dt} \right|_{t_0}. \end{aligned}$$

Adopting the elliptical notations

$$\frac{dc}{dt} \quad \text{for} \quad \left. \frac{dc}{dt} \right|_t, \quad \frac{dg(t)}{dt} \quad \text{for} \quad g'(t),$$

this equation takes the nice form

$$df \left(\frac{dc}{dt} \right) = \frac{d(f(c(t)))}{dt}.$$

If (x, U) is a coordinate system, then the dx^i are sections of T^*M over U . Applying the definition, we see that

$$dx^i(p) \left(\left. \frac{\partial}{\partial x^j} \right|_p \right) = \delta_j^i.$$

Thus $dx^1(p), \dots, dx^n(p)$ is just the basis of M_p^* dual to the basis $\partial/\partial x^1|_p, \dots, \partial/\partial x^n|_p$ of M_p .

This means that every section ω can be expressed uniquely on U as

$$\omega(p) = \sum_{i=1}^n \omega_i(p) dx^i(p),$$

for certain functions ω_i on U . The section ω is continuous or C^∞ if and only if the functions ω_i are.

We can also write

$$\omega = \sum_{i=1}^n \omega_i dx^i,$$

if we define sums of sections and products of functions and sections in the obvious way (“pointwise” addition and multiplication).

The section df must have some such expression. In fact, we obtain a classical formula:

1. THEOREM. If (x, U) is a coordinate system and f is a C^∞ function, then on U we have

$$df = \sum_{i=1}^n \frac{\partial f}{\partial x^i} dx^i.$$

PROOF. If $X_p \in M_p$ is

$$X_p = \sum_{i=1}^n a^i \left. \frac{\partial}{\partial x^i} \right|_p,$$

then

$$a^i = X_p(x^i) = dx^i(p)(X_p).$$

Thus

$$\begin{aligned} df(p)(X_p) &= X_p(f) = \sum_{i=1}^n a^i \frac{\partial f}{\partial x^i}(p) \\ &= \sum_{i=1}^n \frac{\partial f}{\partial x^i}(p) dx^i(p)(X_p). \quad \spadesuit \end{aligned}$$

Classical differential geometers (and classical analysts) did not hesitate to talk about “infinitely small” changes dx^i of the coordinates x^i , just as Leibnitz had. No one wanted to admit that this was nonsense, because true results were obtained when these infinitely small quantities were divided into each other (provided one did it in the right way).

Eventually it was realized that the closest one can come to describing an infinitely small change is to describe a direction in which this change is supposed to occur, i.e., a tangent vector. Since df is supposed to be the infinitesimal change of f under an infinitesimal change of the point, df must be a function of this change, which means that df should be a function on tangent vectors. The dx^i themselves then metamorphosed into functions, and it became clear that they must be distinguished from the tangent vectors $\partial/\partial x^i$.

Once this realization came, it was only a matter of making new definitions, which preserved the *old* notation, and waiting for everybody to catch up. In short, all classical notions involving infinitely small quantities became functions on tangent vectors, like df , except for quotients of infinitely small quantities, which became tangent vectors, like dc/dt .

Looking back at the classical works from our modern vantage point, one can usually see that, no matter how obscurely expressed, this point of view was in

some sense the one always taken by classical geometers. In fact, the differential df was usually introduced in the following way:

CLASSICAL FORMULATION	MODERN FORMULATION
Let f be a function of the x^1, \dots, x^n , say $f = f(x^1, \dots, x^n)$.	Let f be a function on M , and x a coordinate system (so that $f = \tilde{f} \circ x$ for some function \tilde{f} on \mathbb{R}^n , namely $\tilde{f} = f \circ x^{-1}$).
Let x^i be functions of t , say $x^i = x^i(t)$. Then f becomes a function of t , $f(t) = f(x^1(t), \dots, x^n(t))$.	Let $c: \mathbb{R} \rightarrow M$ be a curve. Then $f \circ c: \mathbb{R} \rightarrow \mathbb{R}$, where $f \circ c(t) = \tilde{f}(x^1 \circ c(t), \dots, x^n \circ c(t))$.
<p>We now have</p> $\frac{df}{dt} = \sum_{i=1}^n \frac{\partial f}{\partial x^i} \frac{dx^i}{dt}.$ <p>(The classical notation, which suppresses the curve c, is still used by physicists, as we shall point out once again in Chapter 7.)</p>	<p>We now have</p> $\begin{aligned} (f \circ c)'(t) &= \sum_{i=1}^n D_i \tilde{f}(x(c(t))) \cdot (x^i \circ c)'(t) \\ &= \sum_{i=1}^n \frac{\partial f}{\partial x^i}(c(t)) \cdot (x^i \circ c)'(t) \end{aligned}$ <p>or</p> $\frac{d(f(c(t)))}{dt} = \sum_{i=1}^n \frac{\partial f}{\partial x^i}(c(t)) \cdot \frac{dx^i(c(t))}{dt}$
<p>Multiplying by dt gives</p> $df = \sum_{i=1}^n \frac{\partial f}{\partial x^i} dx^i.$ <p>(This equation signifies that true results are obtained by dividing by dt again, <i>no matter what the functions $x^i(t)$ are</i>. It is the closest approach in classical analysis to the realization of df as a function on tangent vectors.)</p>	<p>Consequently,</p> $df \left(\frac{dc}{dt} \right) = \sum_{i=1}^n \frac{\partial f}{\partial x^i}(c(t)) \cdot dx^i \left(\frac{dc}{dt} \right)$ <p>Since every tangent vector at $c(t)$ is of the form dc/dt, we have</p> $df = \sum_{i=1}^n \frac{\partial f}{\partial x^i} dx^i.$

In preparation for our reading of Gauss and Riemann, we will continually examine the classical way of expressing all concepts which we introduce. After a while, the “translation” of classical terminology becomes only a little more difficult than the translation of the German in which it was written.

Recall that if $f: M \rightarrow N$ is C^∞ , then there is a map $f_*: TM \rightarrow TN$; for each $p \in M$, we have a map $f_{*p}: M_p \rightarrow N_{f(p)}$. Since f_{*p} is a linear transformation between two vector spaces, it gives rise to a map

$$N_{f(p)}^* \rightarrow M_p^*.$$

Strict notational propriety would dictate that this map be denoted by $(f_{*p})^*$, but everyone denotes it simply by

$$f_p^*: N_{f(p)}^* \rightarrow M_p^*.$$

Notice that we cannot put all f_p^* together to obtain a bundle map from T^*N to T^*M ; in fact, the same $q \in N$ may be $f(p_i)$ for more than one $p_i \in M$, and there is no reason why f_{*p_1} should equal f_{*p_2} . On the other hand, we can do something with the cotangent bundle that we could not do with the tangent bundle. Suppose ω is a section of T^*N . Then we can define a section η of T^*M as follows:

$$\eta(p) = \omega(f(p)) \circ f_{*p},$$

i.e.,

$$\eta(p)(X_p) = \omega(f(p))(f_{*p}X_p) \quad \text{for } X_p \in M_p.$$

(The complex symbolism tends to hide the simple idea: to operate on a vector, we push it over to N by f_* , and then operate on it by ω .) This section η is denoted, naturally enough, by $f^*\omega$. There is no corresponding way of transferring a vector field X on M over to a vector field on N .

Despite these differences, we can say, roughly, that a map $f: M \rightarrow N$ produces a map f_* going in the same direction on the tangent bundle and a map f^* going in the opposite direction on the cotangent bundle. Nowadays such situations are always distinguished by calling the things which go in the same direction “covariant” and the things which go in the opposite direction “contravariant”. Classical terminology used these same words, and it just happens to have reversed this: a vector field is called a **contravariant vector field**, while a section of T^*M is called a **covariant vector field**. And no one has had the gall or authority to reverse terminology so sanctified by years of usage. So it’s very easy to remember which kind of vector field is covariant, and which contravariant—it’s just the opposite of what it logically ought to be.

The rationale behind the classical terminology can be seen by considering coordinate systems x on \mathbb{R}^n which are linear transformations. In this case, if $x(v_i) = e_i$, then

$$x(a^1 v_1 + \cdots + a^n v_n) = (a^1, \dots, a^n),$$

so the x coordinate system is just an “oblique Cartesian coordinate system”.

If x' is another such coordinate system, then $x'^j = \sum_{i=1}^n a_{ij} x^i$ for certain a_{ij} . Clearly $a_{ij} = \partial x'^j / \partial x^i$, so

$$(*) \quad x'^j = \sum_{i=1}^n \frac{\partial x'^j}{\partial x^i} x^i;$$

this can be seen directly from the fact that the matrix $(\partial x'^j / \partial x^i)$ is the constant matrix $D(x' \circ x^{-1}) = x' \circ x^{-1}$. Comparing $(*)$ with

$$(**) \quad dx'^j = \sum_{i=1}^n \frac{\partial x'^j}{\partial x^i} dx^i,$$

from Theorem 1, we see that the differentials dx^i “change in the same way” as the coordinates x^i , hence they are “covariant”. Consequently, any combination

$$\omega = \sum_{i=1}^n \omega_i dx^i$$

is also called “covariant”. Notice that if we also have

$$\omega = \sum_{i=1}^n \omega'_i dx'^i,$$

then we can express the ω'_i in terms of the ω_i . Substituting

$$dx^i = \sum_{j=1}^n \frac{\partial x^i}{\partial x'^j} dx'^j$$

into the first expression for ω and comparing coefficients with the second, we find that

$$\omega'_j = \sum_{i=1}^n \omega_i \frac{\partial x^i}{\partial x'^j}.$$

On the other hand, given two expressions

$$\sum_{i=1}^n a^i \frac{\partial}{\partial x^i} = \sum_{i=1}^n a'^i \frac{\partial}{\partial x'^i}$$

for a vector field, the functions a'^j must satisfy

$$a'^j = \sum_{i=1}^n a^i \frac{\partial x'^j}{\partial x^i}.$$

These expressions can always be remembered by noting that indices which are summed over always appear once “above” and once “below”. (Coordinate functions x^1, \dots, x^n used to be denoted by x_1, \dots, x_n . This suggested subscripts ω_i for covariant vector fields and superscripts a^i for contravariant vector fields. After this was firmly established, the indices on the x ’s were shifted upstairs again to make the summation convention work out.)

Covariant and contravariant vector fields, i.e., sections of T^*M and TM , respectively, are also called covariant and contravariant tensors (or tensor fields) of order 1, which is a warning that worse things are to come. We begin with some worse algebra.

If V_1, \dots, V_m are vector spaces, a function

$$T: V_1 \times \dots \times V_m \rightarrow \mathbb{R}$$

is **multilinear** if

$$v \mapsto T(v_1, \dots, v_{k-1}, v, v_{k+1}, \dots, v_m)$$

is linear for each choice of $v_1, \dots, v_{k-1}, v_{k+1}, \dots, v_m$. The set of all such T is clearly a vector space. If $V_1, \dots, V_m = V$, this vector space will be denoted

by $\mathcal{T}^m(V)$. Notice that $\mathcal{T}^1(V) = V^*$. If $f: V \rightarrow W$ is a linear transformation, then there is a linear transformation $f^*: \mathcal{T}^m(W) \rightarrow \mathcal{T}^m(V)$, defined completely analogously to the case $m = 1$:

$$f^*T(v_1, \dots, v_m) = T(f(v_1), \dots, f(v_m)).$$

For $T \in \mathcal{T}^k(V)$, and $S \in \mathcal{T}^l(V)$ we can define the “tensor product” $T \otimes S \in \mathcal{T}^{k+l}(V)$ by

$$T \otimes S(v_1, \dots, v_k, v_{k+1}, \dots, v_{k+l}) = T(v_1, \dots, v_k) \cdot S(v_{k+1}, \dots, v_{k+l}).$$

Of course, $T \otimes S$ is not $S \otimes T$. On the other hand, $(S \otimes T) \otimes U = S \otimes (T \otimes U)$, so we can define n -fold tensor products unambiguously; this tensor product operation is itself multilinear, $(S_1 + S_2) \otimes T = S_1 \otimes T + S_2 \otimes T$, etc. In particular, if v_1, \dots, v_n is a basis for V and v_1^*, \dots, v_n^* is the dual basis for $V^* = \mathcal{T}^1(V)$, then the elements

$$v_{i_1}^* \otimes \cdots \otimes v_{i_k}^* \quad 1 \leq i_1, \dots, i_k \leq n$$

are easily seen to be a basis for $\mathcal{T}^k(V)$, which thus has dimension n^k .

We can use this new algebraic construction to obtain a new bundle from any vector bundle $\xi = \pi: E \rightarrow B$. We let

$$E' = \bigcup_{p \in B} \mathcal{T}^k(\pi^{-1}(p)),$$

and let

$$\pi': E' \rightarrow B \quad \text{take} \quad \mathcal{T}^k(\pi^{-1}(p)) \quad \text{to} \quad p.$$

If $U \subset B$ and

$$t: \pi^{-1}(U) \rightarrow U \times \mathbb{R}^n$$

is a trivialization, then the isomorphisms

$$t_p: \pi^{-1}(p) \rightarrow \{p\} \times \mathbb{R}^n$$

yield isomorphisms

$$(t_p^*)^{-1}: \mathcal{T}^k(\pi^{-1}(p)) \rightarrow \{p\} \times \mathcal{T}^k(\mathbb{R}^n).$$

If we choose an isomorphism $\mathcal{T}^k(\mathbb{R}^n) \rightarrow \mathbb{R}^{n^k}$ once and for all, these maps can be put together to give a map

$$t': \pi'^{-1}(U) \rightarrow U \times \mathbb{R}^{n^k}.$$

We make $\pi': E' \rightarrow B$ into a vector bundle $\mathcal{T}^k(\xi)$ by requiring that all such ι' be local trivializations. The bundle ξ^* is the special case $k = 1$.

For the case of TM , the bundle $\mathcal{T}^k(TM)$ is called the **bundle of covariant tensors of order k** , and a section is called a **covariant tensor field of order k** . If (x, U) is a coordinate system, so that

$$dx^1(p), \dots, dx^n(p)$$

is a basis for $(M_p)^*$, then the k -fold tensor products

$$dx^{i_1}(p) \otimes \dots \otimes dx^{i_k}(p) \in \mathcal{T}^k(M_p) \quad 1 \leq i_1, \dots, i_k \leq n$$

are a basis for $\mathcal{T}^k(M_p)$. Thus, on U every covariant tensor field A of order k can be written

$$A(p) = \sum_{i_1, \dots, i_k} A_{i_1 \dots i_k}(p) dx^{i_1}(p) \otimes \dots \otimes dx^{i_k}(p),$$

or simply

$$A = \sum_{i_1, \dots, i_k} A_{i_1 \dots i_k} dx^{i_1} \otimes \dots \otimes dx^{i_k},$$

where $dx^{i_1} \otimes \dots \otimes dx^{i_k}$ now denotes a section of $\mathcal{T}^k(TM)$. If we also have

$$A = \sum_{i_1, \dots, i_k} A'_{i_1 \dots i_k} dx'^{i_1} \otimes \dots \otimes dx'^{i_k},$$

then

$$A'_{\alpha_1 \dots \alpha_k} = \sum_{i_1, \dots, i_k} A_{i_1 \dots i_k} \frac{\partial x^{i_1}}{\partial x'^{\alpha_1}} \dots \frac{\partial x^{i_k}}{\partial x'^{\alpha_k}}$$

(the products are just ordinary products of functions). To derive this equation, we just use equation (**) on page 114, and multilinearity of \otimes . The section A is continuous or C^∞ if and only if the functions $A_{i_1 \dots i_k}$ are.

A covariant tensor field A of order k can just be thought of as an operation \bar{A} on k vector fields X_1, \dots, X_k which yields a function:

$$\bar{A}(X_1, \dots, X_k)(p) = A(p)(X_1(p), \dots, X_k(p)).$$

Notice that \bar{A} is multilinear on the set \mathcal{V} of C^∞ vector fields:

$$\bar{A}(X_1, \dots, X_i + X'_i, \dots, X_k) = \bar{A}(X_1, \dots, X_i, \dots, X_k) + \bar{A}(X_1, \dots, X'_i, \dots, X_k)$$

$$\bar{A}(X_1, \dots, aX_i, \dots, X_k) = a\bar{A}(X_1, \dots, X_k).$$

Moreover, because \bar{A} is defined “pointwise”, it is actually linear over the C^∞ functions \mathcal{F} ; i.e., if f is C^∞ , then

$$\bar{A}(X_1, \dots, fX_i, \dots, X_k) = f\bar{A}(X_1, \dots, X_i, \dots, X_k),$$

for we have

$$\begin{aligned}\bar{A}(X_1, \dots, fX_i, \dots, X_k)(p) &= A(p)(X_1(p), \dots, f(p)X_i(p), \dots, X_k(p)) \\ &= f(p)A(p)(X_1(p), \dots, X_i(p), \dots, X_k(p)) \\ &= f(p) \cdot \bar{A}(X_1, \dots, X_i, \dots, X_k)(p).\end{aligned}$$

We are finally ready for another theorem, one that is used over and over.

2. THEOREM. If

$$\mathcal{A}: \underbrace{\mathcal{V} \times \dots \times \mathcal{V}}_{k \text{ times}} \rightarrow \mathcal{F}$$

is linear over \mathcal{F} , then there is a unique tensor field A with $\mathcal{A} = \bar{A}$.

PROOF. Note first that if $v \in M_p$ is any tangent vector, then there is a vector field $X \in \mathcal{V}$ with $X(p) = v$. In fact, if (x, U) is a coordinate system and

$$v = \sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_p,$$

then we can define

$$X = \begin{cases} f \sum_{i=1}^n a^i \frac{\partial}{\partial x^i} & \text{on } U \\ 0 & \text{outside } U, \end{cases}$$

where each a^i now denotes a constant function and f is a C^∞ function with $f(p) = 1$ and support $f \subset U$.

Now if $v_1, \dots, v_k \in M_p$ are extended to vector fields $X_1, \dots, X_k \in \mathcal{V}$ we clearly must define

$$A(p)(v_1, \dots, v_k) = \mathcal{A}(X_1, \dots, X_k)(p).$$

The problem is to prove that this is well-defined: If $X_i(p) = Y_i(p)$ for each i , we claim that

$$\mathcal{A}(X_1, \dots, X_k)(p) = \mathcal{A}(Y_1, \dots, Y_k)(p).$$

(The map \mathcal{A} “lives at points”, to use the in terminology.) For simplicity, take the case $k = 1$ (the general case is exactly analogous). The proof that $\mathcal{A}(X)(p) = \mathcal{A}(Y)(p)$ when $X(p) = Y(p)$ is in two steps.

(1) Suppose first that $X = Y$ in a neighborhood U of p . Let f be a C^∞ function with $f(p) = 1$ and support $f \subset U$. Then $fX = fY$, so

$$f\mathcal{A}(X) = \mathcal{A}(fX) = \mathcal{A}(fY) = f\mathcal{A}(Y);$$

evaluating at p gives

$$\mathcal{A}(X)(p) = \mathcal{A}(Y)(p).$$

(2) To prove the result, it obviously suffices to show that $\mathcal{A}(X)(p) = 0$ if $X(p) = 0$. Let (x, U) be a coordinate system around p , so that on U we can write

$$X = \sum_{i=1}^n b^i \frac{\partial}{\partial x^i} \quad \text{where all } b^i(p) = 0.$$

If g is 1 in a neighborhood V of p , and support $g \subset U$, then

$$Y = g \sum_{i=1}^n b^i \frac{\partial}{\partial x^i} = \sum_{i=1}^n b^i g \frac{\partial}{\partial x^i}$$

is a well-defined C^∞ vector field on all of M which equals X on V , so that

$$\mathcal{A}(X)(p) = \mathcal{A}(Y)(p), \quad \text{by (1).}$$

Now

$$\begin{aligned} \mathcal{A}(Y)(p) &= \sum_{i=1}^n b^i(p) \cdot \mathcal{A}\left(g \frac{\partial}{\partial x^i}\right)(p) \\ &= 0, \quad \text{since } b^i(p) = 0. \quad \spadesuit \end{aligned}$$

Because of Theorem 2, we will never distinguish between the tensor field A and the operation \bar{A} , nor will we use the symbol \bar{A} any longer. Note that Theorem 2 applies, in particular, to the case $k = 1$, where $\mathcal{T}^k(TM) = T^*M$, the cotangent bundle: a function from $\mathcal{V} \rightarrow \mathcal{F}$ which is linear over \mathcal{F} comes from a covariant vector field ω . Just as with covariant vector fields, a C^∞ map $f: M \rightarrow N$ gives a map f^* taking covariant tensor fields A of order k on N to covariant tensor fields f^*A of order k on M :

$$f^*A(p)(X_{1p}, \dots, X_{kp}) = A(f(p))(f_*X_{1p}, \dots, f_*X_{kp}).$$

Moreover, if A and B are covariant tensor fields of orders k and l , respectively, then we can define a new covariant tensor field $A \otimes B$ of order $k + l$:

$$(A \otimes B)(p) = A(p) \otimes B(p) \quad (\text{operating on } M_p \times \cdots \times M_p \text{ } k + l \text{ times}).$$

Although covariant tensor fields will be our main concern, if only for the sake of completeness we should define contravariant tensor fields. Recall that a contravariant vector field is a section X of TM . So each $X_p \in M_p$. Now an element v of a vector space V can be thought of as a linear function $v: V^* \rightarrow \mathbb{R}$; we just define $v(\lambda)$ to be $\lambda(v)$. A contravariant tensor field of order k is just a section A of the bundle $\mathcal{T}^k(T^*M)$; thus, each $A(p)$ is a k -linear function on M_p^* . We could also use the notation $\mathcal{T}_k(TM)$, if we use $\mathcal{T}_k(V)$ to denote all k -linear functions on V^* . In local coordinates we can write

$$A(p) = \sum_{j_1, \dots, j_k} A^{j_1 \dots j_k}(p) \left. \frac{\partial}{\partial x^{j_1}} \right|_p \otimes \cdots \otimes \left. \frac{\partial}{\partial x^{j_k}} \right|_p$$

(remember that each $\partial/\partial x^j|_p$ operates on M_p^*), or simply

$$A = \sum_{j_1, \dots, j_k} A^{j_1 \dots j_k} \frac{\partial}{\partial x^{j_1}} \otimes \cdots \otimes \frac{\partial}{\partial x^{j_k}}.$$

If we have another such expression,

$$A = \sum_{j_1, \dots, j_k} A'^{j_1 \dots j_k} \frac{\partial}{\partial x'^{j_1}} \otimes \cdots \otimes \frac{\partial}{\partial x'^{j_k}},$$

then we easily compute that

$$A'^{\beta_1 \dots \beta_k} = \sum_{j_1, \dots, j_k} A^{j_1 \dots j_k} \frac{\partial x'^{\beta_1}}{\partial x^{j_1}} \cdots \frac{\partial x'^{\beta_k}}{\partial x^{j_k}}.$$

A contravariant tensor field A of order k can be considered as an operator \bar{A} taking k covariant vector fields $\omega_1, \dots, \omega_k$ into a function:

$$\bar{A}(\omega_1, \dots, \omega_k)(p) = A(p)(\omega_1(p), \dots, \omega_k(p)).$$

Naturally, there is an analogue of Theorem 2, proved exactly the same way, that allows us to dispense with the notation \bar{A} , and to identify contravariant tensor fields of order k with operators on k covariant vector fields that are *linear over the C^∞ functions \mathcal{F}* .

Finally, we are ready to introduce “mixed” tensor fields. To make the introduction less painful, we consider a special case first. If V is a vector space, let $\mathcal{T}_1^1(V)$ denote all bilinear functions

$$T: V \times V^* \rightarrow \mathbb{R}.$$

A vector bundle $\xi = \pi: E \rightarrow B$ gives rise to a vector bundle $\mathcal{T}_1^1(\xi)$, obtained by replacing each fibre $\pi^{-1}(p)$ by $\mathcal{T}_1^1(\pi^{-1}(p))$. In particular, sections of $\mathcal{T}_1^1(TM)$ are called tensor fields, covariant of order 1 and contravariant of order 1.

There are all sorts of algebraic tricks one can play with $\mathcal{T}_1^1(V)$; although they should be kept to a minimum, certain ones are quite important. Let $End(V)$ denote the vector space of all linear transformations $T: V \rightarrow V$ (“endomorphisms” of V). Notice that each $S \in End(V)$ gives rise to a bilinear $\bar{S} \in \mathcal{T}_1^1(V)$,

$$\bar{S}: V \times V^* \rightarrow \mathbb{R},$$

by the formula

$$(*) \quad \bar{S}(v, \lambda) = \lambda(S(v)).$$

Moreover, the correspondence $S \mapsto \bar{S}$ from $End(V)$ to $\mathcal{T}_1^1(V)$ is linear and one-one, for $\bar{S} = 0$ implies that $\lambda(S(v)) = 0$ for all λ , which implies that $S(v) = 0$, for all v . Since both $End(V)$ and $\mathcal{T}_1^1(V)$ have dimension n^2 , this map is an isomorphism. The inverse, however, is not so easy to describe. Given \bar{S} , for each v the vector $S(v) \in V$ is merely determined by describing the action of a λ on it according to (*). It is not hard to check that this isomorphism of $End(V)$ and $\mathcal{T}_1^1(V)$ makes the identity map $1: V \rightarrow V$ in $End(V)$ correspond to the “evaluation” map

$$e: V \times V^* \rightarrow \mathbb{R} \quad \text{in } \mathcal{T}_1^1(V)$$

given by

$$e(v, \lambda) = \lambda(v).$$

Generally speaking, our isomorphism can be used to transfer any operation from $End(V)$ to $\mathcal{T}_1^1(V)$. In particular, given a bilinear

$$T: V \times V^* \rightarrow \mathbb{R},$$

we can take the trace of the corresponding $S: V \rightarrow V$; this number is called the contraction of T . If v_1, \dots, v_n is a basis of V and

$$T = \sum_{i,j} T_i^j v^*_i \otimes v_j,$$

then we can find the matrix $A = (a_{ij})$ of S , defined by

$$S(v_i) = \sum_{j=1}^n a_{ji} v_j,$$

in terms of the T_i^j ; in fact,

$$a_{ji} = v_j^*(S(v_i)) = T(v_i, v_j^*) = T_i^j.$$

Thus

$$\text{contraction of } T = \sum_{i=1}^n T_i^i.$$

(The term “contraction” comes from the fact that the number of indices is contracted from 2 to 0 by setting the upper and lower indices equal and summing.)

These identifications and operations can be carried out, fibre by fibre, in any fibre bundle $\mathcal{T}_1^1(\xi)$. Thus, a section A of $\mathcal{T}_1^1(\xi)$ can just as well be considered as a section of the bundle $\text{End}(\xi)$, obtained by replacing each fibre $\pi^{-1}(p)$ by $\text{End}(\pi^{-1}(p))$. In this case, each $A(p)$ is an endomorphism of $\pi^{-1}(p)$. Moreover, each section A gives rise to a *function*

$$(\text{contraction of } A): B \rightarrow \mathbb{R}$$

defined by

$$\begin{aligned} p &\mapsto \text{contraction of } A(p) \\ &= \text{trace } A(p) \quad \text{if we consider } A(p) \in \text{End}(\pi^{-1}(p)). \end{aligned}$$

In particular, given a tensor field A , covariant of order 1 and contravariant of order 1, which is a section of $\mathcal{T}_1^1(TM)$, we can consider each $A(p)$ as an endomorphism of M_p , and we obtain a function “contraction of A ”. If in a coordinate system

$$A = \sum_{i,j} A_i^j dx^i \otimes \frac{\partial}{\partial x^j},$$

then

$$(\text{contraction of } A) = \sum_{i=1}^n A_i^i.$$

The general notion of a mixed tensor field is a straightforward generalization. Define $\mathcal{T}_l^k(V)$ to be the set of all $(k + l)$ -linear

$$T: \underbrace{V \otimes \cdots \otimes V}_{k \text{ times}} \times \underbrace{V^* \otimes \cdots \otimes V^*}_{l \text{ times}} \rightarrow \mathbb{R}.$$

Every bundle ξ gives rise to a bundle $\mathcal{T}_i^k(\xi)$. Sections of $\mathcal{T}_i^k(TM)$ are called tensor fields, covariant of order k and contravariant of order l , or simply of type $\binom{k}{l}$, an abbreviation that also saves everybody embarrassment about the use of the words “covariant” and “contravariant”. Locally, a tensor field A of type $\binom{k}{l}$ can be expressed as

$$A = \sum_{\substack{i_1, \dots, i_k \\ j_1, \dots, j_l}} A_{i_1 \dots i_k}^{j_1 \dots j_l} dx^{i_1} \otimes \dots \otimes dx^{i_k} \otimes \frac{\partial}{\partial x^{j_1}} \otimes \dots \otimes \frac{\partial}{\partial x^{j_l}},$$

and if

$$A' = \sum_{\substack{i_1, \dots, i_k \\ j_1, \dots, j_l}} A'_{i_1 \dots i_k}^{j_1 \dots j_l} dx'^{i_1} \otimes \dots \otimes dx'^{i_k} \otimes \frac{\partial}{\partial x'^{j_1}} \otimes \dots \otimes \frac{\partial}{\partial x'^{j_l}},$$

then

$$(*) \quad A'_{\alpha_1 \dots \alpha_k}^{\beta_1 \dots \beta_l} = \sum_{\substack{i_1, \dots, i_k \\ j_1, \dots, j_l}} A_{i_1 \dots i_k}^{j_1 \dots j_l} \frac{\partial x^{i_1}}{\partial x'^{\alpha_1}} \dots \frac{\partial x^{i_k}}{\partial x'^{\alpha_k}} \frac{\partial x'^{\beta_1}}{\partial x^{j_1}} \dots \frac{\partial x'^{\beta_l}}{\partial x^{j_l}}.$$

Classical differential geometry books are filled with monstrosities like this equation. In fact, the classical definition of a tensor field is: an assignment of n^{k+l} functions to every coordinate system so that $(*)$ holds between the n^{k+l} functions assigned to any two coordinate systems x and x' . (!) Or even, “a set of n^{k+l} functions which changes according to $(*)$ ”. Consequently, in classical differential geometry, all important tensors are actually defined by defining the functions A_i^j , in terms of the coordinate system x , and then checking that $(*)$ holds.

Here is an important example. In every classical differential geometry book, one will find the following assertion: “The Kronecker delta δ_i^j is a tensor.” In other words, it is asserted that if one chooses the same n^2 functions δ_i^j for each coordinate system, then $(*)$ holds, i.e.,

$$\delta_\alpha^\beta = \sum_{i,j} \delta_i^j \frac{\partial x^i}{\partial x'^\alpha} \frac{\partial x'^\beta}{\partial x^j};$$

this is certainly true, for

$$\sum_{i,j} \delta_i^j \frac{\partial x^i}{\partial x'^\alpha} \frac{\partial x'^\beta}{\partial x^j} = \sum_{i=1}^n \frac{\partial x^i}{\partial x'^\alpha} \frac{\partial x'^\beta}{\partial x^i} = \delta_\alpha^\beta.$$

From our point of view, what this equation shows is that

$$A = \sum_{i,j} \delta_i^j dx^i \otimes \frac{\partial}{\partial x^j}$$

is a certain tensor field, independent of the choice of the coordinate system x . To identify the mysterious map

$$A(p): M_p \times M_p^* \rightarrow \mathbb{R},$$

we consider $v \in M_p$ and $\lambda \in M_p^*$ with the expressions

$$v = \sum_{\alpha=1}^n a^\alpha \frac{\partial}{\partial x^\alpha} \Big|_p, \quad \lambda = \sum_{\beta=1}^n b_\beta dx^\beta(p);$$

then

$$\begin{aligned} A(p)(v, \lambda) &= \sum_{i,j} \delta_i^j dx^i(p) \otimes \frac{\partial}{\partial x^j} \Big|_p (v, \lambda) \\ &= \sum_{i,j} \delta_i^j dx^i(p) \left(\sum_{\alpha=1}^n a^\alpha \frac{\partial}{\partial x^\alpha} \Big|_p \right) \cdot \frac{\partial}{\partial x^j} \Big|_p \left(\sum_{\beta=1}^n b_\beta dx^\beta(p) \right) \\ &= \sum_{i,j} \delta_i^j a^i b_j \\ &= \sum_{i=1}^n a^i b_i \\ &= \lambda(v). \end{aligned}$$

Thus $A(p)$ is just the evaluation map $M_p \times M_p^* \rightarrow \mathbb{R}$; considered as an endomorphism of M_p , it is just the identity map.

The contraction of a tensor is defined, classically, in a similar manner. Given a tensor, i.e., a collection of functions A_i^j , one for each coordinate system, satisfying

$$A'^\beta_\alpha = \sum_{i,j} A_i^j \frac{\partial x^i}{\partial x'^\alpha} \frac{\partial x'^\beta}{\partial x^j},$$

we note that

$$\begin{aligned}
 \sum_{\alpha=1}^n A'^{\alpha}_{\alpha} &= \sum_{\alpha=1}^n \left(\sum_{i,j} A_i^j \frac{\partial x^i}{\partial x'^{\alpha}} \frac{\partial x'^{\alpha}}{\partial x^j} \right) \\
 &= \sum_{i,j} A_i^j \sum_{\alpha=1}^n \frac{\partial x^i}{\partial x'^{\alpha}} \frac{\partial x'^{\alpha}}{\partial x^j} \\
 &= \sum_{i,j} A_i^j \delta_j^i \\
 &= \sum_{i=1}^n A_i^i,
 \end{aligned}$$

so that this sum is a well-defined function. This calculation tends to obscure the one part which is really necessary—verification of the fact that the trace of a linear transformation, defined as the sum of the diagonal entries of its matrix, is independent of the basis with respect to which the matrix is written.

Incidentally, a tensor of type $\binom{k}{l}$ can be contracted with respect to any pair of upper and lower indices. For example, the functions

$$B_{\mu\nu}^{\beta\gamma} = \sum_{\alpha=1}^n A_{\mu\nu\alpha}^{\alpha\beta\gamma}$$

“transform correctly” if the $A_{\mu\nu\lambda}^{\alpha\beta\gamma}$ do. If we consider each $A(p) \in \mathcal{T}_3^3(M_p)$, then we are taking $B(p) \in \mathcal{T}_2^2(M_p)$ to be

$$B(p)(v_1, v_2, \lambda_1, \lambda_2) = \text{contraction of: } (v, \lambda) \mapsto A(p)(v, v_1, v_2, \lambda_1, \lambda_2, \lambda).$$

While a contravariant vector field is classically a set of n functions which “transforms in a certain way”, a vector at a single point p is classically just an assignment of n numbers a^1, \dots, a^n to each coordinate system x , such that the numbers a'^1, \dots, a'^n assigned to x' satisfy

$$a'^j = \sum_{i=1}^n a^i \frac{\partial x'^j}{\partial x^i}(p).$$

This is *precisely* the definition we adopted when we defined tangent vectors as equivalence classes $[x, a]_p$. The revolution in the modern approach is that the set of all vectors is made into a bundle, so that vector fields can be defined as sections, rather than as equivalence classes of sets of functions, and that all other

types of tensors are constructed from this bundle. The tangent bundle itself was almost a victim of the excesses of revolutionary zeal. For a long time, the party line held that TM must be defined either as derivations, or as equivalence classes of curves; the return to the old definition was influenced by the “functorial” point of view of Theorems 3-1 and 3-4.

The modern revolt against the classical point of view has been so complete in certain quarters that some mathematicians will give a three page proof that avoids coordinates in preference to a three line proof that uses them. We won’t go quite that far, but we will give an “invariant” definition (one that does not use a coordinate system) of any tensors that are defined. Unlike the “Kronecker delta” and contractions, such invariant definitions are usually not so easy to come by. As we shall see, invariant definitions of all the important tensors in differential geometry are made by means of Theorem 2. We seldom define $A(p)$ directly; instead we define a function \mathcal{A} on vector fields, which miraculously turns out to be linear over the C^∞ functions \mathcal{F} , and hence must come from some A . At the appropriate time we will discuss whether or not this is all a big cheat.

PROBLEMS

1. Let $f: M^n \rightarrow N^m$, and suppose that (x, U) and (y, V) are coordinate systems around p and $f(p)$, respectively.

(a) If $g: N \rightarrow \mathbb{R}$, then

$$\frac{\partial(g \circ f)}{\partial x^i}(p) = \sum_{j=1}^m \frac{\partial g}{\partial y^j}(f(p)) \cdot \frac{\partial(y^j \circ f)}{\partial x^i}(p).$$

(Proposition 2-3 is the special case $f = \text{identity}$.)

(b) Show that

$$f_* \left(\frac{\partial}{\partial x^i} \Big|_p \right) = \sum_{j=1}^m \frac{\partial(y^j \circ f)}{\partial x^i}(p) \cdot \frac{\partial}{\partial y^j} \Big|_{f(p)},$$

and, more generally, express $f_* \left(\sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_p \right)$ in terms of the $\partial/\partial y^j|_{f(p)}$.

(c) Show that

$$(f^* dy^j)(p) = \sum_{i=1}^n \frac{\partial(y^j \circ f)}{\partial x^i}(p) \cdot dx^i(p).$$

(d) Express

$$f^* \left(\sum_{j_1, \dots, j_n} a_{j_1 \dots j_n} dy^{j_1} \otimes \dots \otimes dy^{j_n} \right)$$

in terms of the dx^i .

2. If $f, g: M \rightarrow N$ are C^∞ , show that

$$d(fg) = f dg + g df.$$

3. Let $f: M \rightarrow \mathbb{R}$ be C^∞ . For $v \in M_p$, show that

$$f_*(v) = df(v)_{f(p)} \in \mathbb{R}_{f(p)}.$$

4. (a) Show that if the ordered bases v_1, \dots, v_n and w_1, \dots, w_n for V are equally oriented, then the same is true of the bases v_1^*, \dots, v_n^* and w_1^*, \dots, w_n^* for V^* .

(b) Show that a bundle ξ is orientable if and only if ξ^* is orientable.

5. The following statements and problems are all taken from Eisenhart's classical work *Riemannian Geometry*. In each case, check them, using the classical methods, and then translate the problem and solution into modern terms. An "invariant" is just a (well-defined) function. Remember that the summation convention is always used, so $\lambda^i \mu_i$ means $\sum_{i=1}^n \lambda^i \mu_i$. Hints and answers are given at the end, after (xiii).

(i) If the quantity $\lambda^i \mu_i$ is an invariant and either λ^i or μ_i are the components of an arbitrary [covariant or contravariant] vector field, the other sets are components of a vector field.

(ii) If λ_{α}^i are the components of n vector fields [in an n -manifold], where i for $i = 1, \dots, n$ indicates the component and α for $\alpha = 1, \dots, n$ the vector, and these vectors are independent, that is, $\det(\lambda_{\alpha}^i) \neq 0$, then any vector-field λ^i is expressible in the form

$$\lambda^i = a^{\alpha} \lambda_{\alpha}^i,$$

where the a 's are invariants.

(iii) If μ_i are the components of a given vector-field, any vector-field λ^i satisfying $\lambda^i \mu_i = 0$ is expressible linearly in terms of $n - 1$ independent vector fields λ_{α}^i for $\alpha = 1, \dots, n - 1$ which satisfy the equation.

(iv) If $a^{ij} = a^{ji}$ for the components of a tensor field in one coordinate system, then $a'^{ij} = a'^{ji}$ for the coordinates in any other coordinate system.

(v) If a^{ij} and b^{ij} are components of a tensor field, so are $a^{ij} + b^{ij}$. If a^{ij} and b_{kl} are components of a tensor field, so are $a^{ij} b_{kl}$.

(vi) If $a_{ij} \lambda^i \lambda^j$ is an invariant for λ^i an arbitrary vector, then $a_{ij} + a_{ji}$ are the components of a tensor; in particular, if $a_{ij} \lambda^i \lambda^j = 0$, then $a_{ij} + a_{ji} = 0$.

(vii) If $a_{ij} \lambda^i \lambda^j = 0$ for all vectors λ^i such that $\lambda^i \mu_i = 0$, where μ_i is a given covariant vector, if v^i is defined [c.f. (iii)] by $a_{ij} \lambda_{\alpha}^i v^j = 0$, $\alpha = 1, \dots, n - 1$ and $\mu_i v^i \neq 0$, and by definition

$$a_{ij} v^i = \sigma_j \quad v^i \mu_i = \tau,$$

then $(a_{ij} - \frac{1}{\tau} \mu_i \sigma_j) \xi^i \xi^j = 0$ is satisfied by every vector field ξ^i , and consequently

$$a_{ij} + a_{ji} = \frac{1}{\tau} (\mu_i \sigma_j + \mu_j \sigma_i).$$

(viii) If a_{rs} are the components of a tensor and b and c are invariants, show that if $ba_{rs} + ca_{sr} = 0$, then either $b = -c$ and a_{rs} is symmetric, or $b = c$ and a_{rs} is skew-symmetric.

(ix) By definition the *rank* of a tensor of the second order a_{ij} is the rank of the matrix (a_{ij}) . Show that the rank is invariant under all transformations of coordinates.

(x) Show that the rank of the tensor of components $a_i b_j$, where a_i and b_j are the components of two vectors, is one; show that for the symmetric tensor $a_i b_j + a_j b_i$ the rank is two.

(xi) Show that the tensor equation $a^i_j \lambda_i = \alpha \lambda_j$, where α is an invariant, can be written in the form $(a^i_j - \alpha \delta^i_j) \lambda_i = 0$. Show also that $a^i_j = \delta^i_j \alpha$, if the equation is to hold for an arbitrary vector λ_i .

(xii) If $a^i_j \lambda_i = \alpha \lambda_j$ holds for all vectors λ_i such that $\mu^i \lambda_i = 0$, where μ^i is a given vector, then

$$a^i_j = \alpha \delta^i_j + \sigma_j \mu^i.$$

(xiii) If

$$\delta_{i_1 \dots i_p}^{j_1 \dots j_p} = \begin{cases} 0 & \text{if } j_\alpha = j_\beta \text{ for some } \alpha \neq \beta \text{ or } i_\alpha = i_\beta \text{ for some } \alpha \neq \beta \\ & \text{or if } \{j_1, \dots, j_p\} \neq \{i_1, \dots, i_p\} \\ 1 & \text{if } j_1, \dots, j_p \text{ is an even permutation of } i_1, \dots, i_p \\ -1 & \text{if } j_1, \dots, j_p \text{ is an odd permutation of } i_1, \dots, i_p \end{cases}$$

then $\delta_{i_1 \dots i_p}^{j_1 \dots j_p}$ are the components of a tensor in all coordinate systems.

HINTS AND ANSWERS.

(i) ω is determined if $\omega(X)$ is known for all X , and *vice versa*.

(iii) Given ω [with $\omega(p) \neq 0$ for all p], there are everywhere linearly independent vector fields X_1, \dots, X_{n-1} which span $\ker \omega$ at each point. (This is true only locally. For example, on $S^2 \times \mathbb{R}$ there is an ω such that $\ker \omega(p, t)$ consists of vectors tangent to $S^2 \times \{t\}$.)

(vi) For $T: V \times V \rightarrow \mathbb{R}$, let $T'(v, w) = T(w, v)$. Then $T + T'$ is determined by $S(v) = T(v, v)$. For, $T(v + w, v + w) = T(v, v) + T(v, w) + T(w, v) + T(w, w)$. Similarly, $T(v, v) = 0$ for all v implies that $T + T' = 0$.

(vii) Given ω [with $\omega(p) \neq 0$ for all p], choose Y complementary to $\ker \omega$ at all points. If $\sigma(Z) = T(Y, Z)$, then $T(Z, Z) = \omega(Z)\sigma(Z)/\omega(Y)$ for all vector fields Z .

(ix) $T: V \times V \rightarrow \mathbb{R}$ corresponds to $\bar{T}: V \rightarrow V^*$ [where $\bar{T}(v)(w) = T(v, w)$]. The rank of T may be defined as the rank of \bar{T} (consider the matrix of \bar{T} with respect to bases v_1, \dots, v_n and v^*_1, \dots, v^*_n).

(xii) Let $V = M_p^*$. If $T: V \rightarrow V$ and $\mu \in V^*$ and $T(v) = \alpha v$ for all $v \in \ker \mu$, there is a y complementary to $\ker \mu$ such that

$$T(v) = \alpha v + \mu(v)y \quad \text{for all } v.$$

(Begin by choosing y_0 complementary to $\ker \mu$ and writing v uniquely as $v_0 + cy_0$ for $v_0 \in \ker \mu$.)

(xiii) Define

$$\delta: \underbrace{V \times \cdots \times V}_p \times \underbrace{V^* \times \cdots \times V^*}_p \rightarrow \mathbb{R}$$

by

$$\delta(v_1, \dots, v_p, \lambda_1, \dots, \lambda_p) = \det(\lambda_i(v_j)).$$

6. (a) Let $i_V: V \rightarrow V^{**}$ be the “natural isomorphism” $i_V(v)(\lambda) = \lambda(v)$. Show that for any linear transformation $f: V \rightarrow W$, the following diagram commutes:

$$\begin{array}{ccc} V & \xrightarrow{i_V} & V^{**} \\ f \downarrow & & \downarrow f^{**} \\ W & \xrightarrow{i_W} & W^{**} \end{array}$$

(b) Show that there do *not* exist isomorphisms $i_V: V \rightarrow V^*$ such that the following diagram always commutes.

$$\begin{array}{ccc} V & \xrightarrow{i_V} & V^* \\ f \downarrow & & \uparrow f^* \\ W & \xrightarrow{i_W} & W^* \end{array}$$

Hint: There does not even exist an isomorphism $i: \mathbb{R} \rightarrow \mathbb{R}^*$ which makes the diagram commute for all linear $f: \mathbb{R} \rightarrow \mathbb{R}$.

7. A *covariant functor* from (finite dimensional) vector spaces to vector spaces is a function F which assigns to every vector space V a vector space $F(V)$ and to every linear transformation $f: V \rightarrow W$ a linear transformation $F(f): F(V) \rightarrow F(W)$, such that $F(1_V) = 1_{F(V)}$ and $F(g \circ f) = F(g) \circ F(f)$.

- (a) The “identity functor”, $F(V) = V$, $F(f) = f$ is a functor.
- (b) The “double dual functor”, $F(V) = V^{**}$, $F(f) = f^{**}$ is a functor.
- (c) The “ \mathcal{T}_k functor”, $F(V) = \mathcal{T}_k(V) = \mathcal{T}^k(V^*)$,

$$F(f)(T)(\lambda_1, \dots, \lambda_k) = T(\lambda_1 \circ f, \dots, \lambda_k \circ f)$$

is a functor.

(d) If F is any functor and $f: V \rightarrow W$ is an isomorphism, then $F(f)$ is an isomorphism.

A *contravariant functor* is defined similarly, except that $F(f): F(W) \rightarrow F(V)$ and $F(g \circ f) = F(f) \circ F(g)$. Functors of more than one argument, covariant in some and contravariant in others, may also be defined.

- (e) The “dual functor”, $F(V) = V^*$, $F(f) = f^*$ is a contravariant functor.
- (f) The “ \mathcal{T}^k functor”, $F(V) = \mathcal{T}^k(V)$, $F(f) = f^*$ is a contravariant functor.

8. (a) Let $\text{Hom}(V, W)$ denote all linear transformations from V to W . Choosing a basis for V and W , we can identify $\text{Hom}(V, W)$ with the $m \times n$ matrices, and consequently give it the metric of \mathbb{R}^{nm} . Show that a different choice of bases leads to a homeomorphic metric on $\text{Hom}(V, W)$.

(b) A functor F gives a map from $\text{Hom}(V, W)$ to $\text{Hom}(F(V), F(W))$. Call F *continuous* if this map is always continuous [using the metric in part (a)]. Show that if $\xi = \pi: E \rightarrow B$ is any vector bundle, and F is continuous, then there is a bundle $F(\xi) = \pi': E' \rightarrow B$ for which $\pi'^{-1}(p) = F(\pi^{-1}(p))$, and such that to every trivialization

$$t: \pi^{-1}(U) \rightarrow U \times \mathbb{R}^n$$

corresponds a trivialization

$$t': \pi'^{-1}(U) \rightarrow U \times F(\mathbb{R}^n).$$

(c) The functor $\mathcal{T}_1(V) = \mathcal{T}^1(V^*) = V^{**}$ is continuous. (The bundle $\mathcal{T}_1(TM)$ is just a case of the construction in (b).)

(d) Define a continuous contravariant functor F , and show how to construct a bundle $F(\xi)$.

(e) The functor $F(V) = V^*$ is continuous. (The bundle T^*M is a special case of the construction in (d).)

Generally, the same construction can be used when F is a functor of several arguments. The bundles $\mathcal{T}_i^k(M)$ are all special cases. See the next two problems for other examples, as well as an example of a functor which is not continuous.

9. (a) Let F be a functor from \mathbf{V}^n , the class of n -dimensional vector spaces, to \mathbf{V}^k . Given $A \in \text{GL}(n, \mathbb{R})$ we can consider it as a map $A: \mathbb{R}^n \rightarrow \mathbb{R}^n$. Then $F(A): F(\mathbb{R}^n) \rightarrow F(\mathbb{R}^n)$. Choose, once and for all, an isomorphism $F(\mathbb{R}^n) \rightarrow \mathbb{R}^k$. Then $F(A)$ can be considered as a map $h(A): \mathbb{R}^k \rightarrow \mathbb{R}^k$. Show that $h: \text{GL}(n, \mathbb{R}) \rightarrow \text{GL}(k, \mathbb{R})$ is a homomorphism.

(b) How does the homomorphism h depend on the initial choice of the isomorphism $F(\mathbb{R}^n) \rightarrow \mathbb{R}^k$?

(c) Let $\mathbf{v} = (v_1, \dots, v_n)$ and $\mathbf{w} = (w_1, \dots, w_n)$ be ordered bases of V and let $\mathbf{e} = (e_1, \dots, e_n)$ be the standard basis of \mathbb{R}^n . If $\mathbf{e} \rightarrow \mathbf{v}$ denotes the isomorphism taking e_i to v_i , show that the following diagram commutes

$$\begin{array}{ccc} \mathbb{R}^n & \xrightarrow{\mathbf{e} \rightarrow \mathbf{v}} & V \\ A \uparrow & \nearrow \mathbf{e} \rightarrow \mathbf{w} & \\ \mathbb{R}^n & & \end{array} ,$$

where $A = (a_{ij})$ is defined by

$$w_i = \sum_{j=1}^n a_{ji} v_j.$$

After identifying $F(\mathbb{R}^n)$ with \mathbb{R}^k , this means that

$$\begin{array}{ccc} \mathbb{R}^k & \xrightarrow{F(\mathbf{e} \rightarrow \mathbf{v})} & F(V) \\ h(A) \uparrow & \nearrow F(\mathbf{e} \rightarrow \mathbf{w}) & \\ \mathbb{R}^k & & \end{array}$$

also commutes. This suggests a way of proving the following.

THEOREM. If $h: \text{GL}(n, \mathbb{R}) \rightarrow \text{GL}(k, \mathbb{R})$ is any homomorphism, there is a functor $F_h: \mathbf{V}^n \rightarrow \mathbf{V}^k$ such that the homomorphism defined in part (a) is equal to h .

(d) For $q, q' \in \mathbb{R}^k$, define

$$(\mathbf{v}, q) \sim (\mathbf{w}, q')$$

if $q = h(A)q'$ where $w_i = \sum_{j=1}^n a_{ji} v_j$. Show that \sim is an equivalence relation, and that every equivalence class contains exactly one element (\mathbf{v}, q) for a given \mathbf{v} . We will denote the equivalence class of (\mathbf{v}, q) by $[\mathbf{v}, q]$.

(e) Show that the operations

$$\begin{aligned} [\mathbf{v}, q_1] + [\mathbf{v}, q_2] &= [\mathbf{v}, q_1 + q_2] \\ a \cdot [\mathbf{v}, q] &= [\mathbf{v}, aq] \end{aligned}$$

are well-defined operations making the set of all equivalence classes into a k -dimensional vector space $F_h(V)$.

(f) If $V, W \in \mathbf{V}^n$ and $f: V \rightarrow W$, choose ordered bases \mathbf{v}, \mathbf{w} , define A by $f(v_i) = \sum_{j=1}^n a_{ji} w_j$, and define

$$F_h(f)[\mathbf{v}, q] = [\mathbf{w}, h(A)(q)].$$

Show that this is a well-defined linear transformation, that F_h is a functor, and that $F_h(A) = h(A)$ when we identify $F_h(\mathbb{R}^n)$ with \mathbb{R}^k by $[\mathbf{e}, q] \mapsto q$.

(g) Let $\alpha: \mathbb{R} \rightarrow \mathbb{R}$ be a non-continuous homomorphism (compare page 380), and let $h: \text{GL}(n, \mathbb{R}) \rightarrow \text{GL}(1, \mathbb{R}) = \mathbb{R}$ be $h(A) = \alpha(\det A)$. Then $F_h: \mathbf{V}^n \rightarrow \mathbf{V}^1$ is a non-continuous functor.

10. In classical tensor analysis there are, in addition to mixed tensor fields, other “quantities” which are defined as sets of functions which transform according to yet other rules. These new rules are of the form

$$A' = A \text{ operated on by } h \left(\frac{\partial x^\alpha}{\partial x'^\beta} \right).$$

For example, assignments of a single function a to each coordinate system x such that the function a' assigned to x' satisfies

$$a' = \det \left(\frac{\partial x^i}{\partial x'^j} \right) \cdot a$$

are called (even) scalar densities; assignments for which

$$a' = \left| \det \left(\frac{\partial x^i}{\partial x'^j} \right) \right| \cdot a$$

are called odd scalar densities. The Theorem in Problem 9 allows us to construct a bundle whose sections correspond to these classical entities (later we will have a more illuminating way):

(a) Let $h: \text{GL}(n, \mathbb{R}) \rightarrow \text{GL}(1, \mathbb{R})$ take A into multiplication by $\det A$. Let F_h be the functor given by the Theorem, and consider the 1-dimensional bundle $F_h(TM)$ obtained by replacing each fibre M_p with $F_h(M_p)$. If (x, U) is a coordinate system, then

$$\alpha_x(p) = \left[\left(\frac{\partial}{\partial x^1} \Big|_p, \dots, \frac{\partial}{\partial x^n} \Big|_p \right), 1 \right] \in F_h(M_p)$$

is non-zero, so every section on U can be expressed as $a \cdot \alpha_x$ for a unique function a . If x' is another coordinate system and $a \cdot \alpha_x = a' \cdot \alpha_{x'}$, show that

$$a' = \det \left(\frac{\partial x^i}{\partial x'^j} \right) \cdot a.$$

(b) If, instead, h takes A into multiplication by $|\det A|$, show that the corresponding equation is

$$a' = \left| \det \left(\frac{\partial x^i}{\partial x'^j} \right) \right| \cdot a.$$

(c) For this h , show that a non-zero element of $F_h(V)$ determines an orientation for V . Conclude that the bundle of odd scalar densities is *not* trivial if M is not orientable.

(d) We can identify $\mathcal{T}_l^k(\mathbb{R}^n)$ with $\mathbb{R}^{n^{k+l}}$ by taking

$$e^*_{i_1} \otimes \cdots \otimes e^*_{i_k} \otimes e_{j_1} \otimes \cdots \otimes e_{j_l} \mapsto (i_1, \dots, i_k, j_1, \dots, j_l)^{\text{th}} \text{ basis vector of } \mathbb{R}^{n^{k+l}}.$$

Recall that if $f: V \rightarrow V$, we define $\mathcal{T}_l^k(f): \mathcal{T}_l^k(V) \rightarrow \mathcal{T}_l^k(V)$ by

$$\mathcal{T}_l^k(f)(T)(v_1, \dots, v_k, \lambda_1, \dots, \lambda_l) = T(f(v_1), \dots, f(v_k), \lambda_1 \circ f, \dots, \lambda_l \circ f).$$

Given $A \in \text{GL}(n, \mathbb{R})$, we can consider it as a map $A: \mathbb{R}^n \rightarrow \mathbb{R}^n$. Then $\mathcal{T}_l^k(A): \mathcal{T}_l^k(\mathbb{R}^n) \rightarrow \mathcal{T}_l^k(\mathbb{R}^n)$ determines an element $\mathcal{T}_l^k(A)$ of $\text{GL}(n^{k+l}, \mathbb{R})$. Let $h: \text{GL}(n, \mathbb{R}) \rightarrow \text{GL}(n^{k+l}, \mathbb{R})$ be defined by

$$h(A) = (\det A)^w \mathcal{T}_l^k(A) \quad w \text{ an integer.}$$

The bundle $F(TM)$ is called the bundle of (even) relative tensors of type $\binom{k}{l}$ and weight w . For $k = l = 0$ we obtain the bundle of (even) relative scalars of weight w [the (even) scalar densities are the (even) relative scalars of weight 1]. If $(\det A)^w$ is replaced by $|\det A|^w$ (w any real number), we obtain the bundle of odd relative tensors of type $\binom{k}{l}$ and weight w . Show that the transformation law for the components of sections of these bundles is

$$A'^{\beta_1 \dots \beta_l}_{\alpha_1 \dots \alpha_k} = \left[\det \left(\frac{\partial x^i}{\partial x'^j} \right) \right]^w \sum_{\substack{i_1, \dots, i_k \\ j_1, \dots, j_l}} A^{j_1 \dots j_l}_{i_1 \dots i_k} \frac{\partial x^{i_1}}{\partial x'^{\alpha_1}} \cdots \frac{\partial x^{i_k}}{\partial x'^{\alpha_k}} \frac{\partial x'^{\beta_1}}{\partial x^{j_1}} \cdots \frac{\partial x'^{\beta_l}}{\partial x^{j_l}}$$

(or the same formula with $\det(\partial x^i / \partial x'^j)$ replaced by $|\det(\partial x^i / \partial x'^j)|$).

(e) Define

$$\varepsilon_{i_1 \dots i_n} = \begin{cases} +1 & \text{if } i_1, \dots, i_n \text{ is an even permutation of } 1, \dots, n \\ -1 & \text{if } i_1, \dots, i_n \text{ is an odd permutation of } 1, \dots, n \\ 0 & \text{if } i_\alpha = i_\beta \text{ for some } \alpha \neq \beta. \end{cases}$$

Show that there is a covariant relative tensor of weight -1 with these components in every coordinate system. Also show that $\varepsilon^{i_1 \dots i_n} = \varepsilon_{i_1 \dots i_n}$ are the components in every coordinate system of a certain contravariant relative tensor of weight 1. (See Problem 7-12 for a geometric interpretation of these relative tensors.)

CHAPTER 5

VECTOR FIELDS AND DIFFERENTIAL EQUATIONS

We return to a more detailed study of the tangent bundle TM , and its sections, i.e., vector fields. Let X be a vector field defined in a neighborhood of $p \in M$. We would like to know if there is a curve $\rho: (-\varepsilon, \varepsilon) \rightarrow M$ through p whose tangent vectors coincide with X , that is, a curve ρ with

$$\begin{aligned}\rho(0) &= p \\ \rho_* \left(\frac{d}{dt} \Big|_t \right) &= \frac{d\rho}{dt} \Big|_t = X(\rho(t)).\end{aligned}$$

Since this is a local question, we wish to introduce a coordinate system (x, U) around p and transfer the vector field X to $x(U) \subset \mathbb{R}^n$. Recall that, in general, $\alpha_* X$ does not make sense for C^∞ functions $\alpha: M \rightarrow N$. However, if α is a diffeomorphism, then we define

$$(\alpha_* X)_q = \alpha_* (X_{\alpha^{-1}(q)}) \quad [\text{i.e., } = \alpha_{*\alpha^{-1}(q)}(X_{\alpha^{-1}(q)})].$$

It is not hard to check (Problem 1) that $\alpha_* X$ is C^∞ on $\alpha(M)$. In particular, we have a vector field $x_* X$ on $x(U) \subset \mathbb{R}^n$. There is a function $f: x(U) \rightarrow \mathbb{R}^n$ with

$$(x_* X)_q = f(q)_q \in \mathbb{R}^n_q,$$

i.e., $(x_* X)_q$ has “components” $f^1(q), \dots, f^n(q)$. Consider the curve $c = x \circ \rho$. The condition

$$\frac{d\rho}{dt} = X(\rho(t))$$

means that

$$\rho_* \left(\frac{d}{dt} \Big|_t \right) = X(\rho(t));$$

hence

$$\begin{aligned}\left.\frac{dc}{dt}\right|_t &= x_*\rho_*\left(\left.\frac{d}{dt}\right|_t\right) = x_*(X(\rho(t))) = (x_*X)_{x(\rho(t))} \\ &= (x_*X)_{c(t)}.\end{aligned}$$

If we use $c'(t)$ to denote the ordinary derivative of the \mathbb{R}^n -valued function c , then this equation finally becomes simply

$$c'(t) = f(c(t)).$$

This is a simple example of a differential equation for a function $c: \mathbb{R} \rightarrow \mathbb{R}^n$, which may also be considered as a system of n differential equations for the functions c^i ,

$$c^{i'}(t) = f^i(c^1(t), \dots, c^n(t)) \quad i = 1, \dots, n.$$

We also want the “initial conditions”

$$c^i(0) = x^i(p).$$

Solving a differential equation used to be described as “integrating” the equation (the process is integration when the equation has the special form $c'(t) = f(t)$ for $f: \mathbb{R} \rightarrow \mathbb{R}$, a form to which our particular equations never reduce); solutions were consequently called “integrals” of the equation. Part of this terminology is still preserved. A curve $\rho: (-\varepsilon, \varepsilon) \rightarrow M$ with

$$\begin{aligned}\rho(0) &= p \\ \frac{d\rho}{dt} &= X(\rho(t))\end{aligned}$$

is called an **integral curve** for X with **initial condition** $\rho(0) = p$. Similar terminology is applied, of course, to the differential equations one obtains upon introducing a coordinate system. For quite some time, we will work entirely in Euclidean space, and for a while x, y , etc., will denote points of \mathbb{R}^n . If $U \subset \mathbb{R}^n$ is open and $f: U \rightarrow \mathbb{R}^n$, then a curve $c: (-\varepsilon, \varepsilon) \rightarrow M$ with

$$\begin{aligned}c(0) &= x & x &\in U \\ c'(t) &= f(c(t))\end{aligned}$$

is called an **integral curve** for f with **initial condition** $c(0) = x$.

Before stating the main theorem about the existence and uniqueness of such integral curves, we consider some special cases.

The equation for a curve c with range \mathbb{R} ,

$$c'(t) = -[c(t)]^2,$$

which would be written classically in terms of a function $y: \mathbb{R} \rightarrow \mathbb{R}$ as

$$\frac{dy}{dx} = -y^2,$$

is the special case $f(a) = -a^2$. The standard method of solving this equation is to write

$$\begin{aligned}\frac{dy}{-y^2} &= dx \\ \int \frac{dy}{-y^2} &= \int dx \\ \frac{1}{y} &= x + C \\ y &= \frac{1}{x + C}.\end{aligned}$$

Thus the curves

$$c(t) = \frac{1}{t + C}$$

are supposed to be solutions. This can be checked directly if you don't believe the above manipulations. (They really do make sense; the equation in question asserts that $y' = f \circ y$, so

$$\left(\frac{1}{f} \circ y\right) \cdot y' = 1;$$

hence, if $F' = 1/f$, then

$$\begin{aligned}(F \circ y)' &= 1 \\ F(y(x)) &= x + C\end{aligned}$$

for some C .) To obtain the initial conditions $c(0) = a$, we must take

$$c(t) = \frac{1}{t + 1/a}.$$

This works in all cases except $a = 0$. In this case, the correct solution is

$$c(t) = 0 \quad \text{for all } t$$

(which we missed by dividing by y). In terms of vector fields, the curves c are the integral curves of

$$X(a) = -a^2 \frac{d}{dt}.$$

Notice that no integral curve, except $c(t) = 0$, can be defined for all t , even though X is defined on all of \mathbb{R} . It might be thought that this somehow reflects the fact that $X(0) = 0$, but this has nothing to do with the case. For $a > 0$, the curve $c(t) = 1/(t + 1/a)$ is defined for all large t , and as $t \rightarrow \infty$ it approaches, but never reaches, 0. On the other hand, as $t \rightarrow -1/a$ the curve escapes to infinity because the vector field gets big too fast. This will continue to be true even if we modify the vector field near 0 so that it is never 0.

Another phenomenon is illustrated by the equation

$$c'(t) = c(t)^{2/3},$$

written classically as

$$\frac{dy}{dx} = y^{2/3}.$$

There are two different solutions with the initial condition $c(0) = 0$, namely

- (1) $c(t) = 0$ for all t ,
- (2) $c(t) = \frac{1}{27}t^3$ for all t .

In this case, the function f , given by $f(a) = a^{2/3}$, is *not* differentiable. Uniqueness will always be insured when $f: U \rightarrow \mathbb{R}^n$ is C^1 , but it can also be obtained with a rather less stringent condition. We say that the function f satisfies a **Lipschitz condition** on U if there is some K such that

$$|f(x) - f(y)| \leq K|x - y| \quad \text{for all } x, y \in U.$$

Notice that $f(a) = a^{2/3}$ is not Lipschitz; in fact, there is no K with

$$|f(x) - f(0)| \leq K|x|$$

for x near 0, since

$$\frac{x^{2/3}}{x} = x^{-1/3} \rightarrow \pm\infty \quad \text{as } x \rightarrow 0^\pm.$$

A Lipschitz function is clearly continuous, but not necessarily differentiable (for example, $f(x) = |x|$). On the other hand, a C^1 function is locally Lipschitz, that is, it satisfies a Lipschitz condition in a neighborhood of each point—this follows from Lemma 2-5. A Lipschitz function is also clearly bounded on any bounded set.

The basic existence and uniqueness theorem for differential equations depends on a simple lemma about complete metric spaces.

1. THEOREM (THE CONTRACTION LEMMA). Let (M, ρ) be a non-empty complete metric space, and let $f: M \rightarrow M$ be a “contraction”, that is, suppose there is some $C < 1$ such that

$$\rho(f(x), f(y)) \leq C\rho(x, y) \quad \text{for all } x, y \in M.$$

Then there is a unique $x \in M$ such that $f(x) = x$ (the function f has a unique “fixed point”).

PROOF. Notice that f is clearly continuous. Let $x_0 \in M$ and define a sequence $\{x_n\}$ inductively by

$$x_{n+1} = f(x_n),$$

i.e.,

$$x_{n+1} = f^n(x_0) = \underbrace{f \circ f \circ \cdots \circ f}_{n \text{ times}}(x_0).$$

Then an easy induction argument shows that

$$\rho(x_n, x_{n+1}) \leq C^n \rho(x_0, x_1).$$

Thus

$$\begin{aligned} \rho(x_n, x_{n+k}) &\leq \rho(x_n, x_{n+1}) + \cdots + \rho(x_{n+k-1}, x_{n+k}) \\ &\leq (C^n + \cdots + C^{n+k-1})\rho(x_0, x_1). \end{aligned}$$

Since $C < 1$, the sum $\sum_{n=0}^{\infty} C^n$ converges, so $C^n + \cdots + C^{n+k-1} \rightarrow 0$ as $n \rightarrow \infty$. Thus the sequence $\{x_n\}$ is Cauchy, so there is some x with

$$x = \lim_{n \rightarrow \infty} x_n.$$

Continuity of f then shows that

$$f(x) = \lim_{n \rightarrow \infty} f(x_n) = \lim_{n \rightarrow \infty} x_{n+1} = x. \quad \spadesuit$$

We are going to apply the Contraction Lemma to certain spaces of functions. Recall that if (M, ρ) is a metric space and X is compact, then the set of all continuous functions $f: X \rightarrow M$ is a metric space if we define the metric σ by

$$\sigma(f, g) = \sup_{x \in X} \rho(f(x), g(x)).$$

If M is bounded, then we do not even need X to be compact. Moreover, if M is complete, then the new metric space is also complete; this is basically just the theorem that the uniform limit of continuous functions is continuous, plus the fact that each $\lim_{x \rightarrow \infty} f_n(x)$ exists since M is complete. In particular, if M is a compact subset of \mathbb{R}^n , then the set of all continuous functions $f: X \rightarrow M$ is complete with the metric

$$\sigma(f, g) = \|f - g\|, \quad \text{where } \|f\| = \sup_{x \in X} |f(x)|.$$

Our basic strategy in solving differential equations will be to replace differentiable functions and derivatives by continuous functions and integrals. If $U \subset \mathbb{R}^n$ and $f: U \rightarrow \mathbb{R}^n$ is continuous, then a continuous function $\alpha: (-b, b) \rightarrow U$, defined on some interval around 0, clearly satisfies

$$(1) \quad \begin{aligned} \alpha'(t) &= f(\alpha(t)) \\ \alpha(0) &= x \end{aligned}$$

if it satisfies the integral equation

$$(2) \quad \alpha(t) = x + \int_0^t f(\alpha(u)) du,$$

where the integral of an \mathbb{R}^n -valued function is defined by integrating each component function separately. Conversely, if α satisfies (1), then α is differentiable, hence continuous; thus $\alpha' = f \circ \alpha$ is continuous, so

$$\alpha(t) - x = \alpha(t) - \alpha(0) = \int_0^t \alpha'(u) du = \int_0^t f(\alpha(u)) du.$$

For the proof of the basic theorem, we need only one simple estimate. If a continuous function $f: [a, b] \rightarrow \mathbb{R}^n$ satisfies $|f| \leq K$, then

$$\left| \int_a^b f(u) du \right| \leq K(b - a).$$

To prove this, we note that it is true for constant functions, hence for step functions, and thus for continuous functions, which are uniform limits on $[a, b]$ of step functions.

2. THEOREM. Let $f: U \rightarrow \mathbb{R}^n$ be any function, where $U \subset \mathbb{R}^n$ is open. Let $x_0 \in U$ and let $a > 0$ be a number such that the closed ball $\bar{B}_{2a}(x_0)$, of radius $2a$ and center x_0 , is contained in U . Suppose that

$$(1) |f| \leq L \text{ on } \bar{B}_{2a}(x_0)$$

$$(2) |f(x) - f(y)| \leq K|x - y| \text{ for } x, y \in \bar{B}_{2a}(x_0).$$

Choose $b > 0$ so that

$$(3) b \leq a/L$$

$$(4) b < 1/K.$$

Then for each $x \in \bar{B}_a(x_0)$ there is a unique $\alpha_x: (-b, b) \rightarrow U$ such that

$$\alpha_x'(t) = f(\alpha_x(t))$$

$$\alpha_x(0) = x.$$

PROOF. Choose $x \in \bar{B}_a(x_0)$, which will be fixed for the remainder of the proof. Let

$$M = \{\text{continuous } \alpha: (-b, b) \rightarrow \bar{B}_{2a}(x_0)\}.$$

Then M is a complete metric space. For each $\alpha \in M$, define a curve $S\alpha$ on $(-b, b)$ by

$$S\alpha(t) = x + \int_0^t f(\alpha(u)) du$$

(the integral exists since f is continuous on $\bar{B}_{2a}(x_0)$). The curve $S\alpha$ is clearly continuous. Moreover, for any $t \in (-b, b)$ we have

$$\begin{aligned} |S\alpha(t) - x| &= \left| \int_0^t f(\alpha(u)) du \right| \\ &< bL \quad \text{by (1)} \\ &\leq a \quad \text{by (3).} \end{aligned}$$

Since $|x - x_0| \leq a$, it follows that $|S\alpha(t) - x_0| < 2a$, for all $t \in (-b, b)$, so

$$(*) \quad S\alpha(t) \in B_{2a}(x_0) \subset \bar{B}_{2a}(x_0) \quad \text{for } t \in (-b, b).$$

Thus $S: M \rightarrow M$.

Now suppose $\alpha, \beta \in M$. Then

$$\begin{aligned} \|S\alpha - S\beta\| &= \sup_t \left| \int_0^t f(\alpha(u)) - f(\beta(u)) du \right| \\ &< bK \sup_{-b < u < b} |\alpha(u) - \beta(u)| \quad \text{by (2)} \\ &= bK\|\alpha - \beta\|. \end{aligned}$$

Since we chose $bK < 1$ (by (4)), this shows that $S: M \rightarrow M$ is a contraction. Hence S has a unique fixed point:

There is a unique $\alpha: (-b, b) \rightarrow \bar{B}_{2a}(x_0)$ with

$$\alpha(t) = x + \int_0^t f(\alpha(u)) du.$$

This, alas, is not quite what the theorem states. Having used the elegant Contraction Lemma, we pay for it by finishing off with a finicky detail:

The map α is the unique $\beta: (-b, b) \rightarrow U$ satisfying

$$\beta(t) = x + \int_0^t f(\beta(u)) du.$$

Reason: We claim that any such β actually lies in $\bar{B}_{2a}(x_0)$, in fact, in $B_{2a}(x_0)$. Consider first numbers $t > 0$. We have already seen (statement (*)) that for each t with $0 \leq t < b$,

$$(**) \quad \beta(t) = x + \int_0^t f(\beta(u)) du \quad \text{is in } B_{2a}(x_0) \quad [\text{the open ball}]$$

provided that

$$\beta(u) \in \bar{B}_{2a}(x_0) \quad \text{for all } u \text{ with } 0 \leq u < t,$$

so certainly if

$$\beta(u) \in B_{2a}(x_0) \quad \text{for all } u \text{ with } 0 \leq u \leq t.$$

We can now use a simple least upper bound argument. Let

$$A = \{t : 0 \leq t < b \text{ and } \beta(u) \in B_{2a}(x_0) \text{ for } 0 \leq u < t\}.$$

Let $\alpha = \sup A$. Suppose $\alpha < b$. We clearly have $\beta(u) \in B_{2a}(x_0)$ for $0 \leq u < \alpha$. So $\beta(\alpha) \in B_{2a}(x_0)$, by (**). This clearly implies that $\beta(\alpha + s) \in B_{2a}(x_0)$ for sufficiently small $s > 0$, which contradicts the fact that $\alpha = \sup A$. So it must be that $\sup A = b$. A similar argument works for $-b < t \leq 0$.

To sum up, the unique fixed point α_x of the map S is the unique curve with the desired properties. ♦

Notice that solutions of the differential equation

$$\alpha'(t) = f(\alpha(t))$$

remain solutions under additive changes of parameter; that is, if

$$\beta(t) = \alpha(t_0 + t),$$

then

$$\beta'(t) = \alpha'(t_0 + t) = f(\alpha(t_0 + t)) = f(\beta(t)).$$

This remark allows us to extend the uniqueness part of Theorem 2.

3. THEOREM. Suppose $f: U \rightarrow \mathbb{R}^n$ is locally Lipschitz, that is, around each point there is a ball on which f satisfies condition (2) of Theorem 2 for some K (and hence also condition (1) for some L). Let $x \in U$ and let α_1, α_2 be two maps on some open interval I with $\alpha_1(I), \alpha_2(I) \subset U$ and

$$\begin{aligned} \alpha_i'(t) &= f(\alpha_i(t)) \\ \alpha_i(0) &= x \end{aligned} \quad i = 1, 2.$$

Then $\alpha_1 = \alpha_2$ on I .

PROOF. Suppose $\alpha_1(t_0) = \alpha_2(t_0)$ for some $t_0 \in I$. If we define

$$\beta_i(t) = \alpha_i(t_0 + t),$$

then the functions β_i satisfy the same differential equation, $\beta_i'(t) = f(\beta_i(t))$, and have the same initial condition $\beta_i(0) = \alpha_1(t_0) = \alpha_2(t_0) \in U$. Hence $\beta_1(t) = \beta_2(t)$ for sufficiently small t , by Theorem 1. Thus the set

$$\{t \in I : \alpha_1(t) = \alpha_2(t)\}$$

is open. It is clearly also closed and non-empty, so it equals I . ♦

We now revert to the situation in Theorem 2. We will write $\alpha_x(t)$ as $\alpha(t, x)$, so that we have a map

$$\alpha: (-b, b) \times B_a(x_0) \rightarrow U$$

satisfying

$$\begin{aligned} \alpha(0, x) &= x \\ \frac{d}{dt}\alpha(t, x) &= f(\alpha(t, x)) \end{aligned}$$

[i.e., $D_1\alpha(t, x) = f(\alpha(t, x))$], but we will frequently use $\partial/\partial t$ or d/dt in this

discussion]. This map α is called a local flow for f in $(-b, b) \times B_a(x_0)$. To picture this map α , the best we can do is to draw the images of the integral

curves α_x . If $y = \alpha_x(t_0)$, then the integral curve α_x with the initial condition $\alpha_x(0) = x$ differs from the integral curve α_y with initial condition $\alpha_y(0) = y$ only by a change of parameter, so the two images overlap. For each fixed x , the map $t \mapsto \alpha(t, x)$ for $-b < t < b$ lies along *part* of the curve through x . On the other hand, if we fix t , then the map

$$x \mapsto \alpha(t, x)$$

gives the result of pushing each x along the integral curve through it, for a time interval of t . To focus attention on this map, we denote it by ϕ_t :

$$\phi_t(x) = \alpha(t, x) \quad [= \alpha_x(t)].$$

This map ϕ_t is always continuous. In fact, the whole flow α is continuous (as a function of both t and x):

4. THEOREM. If $f: U \rightarrow \mathbb{R}^n$ is locally Lipschitz, then the flow

$$\alpha: (-b, b) \times B_a(x_0) \rightarrow U$$

given by Theorem 2 is continuous.

PROOF. Let us denote the map S defined in the proof of Theorem 2 by S_x , to indicate explicitly the role of x . Then

$$\|\alpha_x - S_y \alpha_x\| = \|S_x \alpha_x - S_y \alpha_x\| = |x - y|.$$

Recall that

$$\|S\alpha - S\beta\| \leq bK\|\alpha - \beta\|.$$

If S_y^n denotes the n -fold iterate of S_y , then

$$\begin{aligned}\|\alpha_x - S_y^n \alpha_x\| &\leq \|\alpha_x - S_y \alpha_x\| + \|S_y \alpha_x - S_y^2 \alpha_x\| + \cdots + \|S_y^{n-1} \alpha_x - S_y^n \alpha_x\| \\ &\leq (1 + bK + \cdots + (bK)^{n-1})|x - y| \leq \frac{1}{1 - bK}|x - y|.\end{aligned}$$

Recall also that in Theorem 1 the fixed point α_y of S_y is the limit of $S_y^n \alpha$ for any α . Hence $\alpha_y = \lim_{n \rightarrow \infty} S_y^n \alpha_x$, so we obtain

$$\|\alpha_x - \alpha_y\| \leq \frac{1}{1 - bK}|x - y|.$$

Since $\|\alpha_x - \alpha_y\| = \sup_t |\alpha(t, x) - \alpha(t, y)|$, this certainly proves continuity of α . ♦

If additional conditions are placed upon the map f , then further smoothness conditions can be proved for α . In fact,

If $f: U \rightarrow \mathbb{R}^n$ is C^k , then the flow $\alpha: (-b, b) \times B_a(x_0) \rightarrow U$ is also C^k .

Unfortunately, this is a very hard theorem. A clean exposition of the classical proof is given in Lang's *Introduction to Differentiable Manifolds* (2nd ed.), and a recently discovered proof can be found in Lang, *Real and Functional Analysis* (3rd ed.), pp. 371–379. In order to read this high-powered proof, you must first learn the elements of Banach spaces, including the Hahn-Banach theorem, and then read about differential calculus in Banach spaces, including the inverse and implicit function theorems (*Real and Functional Analysis*, pp. 360–365), but this is probably easier than reading the classical proof (and, besides, when you're finished you'll also know about Banach spaces, and differential calculus in Banach spaces).

We will just accept this fact. Notice that the maps ϕ_t are consequently C^∞ if f is C^∞ .

Since the map

$$\alpha: (-b, b) \times B_a(x_0) \rightarrow U$$

satisfies $\alpha(0, x) = x$, we have

$$\alpha: \{0\} \times \bar{B}_{a/2}(x_0) \rightarrow \bar{B}_{a/2}(x_0) \subset B_a(x_0).$$

Continuity of α and compactness of $\{0\} \times \bar{B}_{a/2}(x_0)$ imply that there is some $\varepsilon > 0$ such that

$$\alpha: (-\varepsilon, \varepsilon) \times B_{a/2}(x_0) \rightarrow B_a(x_0).$$

[If $x \in B_{a/2}(x_0)$, then the integral curve with initial condition x stays in $B_a(x_0)$ for $|t| < \varepsilon$.]

So if $|s| < \varepsilon$, and $x \in B_{a/2}(x_0)$, then the point $\alpha(s, x) \in B_a(x_0)$, so we can also define

$$\gamma(t) = \alpha(t, \alpha(s, x)) \quad |t| < \varepsilon.$$

This satisfies

$$\begin{aligned} \gamma'(t) &= f(\gamma(t)) \\ \gamma(0) &= \alpha(s, x). \end{aligned}$$

We have also noted that

$$\beta(t) = \alpha(s + t, x), \quad \text{defined for } |s + t| < \varepsilon,$$

satisfies

$$\begin{aligned} \beta'(t) &= f(\beta(t)) \\ \beta(0) &= \alpha(s, x). \end{aligned}$$

Consequently, $\beta(t) = \alpha(t, \alpha(s, x))$ for $|t| < \varepsilon$. In other words,

$$\text{if } |s|, |t|, |s + t| < \varepsilon, \quad \text{then } \alpha(t, \alpha(s, x)) = \alpha(s + t, x).$$

If we now let $\phi_t: B_{a/2}(x_0) \rightarrow \mathbb{R}^n$ be $\phi_t(x) = \alpha(t, x)$ for $x \in B_{a/2}(x_0)$, we can say:

$$\begin{aligned} \text{if } |s|, |t|, |s + t| < \varepsilon \text{ and } x, \phi_t(x) \in B_{a/2}(x_0), \text{ then} \\ \phi_s(\phi_t(x)) &= \phi_{s+t}(x). \end{aligned}$$

Roughly speaking, $\phi_{t+s} = \phi_t \circ \phi_s = \phi_s \circ \phi_t$. This shows, in particular, that for $|s| < \varepsilon$ each ϕ_s is a diffeomorphism, with inverse $\phi_s^{-1} = \phi_{-s}$. Everything we have said, since it is local, can be resaid, without requiring any more proof, on a manifold.

5. THEOREM. Let X be a C^∞ vector field on M , and let $p \in M$. Then there is an open set V containing p and an $\varepsilon > 0$, such that there is a unique collection of diffeomorphisms $\phi_t: V \rightarrow \phi_t(V) \subset M$ for $|t| < \varepsilon$ with the following properties:

(1) $\phi: (-\varepsilon, \varepsilon) \times V \rightarrow M$, defined by $\phi(t, p) = \phi_t(p)$, is C^∞ .

(2) If $|s|, |t|, |s+t| < \varepsilon$, and $q, \phi_t(q) \in V$, then

$$\phi_{s+t}(q) = \phi_s \circ \phi_t(q).$$

(3) If $q \in V$, then X_q is the tangent vector at $t = 0$ of the curve $t \mapsto \phi_t(q)$.

The examples given previously show that we cannot expect ϕ_t to be defined for all t , or on all of M . In one case however, this can be attained. The support of a vector field X is just the closure of $\{p \in M : X_p \neq 0\}$.

6. THEOREM. If X has compact support (in particular, if M is compact), then there are diffeomorphisms $\phi_t: M \rightarrow M$ for all $t \in \mathbb{R}$ with properties (1), (2), (3).

PROOF. Cover support X by a finite number of open sets V_1, \dots, V_n given by Theorem 5 with corresponding $\varepsilon_1, \dots, \varepsilon_n$ and diffeomorphisms ϕ_t^i . Let $\varepsilon = \min(\varepsilon_1, \dots, \varepsilon_n)$. Notice that by uniqueness, $\phi_t^i(q) = \phi_t^j(q)$ for $q \in V_i \cap V_j$. So we can define

$$\phi_t(q) = \begin{cases} \phi_t^i(q) & \text{if } q \in V_i \\ q & \text{if } q \notin \text{support } X. \end{cases}$$

Clearly $\phi: (-\varepsilon, \varepsilon) \times M \rightarrow M$ is C^∞ , and $\phi_{t+s} = \phi_t \circ \phi_s$ if $|t|, |s|, |t+s| < \varepsilon$, and each ϕ_t is a diffeomorphism.

To define ϕ_t for $|t| \geq \varepsilon$, write

$$t = k(\varepsilon/2) + r \quad \text{with } k \text{ an integer, and } |r| < \varepsilon/2.$$

Let

$$\phi_t = \begin{cases} \phi_{\varepsilon/2} \circ \dots \circ \phi_{\varepsilon/2} \circ \phi_r & [\phi_{\varepsilon/2} \text{ iterated } k \text{ times}] & \text{for } k \geq 0 \\ \phi_{-\varepsilon/2} \circ \dots \circ \phi_{-\varepsilon/2} \circ \phi_r & [\phi_{-\varepsilon/2} \text{ iterated } -k \text{ times}] & \text{for } k < 0. \end{cases}$$

It is easy to check that this is the desired $\{\phi_t\}$. ♦

The unique collection $\{\phi_t\}$ given by Theorem 6, or more precisely, the map $t \mapsto \phi_t$ from \mathbb{R} to the group of all diffeomorphisms of M , is called a 1-parameter group of diffeomorphisms, and is said to be generated by X . In the local case of Theorem 5, we obtain a “local 1-parameter group of local diffeomorphisms”. The vector field X is sometimes called the “infinitesimal generator” of $\{\phi_t\}$ (vector fields used to be called “infinitesimal transformations”).

Condition (3) in Theorem 5 can be rephrased in terms of the action of X_q on a C^∞ function $f: M \rightarrow \mathbb{R}$. Recall that

$$\frac{dc}{dt}(f) = \frac{df(c(t))}{dt} = (f \circ c)'(t).$$

Thus, to say that X_q is the tangent vector at $t = 0$ of the curve $t \mapsto \phi_t(q)$ amounts to saying that

$$(Xf)(q) = X_q f = \lim_{h \rightarrow 0} \frac{f(\phi_h(q)) - f(q)}{h}.$$

This equation will be used very frequently. The first use is to derive a corollary of Theorem 5 which allows us to simplify many calculations involving vector fields, and which also has important theoretical uses.

7. THEOREM. Let X be a C^∞ vector field on M with $X(p) \neq 0$. Then there is a coordinate system (x, U) around p such that

$$X = \frac{\partial}{\partial x^1} \quad \text{on } U.$$

PROOF. It is easy to see that we can assume $M = \mathbb{R}^n$ (with the standard coordinate system t^1, \dots, t^n , say), and $p = 0 \in \mathbb{R}^n$. Moreover, we can assume that $X(0) = \partial/\partial t^1|_0$. The idea of the proof is that in a neighborhood of 0 there is a unique integral curve through each point $(0, a^2, \dots, a^n)$; if q lies on the integral

curve through this point, we will use a^2, \dots, a^n as the last $n-1$ coordinates of q and the time interval it takes the curve to get to q as the first coordinate. To do this, let X generate ϕ_t and consider the map χ defined on a neighborhood of 0 in \mathbb{R}^n by

$$\chi(a^1, \dots, a^n) = \phi_{a^1}(0, a^2, \dots, a^n).$$

We compute that for $a = (a^1, \dots, a^n)$,

$$\begin{aligned} \chi_* \left(\frac{\partial}{\partial t^1} \Big|_a \right) (f) &= \frac{\partial}{\partial t^1} \Big|_a (f \circ \chi) \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [f(\chi(a^1 + h, a^2, \dots, a^n)) - f(\chi(a))] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [f(\phi_{a^1+h}(0, a^2, \dots, a^n)) - f(\chi(a))] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [f(\phi_h(\chi(a))) - f(\chi(a))] \\ &= (Xf)(\chi(a)). \end{aligned}$$

Moreover, for $i > 1$ we can at least compute

$$\begin{aligned} \chi_* \left(\frac{\partial}{\partial t^i} \Big|_0 \right) (f) &= \frac{\partial}{\partial t^i} \Big|_0 (f \circ \chi) \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [f(\chi(0, \dots, h, \dots, 0)) - f(0)] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [f(0, \dots, h, \dots, 0) - f(0)] \\ &= \frac{\partial f}{\partial t^i} \Big|_0. \end{aligned}$$

Since $X(0) = \partial/\partial t^1|_0$ by assumption, this shows that $\chi_{*0} = I$ is non-singular. Hence $x = \chi^{-1}$ may be used as a coordinate system in a neighborhood of 0. This is the desired coordinate system, for it is easy to see that the equation $\chi_*(\partial/\partial t^1) = X \circ \chi$, which we have just proved, is equivalent to $X = \partial/\partial x^1$. ♦

The second use of the equation

$$(Xf)(p) = \lim_{h \rightarrow 0} \frac{1}{h} [f(\phi_h(p)) - f(p)]$$

is more comprehensive. The fact that Xf can be defined totally in terms of the diffeomorphisms ϕ_h suggests that an action of X on other objects can be

obtained in a similar way. To emphasize the fundamental similarity of these notions, we first introduce the notation

$$L_X f \quad \text{for} \quad Xf.$$

We call $L_X f$ the (Lie) derivative of f with respect to X ; it is another function, whose value at p is denoted variously by $(L_X f)(p) = L_X f(p) = (Xf)(p) = X_p(f)$. Now if ω is a C^∞ covariant vector field, we define a new covariant vector field, the Lie derivative of ω with respect to X , by

$$(L_X \omega)(p) = \lim_{h \rightarrow 0} \frac{1}{h} [(\phi_h^* \omega)(p) - \omega(p)].$$

This is the limit of certain members of M_p^* . Recall that if $X_p \in M_p$, then

$$(\phi_h^* \omega)(p)(X_p) = \omega(\phi_h(p))(\phi_{h*} X_p).$$

A fairly easy direct argument (Problem 8) shows that this limit always exists, and that the newly defined covariant vector field $L_X \omega$ is C^∞ , but we will soon compute this vector field explicitly in a coordinate system, and these facts will then be obvious.

If Y is another vector field, we can define the Lie derivative of Y with respect to X ,

$$(L_X Y)(p) = \lim_{h \rightarrow 0} \frac{1}{h} [Y_p - (\phi_{h*} Y)_p].$$

The vector field $\phi_{h*} Y$ appearing here is a special case of the vector field $\alpha_* Y$ defined at the beginning of the chapter, for $\alpha: M \rightarrow N$ a diffeomorphism and Y a vector field on M . Thus $(\phi_{h*} Y)_p = \phi_{h*}(Y_{\phi_{-h}(p)})$ is obtained by evaluating Y at $\phi_h^{-1}(p) = \phi_{-h}(p)$, and then moving it back to p by ϕ_{h*} .

The definition of $L_X Y$ can be made to look more closely analogous to $L_X f$ and $L_X \omega$ in the following way. If $\alpha: M \rightarrow N$ is a diffeomorphism and Y is a

vector field on the range N , then a vector field α^*Y on M can be defined by

$$(\alpha^*Y)_p = (\alpha^{-1})_*(Y_{\alpha(p)}).$$

Of course, $\alpha^*(Y)$ is just $(\alpha^{-1})_*Y$. Now notice that

$$\begin{aligned} \lim_{h \rightarrow 0} \frac{1}{h} [(\phi_h^*Y)_p - Y_p] &= \lim_{h \rightarrow 0} \frac{Y_p - (\phi_h^*Y)_p}{-h} = \lim_{k \rightarrow 0} \frac{1}{k} [Y_p - (\phi_{-k}^*Y)_p] \\ &= \lim_{k \rightarrow 0} \frac{1}{k} [Y_p - (\phi_k_*Y)_p] = (L_X Y)(p). \end{aligned}$$

Nevertheless, we will stick to the original (equivalent) definition.

We now wish to compute $L_X \omega$ and $L_X Y$ in a coordinate system. The calculation is made a lot easier by first observing

8. PROPOSITION. If $L_X Y_i$ and $L_X \omega_i$ exist for $i = 1, 2$, then

$$(1) \quad L_X (Y_1 + Y_2) = L_X Y_1 + L_X Y_2,$$

$$(2) \quad L_X (\omega_1 + \omega_2) = L_X \omega_1 + L_X \omega_2.$$

If $L_X Y$ and $L_X \omega$ exist, then

$$(3) \quad L_X fY = Xf \cdot Y + f \cdot L_X Y,$$

$$(4) \quad L_X f \cdot \omega = Xf \cdot \omega + f \cdot L_X \omega.$$

Finally, if $\omega(Y)$ denotes the function $p \mapsto \omega(p)(Y_p)$ and $L_X \omega$ and $L_X Y$ exist, then

$$(5) \quad L_X (\omega(Y)) = (L_X \omega)(Y) + \omega(L_X Y).$$

PROOF. (1) and (2) are trivial. The remaining equations are all proved by the same trick, the one used in finding $(fg)'(x)$. We will do number (3) here.

$$\begin{aligned} (L_X fY)_p &= \lim_{h \rightarrow 0} \frac{1}{h} [(fY)_p - (\phi_h^* fY)_p] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [f(p)Y_p - \phi_{h*}(fY)_{\phi_{-h}(p)}] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [f(p)Y_p - f(\phi_{-h}(p))\phi_{h*}Y_{\phi_{-h}(p)}] \\ &= \lim_{h \rightarrow 0} f(p) \frac{1}{h} [Y_p - \phi_{h*}Y_{\phi_{-h}(p)}] \\ &\quad + \lim_{h \rightarrow 0} \left[\frac{f(p) - f(\phi_{-h}(p))}{h} \right] \phi_{h*}Y_{\phi_{-h}(p)}. \end{aligned}$$

The first limit is clearly $f(p) \cdot L_X Y(p)$. In the second limit, the term in brackets approaches

$$\lim_{k \rightarrow 0} \frac{f(p) - f(\phi_k(p))}{-k} = Xf(p),$$

while an easy argument shows that $\phi_{h*} Y_{\phi_{-h}(p)} \rightarrow Y_p$. ♦

We are now ready to compute L_X in terms of a coordinate system (x, U) on M . Suppose $X = \sum_{i=1}^n a^i \partial/\partial x^i$. We first compute $L_X(dx^i)$. Recall (Problem 4-1) that if $f: M \rightarrow N$ and y is a coordinate system on N , then

$$f^*(dy^i) = \sum_{j=1}^n \frac{\partial(y^i \circ f)}{\partial x^j} dx^j.$$

We can apply this to ϕ_h^* , where y is x . Then

$$\begin{aligned} L_X(dx^i)(p) &= \lim_{h \rightarrow 0} \frac{1}{h} [(\phi_h^*)dx^i(p) - dx^i(p)] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} \left[\sum_{j=1}^n \frac{\partial(x^i \circ \phi_h)}{\partial x^j}(p) dx^j(p) - dx^i(p) \right]. \end{aligned}$$

Now the coefficient of $dx^j(p)$ is

$$\begin{aligned} \lim_{h \rightarrow 0} \frac{1}{h} \left[\frac{\partial(x^i \circ \phi_h)}{\partial x^j} - \delta_j^i \right] &= \lim_{h \rightarrow 0} \frac{1}{h} \left[\frac{\partial(x^i \circ \phi_h)}{\partial x^j}(p) - \frac{\partial(x^i \circ \phi_0)}{\partial x^j}(p) \right] \\ (*) &= \frac{\partial}{\partial x^j} \bigg|_p \lim_{h \rightarrow 0} \frac{1}{h} [(x^i \circ \phi_h) - (x^i \circ \phi_0)] \\ &\quad \{\text{this step will be justified in a moment}\} \\ &= \frac{\partial}{\partial x^j} \bigg|_p X(x^i) = \frac{\partial a^i}{\partial x^j}(p). \end{aligned}$$

To justify (*) we note that the map $A(h, q) = x^i(\phi_h(q))$ is C^∞ from $\mathbb{R} \times M$ to \mathbb{R} ; thus $\partial^2 A / \partial h \partial x^j = \partial^2 A / \partial x^j \partial h$, which is what the interchange of limits amounts to.

It now follows that

$$L_X dx^i = \sum_{j=1}^n \frac{\partial a^i}{\partial x^j} dx^j.$$

We could now use (2) and (4) of Proposition 8 to compute $L_X \omega$ in general, but

we are really interested in computing $L_X Y$. To compute $L_X(\partial/\partial x^i)$ we could imitate the calculations of $L_X dx^i$; but there would be a complication, because ϕ_{h*} on vector fields involves one more composition than ϕ_h^* on covariant vector fields. The trick needed to deal with this complication has already been used to prove (3), (4), and (5) of Proposition 8, and we can now use (5) to get the answer immediately:

$$0 = L_X \delta_j^i = L_X \left[dx^i \left(\frac{\partial}{\partial x^j} \right) \right] = (L_X dx^i) \left(\frac{\partial}{\partial x^j} \right) + dx^i \left(L_X \frac{\partial}{\partial x^j} \right),$$

so

$$dx^i \left(L_X \frac{\partial}{\partial x^j} \right) = - \frac{\partial a^i}{\partial x^j};$$

thus,

$$L_X \frac{\partial}{\partial x^j} = - \sum_{i=1}^n \frac{\partial a^i}{\partial x^j} \frac{\partial}{\partial x^i}.$$

Using (3) we obtain

$$\begin{aligned} L_X \left(b^j \frac{\partial}{\partial x^j} \right) &= L_X b^j \cdot \frac{\partial}{\partial x^j} + b^j L_X \left(\frac{\partial}{\partial x^j} \right) \\ &= \sum_{i=1}^n a^i \frac{\partial b^j}{\partial x^i} \frac{\partial}{\partial x^j} - \sum_{i=1}^n b^j \frac{\partial a^i}{\partial x^j} \frac{\partial}{\partial x^i}. \end{aligned}$$

Summing over j and then interchanging i and j in the second double sum we obtain

$$L_X Y = \sum_{j=1}^n \left(\sum_{i=1}^n a^i \frac{\partial b^j}{\partial x^i} - b^i \frac{\partial a^j}{\partial x^i} \right) \frac{\partial}{\partial x^j}, \quad X = \sum_{i=1}^n a^i \frac{\partial}{\partial x^i}, \quad Y = \sum_{i=1}^n b^i \frac{\partial}{\partial x^i}.$$

This somewhat complicated expression immediately leads to a much simpler coordinate-free expression for $L_X Y$. If $f: M \rightarrow N$ is a C^∞ function, then Yf is a function, so $XYf = X(Yf)$ makes sense. Clearly

$$X(Yf) = \sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \left(\sum_{j=1}^n b^j \frac{\partial f}{\partial x^j} \right) = \sum_{i,j} a^i \frac{\partial b^j}{\partial x^i} \frac{\partial f}{\partial x^j} + a^i b^j \frac{\partial^2 f}{\partial x^j \partial x^i}.$$

The second partial derivatives which arise here cancel those in the expression for $Y(Xf)$, and we find that

$$L_X Y = XY - YX, \quad \text{also denoted by } [X, Y].$$

Often, $[X, Y]$ (which is called the “bracket” of X and Y) is just defined as $XY - YX$; note that this means

$$[X, Y]_p(f) = X_p(Yf) - Y_p(Xf).$$

A straightforward verification shows that

$$[X, Y]_p(fg) = f(p)[X, Y]_p(g) + g(p)[X, Y]_p(f),$$

so that $[X, Y]_p$ is a derivation at p , and can therefore be considered as a member of M_p .

We are now in a very strange situation. Two vector fields $L_X Y$ and $[X, Y]$ have both been defined independently of any coordinate system, but they have been proved equal using a coordinate system. This sort of thing irks some people to no end. Fortunately, in this case the coordinate-free proof is short, though hardly obvious.

In Chapter 3 we proved a lemma which for the special case of \mathbb{R} says that a C^∞ function $f: (-\varepsilon, \varepsilon) \rightarrow \mathbb{R}$ with $f(0) = 0$ can be written

$$f(t) = t g(t)$$

for a C^∞ function $g: (-\varepsilon, \varepsilon) \rightarrow \mathbb{R}$ with $g(0) = f'(0)$, namely

$$g(t) = \int_0^1 f'(st) ds.$$

This has an immediate generalization.

9. LEMMA. If $f: (-\varepsilon, \varepsilon) \times M \rightarrow \mathbb{R}$ is C^∞ and $f(0, p) = 0$ for all $p \in M$, then there is a C^∞ function $g: (-\varepsilon, \varepsilon) \times M \rightarrow \mathbb{R}$ with

$$\begin{aligned} f(t, p) &= t g(t, p) \\ \frac{\partial f}{\partial t}(0, p) &= g(0, p). \end{aligned}$$

PROOF. Define

$$g(t, p) = \int_0^1 \frac{\partial}{\partial s} f(st, p) ds. \quad \spadesuit$$

10. THEOREM. If X and Y are C^∞ vector fields, then

$$L_X Y = [X, Y].$$

PROOF. Let $f: M \rightarrow \mathbb{R}$ be C^∞ . Let X generate ϕ_t , $|t| < \varepsilon$. By Lemma 9 there is a family of C^∞ functions g_t on M such that

$$\begin{aligned} f \circ \phi_t &= f + t g_t \\ g_0 &= Xf. \end{aligned}$$

Then

$$\begin{aligned} (\phi_{h*} Y)_p(f) &= \phi_{h*}(Y_{\phi_{-h}(p)})(f) = Y_{\phi_{-h}(p)}(f \circ \phi_h) \\ &= Y_{\phi_{-h}(p)}(f + h g_h), \end{aligned}$$

so

$$\begin{aligned} \lim_{h \rightarrow 0} \frac{1}{h} [Y_p - (\phi_{h*} Y)_p](f) &= \lim_{h \rightarrow 0} \frac{1}{h} [(Yf)(p) - (Yf)(\phi_{-h}(p))] \\ &\quad - \lim_{h \rightarrow 0} (Yg_h)(\phi_{-h}(p)) \\ &= (L_X Yf)(p) - (Yg_0)(p) \\ &= X_p(Yf) - Y_p(Xf). \quad \spadesuit \end{aligned}$$

The equality $L_X Y = [X, Y] = XY - YX$ reveals certain facts about $L_X Y$ which are by no means obvious from the definition. Clearly

$$[X, Y] = -[Y, X], \quad \text{so} \quad [X, X] = 0.$$

Consequently,

$$L_X Y = -L_Y X, \quad \text{so} \quad L_X X = 0.$$

Since we obviously have $L_X(aY_1 + bY_2) = aL_X Y_1 + bL_X Y_2$, it follows immediately that L is also linear with respect to X :

$$L_{aX_1 + bX_2} Y = aL_{X_1} Y + bL_{X_2} Y.$$

Finally, a straightforward calculation proves the "Jacobi identity":

$$[X, [Y, Z]] + [Z, [X, Y]] + [Y, [Z, X]] = 0.$$

This equation is capable of two interpretations in terms of Lie derivatives:

(a) $L_X[Y, Z] = [L_X Y, Z] + [Y, L_X Z],$

(b) as operators on C^∞ functions, we have

$$L_{[X, Y]} = L_X \circ L_Y - L_Y \circ L_X \quad (\text{which might be written as } [L_X, L_Y]).$$

Finally, note that $L_X Y$ is linear over constants only, *not* over the C^∞ functions \mathcal{F} . In fact, Proposition 8, or a simple calculation using the definition of $[X, Y]$, shows that

$$[fX, gY] = fg[X, Y] + f(Xg)Y - g(Yf)X.$$

Thus, the bracket operation $[\ , \]$ is *not* a tensor—that is, $[X, Y]_p$ does not depend only on X_p and Y_p (which is not surprising—what can one do to two vectors in a vector space except take linear combinations of them?), but on the vector fields X and Y . In particular, even if $X_p = 0$, it does not necessarily follow that $[X, Y]_p = 0$ —in the formula

$$[X, Y]_p(f) = X_p(Yf) - Y_p(Xf)$$

the first term $X_p(Yf)$ is zero, but the second may not be, for Xf may have a non-zero derivative in the Y_p direction even though $(Xf)(p) = 0$.

The bracket $[X, Y]$, although not a tensor, pops up in the definition of practically all other tensors, for reasons that will become more and more apparent. Before proceeding to examine its geometric interpretation, we will endeavor to become more at ease with the Lie derivative by taking time out to prove directly from the definition of $L_X Y$ two facts which are obvious from the definition of $[X, Y]$.

(I) $L_X X = 0$.

If X generates ϕ_t , it certainly suffices to show that $(\phi_{h*} X)_p = X_p$ for all h . Recall that $(\phi_{h*} X)_p = \phi_{h*} X_{\phi_{-h}(p)}$. Now $X_{\phi_{-h}(p)}$ is just the tangent vector at

time $t = -h$ to the curve $t \mapsto \phi_t(p)$, and thus the tangent vector, at time $t = 0$, to the curve

$$\gamma(t) = \phi_{t-h}(p).$$

Thus $\phi_{h*} X_{\phi_{-h}(p)}$ is the tangent vector, at time $t = 0$, to the curve

$$\phi_h \circ \gamma(t) = \phi_h(\phi_{t-h}(p)) = \phi_t(p).$$

But this tangent vector is just X_p .

(2) If X_p and Y_p are both 0, then $L_X Y(p) = 0$.

Since $X_p = 0$, the unique integral curve c with $c(0) = p$ and $dc/dt = X(c(t))$ is simply $c(t) = p$ (an integral curve starting at p can never get away; conversely, of course, an integral curve starting at some other point can never get to p). Then $Y_p = 0$ and

$$(\phi_{h*} Y)_p = \phi_{h*} Y_{\phi_{-h}(p)} = \phi_{h*} Y_p = \phi_{h*} 0 = 0,$$

so $L_X Y(p) = 0$.

To develop an interpretation of $[X, Y]$ we first prove two lemmas.

11. LEMMA. Let $\alpha: M \rightarrow N$ be a diffeomorphism and X a vector field on M which generates $\{\phi_t\}$. Then $\alpha_* X$ generates $\{\alpha \circ \phi_t \circ \alpha^{-1}\}$.

PROOF. We have

$$\begin{aligned} (\alpha_* X)_q(f) &= [\alpha_* X_{\alpha^{-1}(q)}](f) \\ &= X_{\alpha^{-1}(q)}(f \circ \alpha) \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [(f \circ \alpha)(\phi_h(\alpha^{-1}(q))) - (f \circ \alpha)(\alpha^{-1}(q))] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [f(\alpha \circ \phi_h \circ \alpha^{-1}(q)) - f(q)]. \quad \spadesuit \end{aligned}$$

12. COROLLARY. If $\alpha: M \rightarrow M$, then $\alpha_* X = X$ if and only if $\phi_t \circ \alpha = \alpha \circ \phi_t$ for all t .

13. LEMMA. Let X generate $\{\phi_t\}$ and Y generate $\{\psi_t\}$. Then $[X, Y] = 0$ if and only if $\phi_t \circ \psi_s = \psi_s \circ \phi_t$ for all s, t .

PROOF. If $\phi_t \circ \psi_s = \psi_s \circ \phi_t$ for all s , then $\phi_{t*} Y = Y$ by Corollary 12. If this is true for all t , then clearly $L_X Y = 0$.

Conversely, suppose that $[X, Y] = 0$, so that

$$(*) \quad 0 = \lim_{h \rightarrow 0} \frac{1}{h} [Y_q - (\phi_{h*} Y)_q] \quad \text{for all } q.$$

Given $p \in M$, consider the curve $c: (-\varepsilon, \varepsilon) \rightarrow M_p$ given by

$$c(t) = (\phi_{t*} Y)_p.$$

For the derivative, $c'(t)$, of this map into the vector space M_p we have

$$\begin{aligned}
 c'(t) &= \lim_{h \rightarrow 0} \frac{1}{h} [c(t+h) - c(t)] \\
 &= \lim_{h \rightarrow 0} \frac{1}{h} [(\phi_{[t+h]*} Y)_p - (\phi_{t*} Y)_p] \\
 &= \lim_{h \rightarrow 0} \frac{1}{h} [\phi_{t*} (\phi_{h*} Y)_{\phi_{-t}(p)} - \phi_{t*} Y_{\phi_{-t}(p)}] \\
 &= \phi_{t*} \left\{ \lim_{h \rightarrow 0} \frac{1}{h} [(\phi_{h*} Y)_{\phi_{-t}(p)} - Y_{\phi_{-t}(p)}] \right\} \\
 &= \phi_{t*}(0) \quad \text{using (*) with } q = \phi_{-t}(p) \\
 &= 0.
 \end{aligned}$$

Consequently $c(t) = c(0)$, so $\phi_{t*} Y = Y$. By Corollary 12, $\phi_t \circ \psi_s = \psi_s \circ \phi_t$ for all s, t . ♦

We have already shown that if $X(p) \neq 0$, then there is a coordinate system x with $X = \partial/\partial x^1$. If Y is another vector field, everywhere linearly independent of X , then we might expect to find a coordinate system with

$$(*) \quad X = \frac{\partial}{\partial x^1}, \quad Y = \frac{\partial}{\partial x^2}.$$

However, a short calculation immediately gives the result

$$\left[\frac{\partial}{\partial x^1}, \frac{\partial}{\partial x^2} \right] = 0,$$

so there is no hope of finding a coordinate system satisfying (*) unless $[X, Y] = 0$. The remarkable fact is that the condition $[X, Y] = 0$ is *sufficient*, as well as necessary, for the existence of the desired coordinate system.

14. THEOREM. If X_1, \dots, X_k are linearly independent C^∞ vector fields in a neighborhood of p , and $[X_\alpha, X_\beta] = 0$ for $1 \leq \alpha, \beta \leq k$, then there is a coordinate system (x, U) around p such that

$$X_\alpha = \frac{\partial}{\partial x^\alpha} \quad \text{on } U, \quad \alpha = 1, \dots, k.$$

PROOF. As in the proof of Theorem 7, we can assume that $M = \mathbb{R}^n$, that $p = 0$, and, by a linear change of coordinates, that

$$X_\alpha(0) = \frac{\partial}{\partial x^\alpha} \Big|_0 \quad \alpha = 1, \dots, k.$$

If X_α generates $\{\phi_t^\alpha\}$, define χ by

$$\chi(a^1, \dots, a^n) = \phi_{a^1}^1(\phi_{a^2}^2(\dots(\phi_{a^k}^k(0, \dots, 0, a^{k+1}, \dots, a^n)) \dots)).$$

As in the proof of Theorem 7, we can compute that

$$\chi_* \left(\frac{\partial}{\partial t^\alpha} \Big|_0 \right) = \begin{cases} X_\alpha(0) = \frac{\partial}{\partial t^\alpha} \Big|_0 & \alpha = 1, \dots, k \\ \frac{\partial}{\partial t^\alpha} \Big|_0 & \alpha = k+1, \dots, n. \end{cases}$$

Thus $x = \chi^{-1}$ can be used as a coordinate system in a neighborhood of $p = 0$. Moreover, just as before we see that

$$X_1 = \frac{\partial}{\partial x^1}.$$

Nothing said so far uses the hypothesis $[X_\alpha, X_\beta] = 0$. To make use of it, we appeal to Lemma 13; it shows that for each α between 1 and k , the map χ can also be written

$$\chi(a^1, \dots, a^n) = \phi_{a^\alpha}^\alpha(\phi_{a^1}^1(\dots(0, \dots, 0, a^{k+1}, \dots, a^n) \dots)),$$

and our previous argument then shows that

$$X_\alpha = \frac{\partial}{\partial x^\alpha}. \quad \spadesuit$$

We thus see that the bracket $[X, Y]$ measures, in some sense, the extent to which the integral curves of X and Y can be used to form the “coordinate lines” of a coordinate system. There is a more complicated, more difficult to prove, and less important result, which makes this assertion much more precise. If X and Y are two vector fields in a neighborhood of p , then for sufficiently small h we can

- (1) follow the integral curve of X through p for time h ;
- (2) starting from that point, follow the integral curve of Y for time h ;
- (3) then follow the integral curve of X backwards for time h ;
- (4) then follow the integral curve of Y backwards for time h .

If there happens to be a coordinate system x with $x(p) = 0$ and

$$X = \frac{\partial}{\partial x^1}, \quad Y = \frac{\partial}{\partial x^2},$$

then these steps take us to points with coordinates

$$(1) \quad (h, 0, 0, \dots, 0)$$

$$(2) \quad (h, h, 0, \dots, 0)$$

$$(3) \quad (0, h, 0, \dots, 0)$$

$$(4) \quad (0, 0, 0, \dots, 0),$$

so that this “parallelogram” is always closed. Even when X and Y are (linearly independent) vector fields with $[X, Y] \neq 0$, the parallelogram is “closed up to first order”. The meaning of this phrase [an extension of the terminology “ $c = \gamma$ up to first order at 0”, which means that $c'(0) = \gamma'(0)$] is the following. Let $c(h)$ be the point which step (4) ends up at,

$$c(h) = \psi_{-h}(\phi_{-h}(\psi_h(\phi_h(0)))).$$

Then the curve c is the constant curve p up to first order, that is,

15. PROPOSITION. $c'(0) = 0$.

PROOF. If we define

$$\alpha_1(t, h) = \psi_t(\phi_h(p))$$

$$\alpha_2(t, h) = \phi_{-t}(\psi_h(\phi_h(p)))$$

$$\alpha_3(t, h) = \psi_{-t}(\phi_{-h}(\psi_h(\phi_h(p)))),$$

then

$$c(t) = \alpha_3(t, t).$$

Moreover,

$$(a) \quad \alpha_2(0, t) = \alpha_1(t, t)$$

$$(b) \quad \alpha_3(0, t) = \alpha_2(t, t)$$

and for any C^∞ function $f: M \rightarrow \mathbb{R}$,

$$\begin{aligned} \text{(c)} \quad & \frac{\partial(f \circ \alpha_1)}{\partial t} = Yf \circ \alpha_1 \\ \text{(d)} \quad & \frac{\partial(f \circ \alpha_2)}{\partial t} = -Xf \circ \alpha_2 \\ \text{(e)} \quad & \frac{\partial(f \circ \alpha_3)}{\partial t} = -Yf \circ \alpha_3 \end{aligned}$$

while

$$\text{(f)} \quad \frac{\partial(f \circ \alpha_1)}{\partial h}(0, h) = Xf(\alpha_1(0, h)).$$

Consequently, repeated use of the chain rule gives

$$\begin{aligned} (f \circ c)'(0) &= D_1(f \circ \alpha_3)(0, 0) + D_2(f \circ \alpha_3)(0, 0) \\ &= D_1(f \circ \alpha_3)(0, 0) \\ &\quad + [D_1(f \circ \alpha_2)(0, 0) + D_2(f \circ \alpha_2)(0, 0)] \quad \text{using (b)} \\ &= D_1(f \circ \alpha_3)(0, 0) + D_1(f \circ \alpha_2)(0, 0) \\ &\quad + [D_1(f \circ \alpha_1)(0, 0) + D_2(f \circ \alpha_1)(0, 0)] \quad \text{using (a)}. \end{aligned}$$

Thus, (c), (d), (e), and (f) give

$$(f \circ c)'(0) = -Yf(p) - Xf(p) + Yf(p) + Xf(p) = 0. \quad \spadesuit$$

Whenever we have a curve $c: (-\varepsilon, \varepsilon) \rightarrow M$ with $c(0) = p$ and $c'(0) = 0 \in M_p$, we can define a new vector $c''(0)$ or $d^2c/dt^2|_0$ by

$$c''(0)(f) = (f \circ c)''(0).$$

A simple calculation shows, *using the assumption* $c'(0) = 0$, that this operator $c''(0)$ is a derivation, $c''(0) \in M_p$. (A more general construction is presented in Problem 17.) It turns out that for the curve c defined previously, the bracket $[X, Y]_p$ is related to this “second order” derivation. Until we get to Lie groups it will not be clear how anyone ever thought of the next theorem. The proof, which ends the chapter, but can easily be skipped, is an horrendous, but clever, calculation. It is followed by an addendum containing some additional important points about differential equations which are used later, and a second addendum concerning linearly independent vector fields in dimension 2.

16. THEOREM. $c''(0) = 2[X, Y]_p$.

PROOF. Using the notation of the previous proof, since $(f \circ c)(t) = (f \circ \alpha_3)(t, t)$ we have

$$(*) \quad (f \circ c)''(0) = D_{1,1}(f \circ \alpha_3)(0, 0) + 2D_{2,1}(f \circ \alpha_3)(0, 0) + D_{2,2}(f \circ \alpha_3)(0, 0).$$

Now

$$\begin{aligned} (1) \quad D_{1,1}(f \circ \alpha_3)(0, 0) &= D_1(-Yf \circ \alpha_3)(0, 0) && \text{by (e)} \\ &= YYf(p) && \text{by (e).} \end{aligned}$$

We also have

$$\begin{aligned} (2) \quad & 2D_{2,1}(f \circ \alpha_3)(0, 0) \\ &= 2D_1(-Yf \circ \alpha_3) && \text{by (e)} \\ &= 2[D_1(Yf \circ \alpha_2)(0, 0) \\ &\quad + D_2(Yf \circ \alpha_2)(0, 0)] && \text{by (b) and the chain rule} \\ &= 2XYf(p) - 2D_2(Yf \circ \alpha_2)(0, 0) && \text{by (d)} \\ &= 2XYf(p) - 2[D_1(Yf \circ \alpha_1)(0, 0) \\ &\quad + D_2(Yf \circ \alpha_1)(0, 0)] && \text{by (a) and the chain rule} \\ &= 2XYf(p) - 2YYf(p) - 2XYf(p) && \text{by (c) and (f).} \end{aligned}$$

Since (b) gives

$$D_2(f \circ \alpha_3)(0, s) = D_1(f \circ \alpha_2)(s, s) + D_2(f \circ \alpha_2)(s, s),$$

we have

$$\begin{aligned} (3) \quad & D_{2,2}(f \circ \alpha_3)(0, 0) = D_{1,1}(f \circ \alpha_2)(0, 0) + 2D_{2,1}(f \circ \alpha_2)(0, 0) \\ &\quad + D_{2,2}(f \circ \alpha_2)(0, 0) \\ &= D_1(-Xf \circ \alpha_2)(0, 0) + 2D_2(-Xf \circ \alpha_2)(0, 0) \\ &\quad + D_{2,2}(f \circ \alpha_2)(0, 0) && \text{by (d)} \\ &= XXf(p) - 2[D_1(Xf \circ \alpha_1)(0, 0) + D_2(Xf \circ \alpha_1)(0, 0)] \\ &\quad + D_{2,2}(f \circ \alpha_2)(0, 0) && \text{by (d) and the chain rule} \\ &= XXf(p) - 2YXf(p) - 2XXf(p) \\ &\quad + D_{2,2}(f \circ \alpha_2)(0, 0) && \text{by (c) and (f).} \end{aligned}$$

Finally, from

$$D_2(f \circ \alpha_2)(0, s) = D_1(f \circ \alpha_1)(s, s) + D_2(f \circ \alpha_2)(s, s) \quad [\text{from (a)}]$$

we have

$$\begin{aligned} (4) \quad D_{2,2}(f \circ \alpha_2)(0, 0) &= D_{1,1}(f \circ \alpha_1)(0, 0) \\ &\quad + 2D_{2,1}(f \circ \alpha_1)(0, 0) + D_{2,2}(f \circ \alpha_1)(0, 0) \\ &= YYf(p) + 2XYf(p) + XXf(p) \\ &\quad \text{by (c) and (f).} \end{aligned}$$

Substituting (1)–(4) in (*) yields the theorem. ❖

ADDENDUM 1

DIFFERENTIAL EQUATIONS

Although we have always solved differential equations

$$\frac{\partial}{\partial t}\alpha(t, x) = f(\alpha(t, x))$$

with the initial condition

$$\alpha(0, x) = x,$$

we could just as well have required, for some t_0 , that

$$\alpha(t_0, x) = x.$$

To prove this, one can replace 0 by t_0 everywhere in the proof of Theorem 2, or else just replace α by $t \mapsto \alpha(t - t_0, x)$.

Another omission in our treatment of differential equations is more glaring: the differential equations $\alpha'(t) = f(\alpha(t))$ do not even include simple equations of the form $\alpha'(t) = g(t)$, let alone equations like $\alpha'(t) = t\alpha(t)$. In general, we would like to solve equations

$$\begin{aligned}\frac{\partial}{\partial t}\alpha(t, x) &= f(t, \alpha(t, x)) \\ \alpha(0, x) &= x,\end{aligned}$$

where $f: (-c, c) \times U \rightarrow \mathbb{R}^n$. One way to do this is to replace $f(\alpha(t, x))$ by $f(t, \alpha(t, x))$ wherever it occurs in the proof. There is also a clever trick. Define

$$\bar{f}: (-c, c) \times U \rightarrow \mathbb{R}^{n+1}$$

by

$$\bar{f}(s, x) = (1, f(s, x)).$$

Then there is a flow $(\bar{\alpha}^1, \bar{\alpha}^2) = \bar{\alpha}: (-b, b) \times W \rightarrow \mathbb{R} \times \mathbb{R}^n$ with

$$\begin{aligned}\frac{\partial}{\partial t}\bar{\alpha}(t, s, x) &= \bar{f}(\bar{\alpha}(t, s, x)) \\ \bar{\alpha}(0, s, x) &= (s, x).\end{aligned}$$

For the first component function $\bar{\alpha}^1$ this means that

$$\begin{aligned}\frac{\partial}{\partial t}\bar{\alpha}^1(t, s, x) &= 1 \\ \bar{\alpha}^1(0, s, x) &= s;\end{aligned}$$

thus

$$\tilde{\alpha}^1(t, s, x) = s + t.$$

For the second component $\tilde{\alpha}^2$ we have

$$\begin{aligned}\frac{\partial}{\partial t}\tilde{\alpha}^2(t, s, x) &= f(\tilde{\alpha}(t, s, x)) \\ &= f(\tilde{\alpha}^1(t, s, x), \tilde{\alpha}^2(t, s, x)) \\ &= f(s + t, \tilde{\alpha}^2(t, s, x)).\end{aligned}$$

Then

$$\beta(t, x) = \tilde{\alpha}^2(t, 0, x)$$

is the desired flow with

$$\begin{aligned}\frac{\partial}{\partial t}\beta(t, x) &= f(t, \beta(t, x)) \\ \beta(0, x) &= x.\end{aligned}$$

Of course, we could also have arranged for $\beta(t_0, x) = x$ (by first finding $\tilde{\alpha}$ with $\tilde{\alpha}(t_0, s, x) = (s, x)$, *not* by considering the curve $t \mapsto \beta(t - t_0, x)$).

Finally, consider the special case of a *linear* differential equation

$$\alpha'(t) = g(t) \cdot \alpha(t),$$

where g is an $n \times n$ matrix-valued function on (a, b) . In this case

$$f(t, x) = g(t) \cdot x.$$

If c is any $n \times n$ (constant) matrix, then

$$(c \cdot \alpha)'(t) = c \cdot \alpha'(t) = g(t) \cdot c \cdot \alpha(t)$$

so $c \cdot \alpha$ is also a solution of the same differential equation. This remark allows us to prove an important property of linear differential equations, distinguishing them from general differential equations $\alpha'(t) = f(t, \alpha(t))$, which may have solutions defined only on a small time interval, even if $f: (a, b) \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ is C^∞ .

17. PROPOSITION. If g is a continuous $n \times n$ matrix-valued function on (a, b) , then the solutions of the equation

$$\alpha'(t) = g(t) \cdot \alpha(t)$$

can all be defined on (a, b) .

PROOF. Notice that continuity of g implies that $f(t, x) = g(t) \cdot x$ is locally Lipschitz. So for any $t_0 \in (a, b)$ we can solve the equation, with any given initial condition, in a neighborhood of t_0 . Extend it as far as possible. If the extended solution α is not defined for all t with $t_0 \leq t < b$, let t_1 be the least upper bound of the set of t 's for which it is defined. Pick β with

$$\begin{aligned}\beta'(t) &= g(t) \cdot \beta(t) \quad \text{for } t \text{ near } t_1 \\ \beta(t_1) &\neq 0.\end{aligned}$$

Then $\beta(t^*) \neq 0$ for $t^* < t_1$ close enough to t_1 . Hence there is c with

$$(c \cdot \beta)(t^*) = \alpha(t^*).$$

By uniqueness, $c \cdot \beta$ coincides with α on the interval where they are defined. Thus α may be extended past t_1 as $c \cdot \beta$, a contradiction. Similarly, α must be defined for all t with $a < t \leq t_0$. ♦

ADDENDUM 2

PARAMETER CURVES IN TWO DIMENSIONS

If $f: U \rightarrow M$ is an immersion from an open set $U \subset \mathbb{R}^n$ into an n -dimensional manifold M , the curve $t \mapsto f(a_1, \dots, a_{i-1}, t, a_{i+1}, \dots, a_n)$ is called a *parameter curve* in the i^{th} direction. Given n vector fields X_1, \dots, X_n defined in a neighborhood of $p \in M$ and linearly independent at p , we know that there is usually no immersion $f: U \rightarrow M$ with $p \in f(U)$, whose parameter curves in the i^{th} direction are the integral curves of the X_i —for we might not have $[X_i, X_j] = 0$. However, we might hope to find an immersion f for which the parameter curves in the i^{th} direction lie along the integral curves of the X_i , but have different parameterizations. A simple example (Problem 20) shows that even this modest hope cannot be fulfilled in dimension 3.

On the other hand, in the special case of dimension 2, such an imbedding can be found:

18. PROPOSITION. Let X_1, X_2 be linearly independent vector fields in a neighborhood of a point p in a 2-dimensional manifold M . Then there is an imbedding $f: U \rightarrow M$, where $U \subset \mathbb{R}^2$ is open and $p \in f(U)$, whose i^{th} parameter lines lie along the integral curves of X_i .

PROOF. We can assume that $p = 0 \in \mathbb{R}^2$, and that $X_i(0) = (e_i)_0$. Every point q in a sufficiently small neighborhood of 0 is on a unique integral curve of X_1 through a point $(0, x^2(q))$ —we proved precisely this fact in Theorem 7. Similarly, q is on a unique integral curve of X_2 through a point $(x^1(q), 0)$.

The map $q \mapsto (x^1(q), x^2(q))$ is C^∞ , with Jacobian equal to I at 0 (these facts also follow from the proof of Theorem 7). Its inverse, in a sufficiently small neighborhood of 0, is the required diffeomorphism. ♦

We can always compose f with a map of the form $(x, y) \mapsto (\alpha(x), \beta(y))$ for diffeomorphisms α and β of \mathbb{R} , which gives us considerable flexibility. If, for example, $C \subset \mathbb{R}^2$ is the graph of a monotone function g , then the map

$(x, y) \mapsto (x, g(y))$ takes the diagonal $\{(x, x)\}$ to C . Moreover, for any particular parameterization $c = (c_1, c_2): \mathbb{R} \rightarrow \mathbb{R}^2$ of C , we can further arrange that $c(t)$ maps to $(c(t), c(t))$, by composing with $(x, y) \mapsto (c_1^{-1}(x), y)$. Consequently, we can state

19. PROPOSITION. Let X_1, X_2 be linearly independent vector fields in a neighborhood of a point p in a 2-dimensional manifold M , and let c be a curve in M with $c(0) = p$ and $c'(t)$ never a multiple of X_1 or X_2 . Then there is an imbedding $f: U \rightarrow M$, where $U \subset \mathbb{R}^2$ is open and $p \in f(U)$, whose i^{th} parameter lines lie along the integral curves of X_i , and for which $f(t, t) = c(t)$.

PROBLEMS

1. (a) If $\alpha: M \rightarrow N$ is C^∞ , then $\alpha_*: TM \rightarrow TN$ is C^∞ .
 (b) If $\alpha: M \rightarrow N$ is a diffeomorphism, and X is a C^∞ vector field on M , then α_*X is a C^∞ vector field on N .
 (c) If $\alpha: \mathbb{R} \rightarrow \mathbb{R}$ is $\alpha(t) = t^3$, then there is a C^∞ vector field X on \mathbb{R} such that α_*X is not a C^∞ vector field.
2. Find a nowhere 0 vector field on \mathbb{R} such that all integral curves can be defined only on some interval around 0.
3. Find an example of a complete metric space (M, ρ) and a function $f: M \rightarrow M$ such that $\rho(f(x), f(y)) < \rho(x, y)$ for all $x, y \in M$, but f has no fixed point.
4. Let $f: (-c, c) \times U \times V \rightarrow \mathbb{R}^n$ be C^∞ , where $U, V \subset \mathbb{R}^n$ are open, and let $(x_0, y_0) \in U \times V$. Prove that there is a neighborhood W of (x_0, y_0) and a number $b > 0$ such that for each $(x, y) \in W$ there is a unique $\alpha = \alpha_{(x,y)}: (-b, b) \rightarrow U$ with $\alpha'(t) \in V$ for $t \in (-b, b)$ and

$$\begin{cases} \alpha''(t) = f(t, \alpha(t), \alpha'(t)) \\ \alpha(0) = x \\ \alpha'(0) = y. \end{cases}$$

Moreover, if we write $\alpha_{(x,y)}(t) = \alpha(t, x, y)$, then $\alpha: (-b, b) \times W \rightarrow U$ is C^∞ .
Hint: Consider the system of equations

$$\begin{aligned} \alpha'(t) &= \beta(t) \\ \beta'(t) &= f(t, \alpha(t), \beta(t)). \end{aligned}$$

5. We sometimes have to solve equations “depending on parameters”,

$$\begin{aligned} (*) \quad \frac{\partial}{\partial t} \alpha(t, y, x) &= f(t, y, \alpha(t, y, x)) \\ \alpha(0, y, x) &= x, \end{aligned}$$

where $f: (-c, c) \times V \times U \rightarrow \mathbb{R}^n$, for open $U \subset \mathbb{R}^n$ and $V \subset \mathbb{R}^m$, and we are solving for $\alpha_{(y,x)}: (-b, b) \rightarrow U$ for each initial condition x and “parameter” y . For example, the equation

$$\begin{aligned} \alpha'(t) &= y\alpha(t) \\ \alpha(0) &= x, \end{aligned}$$

with solution

$$\alpha(t) = xe^{yt},$$

is such a case.

(a) Define

$$\tilde{f}: (-c, c) \times V \times U \rightarrow \mathbb{R}^m \times \mathbb{R}^n$$

by

$$\tilde{f}(t, y, x) = (0, f(t, y, x)).$$

If $(\bar{\alpha}^1, \bar{\alpha}^2) = \bar{\alpha}: (-b, b) \times W \rightarrow \mathbb{R}^m \times \mathbb{R}^n$ is a flow for \tilde{f} in a neighborhood of (y_0, x_0) , so that

$$\begin{aligned} \frac{\partial}{\partial t} \bar{\alpha}(t, y, x) &= \tilde{f}(t, \bar{\alpha}(t, y, x)) \\ \bar{\alpha}(0, y, x) &= (y, x), \end{aligned}$$

show that we can write

$$\bar{\alpha}(t, y, x) = (y, \alpha(t, y, x))$$

for some α , and conclude that α satisfies (*).

(b) Show that equations of the form

$$\begin{aligned} (**) \quad \frac{\partial}{\partial t} \alpha(t, x) &= f(t, x, \alpha(t, x)) \\ \alpha(0, x) &= x \end{aligned}$$

can be reduced to equations of the form (*) (and thus to equations

$$\frac{\partial}{\partial t} \alpha(t, x) = f(\alpha(t, x)),$$

ultimately). [When one proves that a C^k function $f: U \rightarrow \mathbb{R}^n$ has a C^k flow $\alpha: (-b, b) \times W \rightarrow U$, the hard part is to prove that if f is C^1 , then α is differentiable with respect to the arguments in W , and that if the derivative with respect to these arguments is denoted by $D_2\alpha$, then

$$(***) \quad D_1 D_2 \alpha(t, x) = D_2 f(\alpha(t, x)) \cdot D_2 \alpha(t, x)$$

(a result which follows directly from the original equation

$$D_1 \alpha(t, x) = f(\alpha(t, x))$$

if f is C^2 , since $D_1 D_2 = D_2 D_1$). Since (***) is an equation for $D_2 \alpha$ of the form (**), it follows that $D_2 \alpha$ is differentiable if $D_2 f$ is C^1 , i.e., if f is C^2 . Differentiability of class C^k is then proved similarly, by induction.]

6. (a) Consider a linear differential equation

$$\alpha'(t) = g(t)\alpha(t),$$

where $g: \mathbb{R} \rightarrow \mathbb{R}$, so that we are solving for a real-valued function α . Show that all solutions are multiples of

$$\alpha(t) = e^{\int g(t) dt},$$

where $\int g(t) dt$ denotes some function G with $G'(t) = g$ (one can obtain all *positive* multiples simply by changing G). The remainder of this problem investigates the extent to which similar results hold for a system of linear differential equations.

(b) Let $A = (a_{ij})$ be an $n \times n$ matrix, and let $|A|$ denote the maximum of all $|a_{ij}|$. Show that

$$|A + B| \leq |A| + |B|$$

$$|AB| \leq n|A| \cdot |B|.$$

(c) Conclude that the infinite series of $n \times n$ matrices

$$\exp A = e^A = I + A + \frac{A^2}{2!} + \frac{A^3}{3!} + \frac{A^4}{4!} + \cdots$$

converges absolutely [in the sense that the $(i, j)^{\text{th}}$ entry of the partial sums converge absolutely for each (i, j)] and uniformly in any bounded set.

(d) Show that

$$\exp(TAT^{-1}) = T(\exp A)T^{-1}.$$

(e) If $AB = BA$, then

$$\exp(A + B) = (\exp A)(\exp B).$$

Hint: Write

$$\sum_{p=0}^{2N} \frac{(A+B)^p}{p!} = \left(\sum_{p=0}^N \frac{A^p}{p!} \right) \left(\sum_{p=0}^N \frac{B^p}{p!} \right) + R_N$$

and show that $|R_N| \rightarrow 0$ as $N \rightarrow \infty$.

(f) $(\exp A)(\exp -A) = I$, so $\exp A$ is always invertible.

(g) The map \exp , considered as a map $\exp: \mathbb{R}^{n^2} \rightarrow \mathbb{R}^{n^2}$, is clearly differentiable (it is even analytic). Show that

$$\exp'(0)(B) = B \quad (= \exp(0) \cdot B).$$

(Notice that for $|A|$, the usual norm of $A \in \mathbb{R}^{n^2}$, we have $|A| \leq |A| \leq n|A|$.)

(h) Use the limit established in part (g) to show that $\exp'(A)(B) = \exp(A) \cdot B$ if $AB = BA$.

(i) Let $A: \mathbb{R} \rightarrow \mathbb{R}^{n^2}$ be differentiable, and let

$$B(t) = \exp(A(t)).$$

If $B'(t)$ denotes the matrix whose entries are the derivatives of the entries of B , show that

$$B'(t) = A'(t) \cdot \exp(A(t)),$$

provided that $A(t)A'(t) = A'(t)A(t)$. (This is clearly true if $A(s)A(t) = A(t)A(s)$ for all s, t .)

(j) Show that the linear differential equation

$$\alpha'(t) = g(t) \cdot \alpha(t)$$

has the solution

$$\alpha(t) = \exp\left(\int_0^t g(s) ds\right)$$

provided that $g(s)g(t) = g(t)g(s)$ for all s, t . (This certainly happens when $g(t)$ is a constant matrix A , so every system of linear equations with constant coefficients can be solved explicitly—the exponential of $\int_0^t g(s) ds = tA$ can be found by putting A in Jordan canonical form.)

7. Check that if the coordinate system x is $x = \chi^{-1}$, for $\chi: \mathbb{R}^n \rightarrow M$, then $X = \partial/\partial x^1$ is equivalent to $\chi_*(\partial/\partial t^1) = X \circ \chi$.

8. (a) Let M and N be C^∞ manifolds. For a C^∞ function $f: M \times N \rightarrow \mathbb{R}$ and $q \in N$, let $f(\cdot, q)$ denote the function from M to \mathbb{R} defined by

$$p \mapsto f(p, q).$$

If (x, U) is a coordinate system on M , show that the function $\partial f/\partial x^i$, defined by

$$\frac{\partial f}{\partial x^i}(p, q) = \frac{\partial(f(\cdot, q))}{\partial x^i}(p),$$

is a C^∞ function on $M \times N$.

(b) If $\phi: (-\varepsilon, \varepsilon) \times M \rightarrow M$ is a 1-parameter group of diffeomorphisms, show that for every C^∞ function $f: M \rightarrow \mathbb{R}$, the limit

$$\lim_{h \rightarrow 0} \frac{1}{h} [f(\phi_h(p)) - f(p)]$$

exists, and defines a C^∞ function on M .

(c) If $\phi_*: (-\varepsilon, \varepsilon) \times TM \rightarrow TM$ is defined by

$$\phi_*(t, v) = \phi_{t*}(v),$$

show that ϕ_* is C^∞ , and conclude that for every C^∞ vector field X and covariant vector field ω on M , the limit

$$\lim_{h \rightarrow 0} \frac{1}{h} [(\phi_h^* \omega)(X_p) - \omega(X_p)]$$

exists and defines a C^∞ function on M .

(d) Treat $L_X Y$ similarly.

9. Give the argument to show that $\phi_{h*} Y_{\phi_{-h}(p)} \rightarrow Y_p$ in the proof of Proposition 8.

10. (a) Prove that

$$\begin{aligned} L_X(f \cdot \omega) &= Xf \cdot \omega + f \cdot L_X \omega \\ L_X[\omega(Y)] &= (L_X \omega)(Y) + \omega(L_X Y). \end{aligned}$$

(b) How would Proposition 8 have to be changed if we had defined $(L_X Y)(p)$ as

$$\lim_{h \rightarrow 0} \frac{1}{h} [(\phi_h^* Y)_p - Y_p]?$$

11. (a) Show that

$$\phi^*(df)(Y) = Y(f \circ \phi).$$

(b) Using (a), show directly from the definition of L_X that for $Y \in M_p$,

$$[L_X df(p)](Y_p) = Y_p(L_X f),$$

and conclude that

$$L_X df = d(L_X f).$$

The formula for $L_X dx^i$, derived in the text, is just a special case derived in an unnecessarily clumsy way. In the next part we get a much simpler proof that $L_X Y = [X, Y]$, using the technique which appeared in the proof of Proposition 15.

(c) Let X and Y be vector fields on M , and $f: M \rightarrow \mathbb{R}$ a C^∞ function. If X generates $\{\phi_t\}$, define

$$\alpha(t, h) = Y_{\phi_{-t}(p)}(f \circ \phi_h).$$

Show that

$$D_1\alpha(0,0) = -X_p(Yf)$$

$$D_2\alpha(0,0) = Y_p(Xf).$$

Conclude that for $c(h) = \alpha(h, h)$ we have

$$-c'(0) = L_X Y(p)(f) = [X, Y]_p(f).$$

12. Check the Jacobi identity.

13. On \mathbb{R}^3 let X, Y, Z be the vector fields

$$X = z \frac{\partial}{\partial y} - y \frac{\partial}{\partial z}$$

$$Y = -z \frac{\partial}{\partial x} + x \frac{\partial}{\partial z}$$

$$Z = y \frac{\partial}{\partial x} - x \frac{\partial}{\partial y}.$$

(a) Show that the map

$$aX + bY + cZ \mapsto (a, b, c) \in \mathbb{R}^3$$

is an isomorphism (from a certain set of vector fields to \mathbb{R}^3) and that $[U, V] \mapsto$ the cross-product of the images of U and V .

(b) Show that the flow of $aX + bY + cZ$ is a rotation of \mathbb{R}^3 about some axis through 0.

14. If A is a tensor field of type $\binom{k}{l}$ on N and $\phi: M \rightarrow N$ is a diffeomorphism, we define ϕ^*A on M as follows. If $v_1, \dots, v_k \in M_p$, and $\lambda_1, \dots, \lambda_l \in M_p^*$, then

$$\begin{aligned} [\phi^*A(p)](v_1, \dots, v_k, \lambda_1, \dots, \lambda_l) \\ = A(\phi(p))(\phi_*v_1, \dots, \phi_*v_k, (\phi^{-1})^*\lambda_1, \dots, (\phi^{-1})^*\lambda_l). \end{aligned}$$

(a) Check that under the identification of a vector field [or covariant vector field] with a tensor field of type $\binom{0}{1}$ [or type $\binom{1}{0}$] this agrees with our old ϕ^*Y .

(b) If the vector field X on M generates $\{\phi_t\}$, and A is a tensor field of type $\binom{k}{l}$ on M , we define

$$(L_X A)(p) = \lim_{h \rightarrow 0} \frac{1}{h} [(\phi_h^* A)(p) - A(p)].$$

Show that

$$\begin{aligned} L_X(A + B) &= L_X A + L_X B \\ L_X(A \otimes B) &= (L_X A) \otimes B + A \otimes L_X B \end{aligned}$$

(so that

$$L_X(fA) = X(f)A + fL_X A,$$

in particular).

(c) Show that

$$L_{X_1+X_2} A = L_{X_1} A + L_{X_2} A.$$

Hint: We already know that it is true for A of type $\begin{pmatrix} 0 \\ 0 \end{pmatrix}$, $\begin{pmatrix} 0 \\ 1 \end{pmatrix}$, $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$.

(d) Let

$$C: \mathcal{T}_l^k(V) \rightarrow \mathcal{T}_{l-1}^{k-1}(V)$$

be any contraction

$$(CT)(v_1, \dots, v_{k-1}, \lambda_1, \dots, \lambda_{l-1})$$

= contraction of

$$(v, \lambda) \mapsto T(v_1, \dots, v_{\alpha-1}, v, v_{\alpha+1}, \dots, v_{k-1}, \lambda_1, \dots, \lambda_{\beta-1}, \lambda, \lambda_{\beta+1}, \dots, \lambda_{l-1}).$$

Show that

$$L_X(CA) = C(L_X A).$$

(e) Noting that $A(X_1, \dots, X_k, \omega_1, \dots, \omega_l)$ can be obtained by applying contractions repeatedly to $A \otimes X_1 \otimes \dots \otimes X_k \otimes \omega_1 \otimes \dots \otimes \omega_l$, use (d) to show that

$$\begin{aligned} L_X(A(X_1, \dots, X_k, \omega_1, \dots, \omega_l)) \\ &= (L_X A)(X_1, \dots, X_k, \omega_1, \dots, \omega_l) \\ &\quad + \sum_{i=1}^k A(X_1, \dots, L_X X_i, \dots, X_k, \omega_1, \dots, \omega_l) \\ &\quad + \sum_{i=1}^l A(X_1, \dots, X_k, \omega_1, \dots, L_X \omega_i, \dots, \omega_l). \end{aligned}$$

(f) If A has components $A_{i_1 \dots i_k}^{j_1 \dots j_l}$ in a coordinate system x and $X = \sum_{i=1}^n a^i \partial / \partial x^i$, show that the coordinates of $L_X A$ are given by

$$\begin{aligned} (L_X A)_{i_1 \dots i_k}^{j_1 \dots j_l} &= \sum_{i=1}^n a^i \frac{\partial A_{i_1 \dots i_k}^{j_1 \dots j_l}}{\partial x^i} - \sum_{\alpha=1}^k \sum_{j=1}^n A_{i_1 \dots i_k}^{j_1 \dots j_{\alpha-1} j j_{\alpha+1} \dots j_l} \frac{\partial a^{j_{\alpha}}}{\partial x^j} \\ &\quad + \sum_{\alpha=1}^l \sum_{i=1}^n A_{i_1 \dots i_{\alpha-1} i i_{\alpha+1} \dots i_k}^{j_1 \dots j_l} \frac{\partial a^{j_{\alpha}}}{\partial x^i}. \end{aligned}$$

15. Let D be an operator taking the C^∞ functions \mathcal{F} to \mathcal{F} , and the C^∞ vector fields \mathcal{V} to \mathcal{V} , such that $D: \mathcal{F} \rightarrow \mathcal{F}$ and $D: \mathcal{V} \rightarrow \mathcal{V}$ are linear over \mathbb{R} and

$$D(fY) = f \cdot DY + Df \cdot Y.$$

(a) Show that D has a unique extension to an operator taking tensor fields of type $\binom{k}{l}$ to themselves, such that

- (1) D is linear over \mathbb{R}
- (2) $D(A \otimes B) = DA \otimes B + A \otimes DB$
- (3) for any contraction C , $DC = CD$.

If we take $Df = Xf$ and $DY = L_X Y$, then this unique extension is L_X .

(b) Let A be a tensor field of type $\binom{1}{1}$, so that we can consider $A(p) \in \text{End}(M_p)$; then $A(X)$ is a vector field for each vector field X . Show that if we define $D_A f = 0$, $D_A X = A(X)$, then D_A has a unique extension satisfying (1), (2), and (3).

(c) Show that

$$(D_A \omega)(p) = -A(p)^*(\omega(p)).$$

(d) Show that

$$L_f X = f L_X - D_{X \otimes df}.$$

Hint: Check this for functions and vector fields first.

(e) If T is of type $\binom{2}{1}$, show that

$$(D_A T)_k^{ij} = \sum_{\alpha=1}^n T_k^{\alpha j} A_\alpha^i + \sum_{\alpha=1}^n T_k^{i\alpha} A_\alpha^j - \sum_{\alpha=1}^n T_\alpha^{ij} A_k^\alpha.$$

Generalize to tensors of type $\binom{k}{l}$.

16. (a) Let $f: \mathbb{R} \rightarrow \mathbb{R}$ satisfy $f'(0) = 0$. Define $g(t) = f(\sqrt{t})$ for $t \geq 0$. Show that the right-hand derivative

$$g'_+(0) = \lim_{h \rightarrow 0^+} \frac{g(h) - g(0)}{h} = \frac{f''(0)}{2}.$$

(Use Taylor's Theorem.)

(b) Given $c: \mathbb{R} \rightarrow M$ with $c'(0) = 0 \in M_p$, define $\gamma(t) = c(\sqrt{t})$ for $t \geq 0$. Show that the tangent vector $c''(0)$ defined by $c''(0)(f) = (f \circ c)''(0)$ can also be described by $c''(0) = 2\gamma'(0)$.

17. (a) Let $f: M \rightarrow \mathbb{R}$ have p as a critical point, so that $f_{*p} = 0$. Given vectors $X_p, Y_p \in M_p$, choose vector fields \tilde{X}, \tilde{Y} with $\tilde{X}_p = X_p$ and $\tilde{Y}_p = Y_p$. Define

$$f_{**}(X_p, Y_p) = \tilde{X}_p(\tilde{Y}f).$$

Using the fact that $[X, Y]_p(f) = 0$, show that $f_{**}(X_p, Y_p)$ is symmetric, and conclude that it is well-defined.

(b) Show that

$$f_{**}\left(\sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_p, \sum_{j=1}^n b^j \frac{\partial}{\partial x^j} \Big|_p\right) = \sum_{i,j=1}^n a^i b^j \frac{\partial^2 f}{\partial x^i \partial x^j}(p).$$

(c) The rank of $(\partial^2 f / \partial x^i \partial x^j(p))$ is independent of the coordinate system.

(d) Let $f: M \rightarrow N$ have p as a critical point. For $X_p, Y_p \in M$ and $g: N \rightarrow \mathbb{R}$ define

$$f_{**}(X, Y)(g) = \tilde{X}_p(\tilde{Y}(g \circ f)).$$

Show that

$$f_{**}: M_p \times M_p \rightarrow N_{f(p)}$$

is a well-defined bilinear map.

(e) If $c: \mathbb{R} \rightarrow M$ has 0 as a critical point, show that

$$c_{**}(0): \mathbb{R}_0 \times \mathbb{R}_0 \rightarrow M_{c(0)}$$

takes $(1_0, 1_0)$ to the tangent vector $c''(0)$ defined by $c''(0)(f) = (f \circ c)''(0)$.

18. Let c be the curve of Theorems 15 and 16. If x is a coordinate system around p with $x(p) = 0$, and

$$[X, Y]_p = \sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_p,$$

show that

$$x^i(c(t)) = a^i t^2 + o(t^2),$$

where $o(t^2)$ denotes a function such that

$$\lim_{t \rightarrow 0} o(t^2)/t^2 = 0.$$

19. (a) If M is compact and 0 is a regular value of $f: M \rightarrow \mathbb{R}$, then there is a neighborhood U of $0 \in \mathbb{R}$ such that $f^{-1}(U)$ is diffeomorphic to $f^{-1}(0) \times U$,

by a diffeomorphism $\phi: f^{-1}(0) \times U \rightarrow f^{-1}(U)$ with $f(\phi(p, t)) = t$. *Hint:* Use Theorem 7 and a partition of unity to construct a vector field X on a neighborhood of $f^{-1}(0)$ such that $f_*X = d/dt$.

(b) More generally, if M is compact and $q \in N$ is a regular value of $f: M \rightarrow N$, then there is a neighborhood U of q and a diffeomorphism $\phi: f^{-1}(q) \times U \rightarrow f^{-1}(U)$ with $f(\phi(p, q')) = q'$.

(c) It follows from (b) that if all points of N are regular values, then $f^{-1}(q_1)$ and $f^{-1}(q_2)$ are diffeomorphic for q_1, q_2 sufficiently close. If f is onto N , does it follow that M is diffeomorphic to $f^{-1}(q) \times N$?

20. In \mathbb{R}^3 , let Y and Z be unit vector fields always pointing along the y - and z -axes, respectively, and let X will be a vector field one of whose integral curves is the x -axis, while certain other integral curves are parabolas in the planes $y = \text{constant}$, as shown in the first part of the figure below. Using the second part of the figure, show that Proposition 18 does not hold in dimension 3.

CHAPTER 6

INTEGRAL MANIFOLDS

PROLOGUE

A mathematician's reputation rests on
the number of bad proofs he has given.
[Pioneer work is clumsy]

A. S. Besicovitch,
quoted in J. E. Littlewood,
A Mathematician's Miscellany

Beauty is the first test: there is no
permanent place in the world for
ugly mathematics.

G. H. Hardy,
A Mathematician's Apology

In the previous chapter, we have seen that the integral curves of a vector field on a manifold M may be definable only for some small time interval, even though the vector field is C^∞ on all of M . We will now vary our question a little, so that global results can be obtained. Instead of a vector field, suppose that for each $p \in M$ we have a 1-dimensional subspace $\Delta_p \subset M_p$. The function Δ is called a **1-dimensional distribution** (this kind of distribution has nothing whatsoever to do with the distributions of analysis, which include such things as the “ δ -function”). Then Δ is spanned by a vector field *locally*; that is, we can choose (in many possible ways) a vector field X such that $0 \neq X_q \in \Delta_q$ for all q in some open set around p . We call Δ a C^∞ distribution if such a vector field X can be chosen to be C^∞ in a neighborhood of each point.

For a 1-dimensional distribution the notion of an integral curve makes no sense, but we define a (1-dimensional) submanifold N of M to be an **integral manifold** of Δ if for every $p \in N$ we have

$$i_*(N_p) = \Delta_p \quad \text{where} \quad i: N \rightarrow M \quad \text{is the inclusion map.}$$

For a given $p \in M$, we can always find an integral manifold N of a C^∞ distribution Δ with $p \in N$; we just choose a vector field X with $0 \neq X_q \in \Delta_q$ for q in a neighborhood of p , find an integral curve c of X with initial condition $c(0) = p$, and then forget about the parameterization of c , by defining N to be $\{c(t)\}$. This argument actually shows that for every $p \in M$ there is a coordinate system (x, U) such that for each fixed set of numbers a^2, \dots, a^n , the set

$$\{q \in U : x^2(q) = a^2, \dots, x^n(q) = a^n\}$$

is an integral manifold of Δ on U , and that these are the only integral manifolds in U .

This is still a local result, but because we are dealing with submanifolds, rather than curves with a particular parameterization, we can join overlapping integral submanifolds together. The entire manifold M can be written as a disjoint union of connected integral submanifolds of Δ , which locally look like

(rather than like

or something even more complicated). For example, there is a distribution on the torus whose integral manifolds all look like the dense 1-dimensional

submanifold pictured in Chapter 2. On the other hand, there is a distribution on the torus which has one compact connected integral manifold, and all other

integral manifolds non-compact. It happens that the integral manifolds of these two distributions are also the integral curves for certain vector fields, but on the

Möbius strip there is a distribution which is spanned by a vector field only locally.

We are leaving out the details involved in fitting together these local integral manifolds because we will eventually do this over again in the higher dimensional case. For the moment we will investigate higher dimensional cases only locally.

A k -dimensional distribution on M is a function $p \mapsto \Delta_p$, where $\Delta_p \subset M_p$ is a k -dimensional subspace of M_p . For any $p \in M$ there is a neighborhood U and k vector fields X_1, \dots, X_k such that $X_1(q), \dots, X_k(q)$ are a basis for Δ_q , for each $q \in U$. We call Δ a C^∞ distribution if it is possible to choose C^∞ vector fields X_1, \dots, X_k with this property, in a neighborhood of each point p . A (k -dimensional) submanifold N of M is called an **integral manifold** of Δ if for every $p \in N$ we have

$$i_*(N_p) = \Delta_p \quad \text{where} \quad i: N \rightarrow M \quad \text{is the inclusion map.}$$

Although the definitions given so far all look the same as the 1-dimensional case, the results will look very different. In general, integral manifolds *do not exist*, even locally.

As the simplest example, consider the 2-dimensional distribution Δ in \mathbb{R}^3 for which $\Delta_p = \Delta_{(a,b,c)}$ is spanned by

$$\left. \frac{\partial}{\partial x} \right|_p + b \left. \frac{\partial}{\partial z} \right|_p \quad \text{and} \quad \left. \frac{\partial}{\partial y} \right|_p.$$

Thus

$$\Delta_p = \left\{ r \left. \frac{\partial}{\partial x} \right|_p + s \left. \frac{\partial}{\partial y} \right|_p + br \left. \frac{\partial}{\partial z} \right|_p : r, s \in \mathbb{R} \right\}.$$

If we identify $T\mathbb{R}^3$ with $\mathbb{R}^3 \times \mathbb{R}^3$, then Δ_p consists of all $(r, s, br)_p$. Thus Δ_p may be pictured as the plane with the equation

$$z - c = b(x - a).$$

The figure below shows Δ_p for points $p = (a, b, 0)$. The plane $\Delta_{(a,b,c)}$ through (a, b, c) is just parallel to the one through $(a, b, 0)$.

If you can picture this distribution, you can probably see that it has no integral manifolds; a proof can be given as follows. Suppose there were an integral manifold N of Δ with $0 \in N$. The intersection of N and $\{(0, y, z)\}$ would be a curve γ in the (y, z) -plane through 0 whose tangent vectors would have to lie in the intersection of $\Delta_{(0,y,z)}$ and the (y, z) -plane. The only such vectors have third component 0 , so γ must be the y -axis. Now consider, for each fixed y_0 , the intersection $N \cap \{(x, y_0, z)\}$. This will be a curve in the plane $\{(x, y_0, z)\}$ through $(0, y_0, 0)$, with all tangent vectors having slope y_0 , so it must be the line $\{(x, y_0, y_0 x)\}$. Our integral manifold would have to look like the following picture. But this submanifold does not work. For example, its tangent space at $(1, 0, 0)$ contains vectors with third component non-zero.

To see in greater detail what is happening here, consider the somewhat more general case where $\Delta_{(a,b,c)} = \Delta_p$ is

$$\Delta_p = \left\{ r \frac{\partial}{\partial x} \Big|_p + s \frac{\partial}{\partial y} \Big|_p + [rf(a,b) + sg(a,b)] \frac{\partial}{\partial z} \Big|_p : r, s \in \mathbb{R} \right\};$$

geometrically, Δ_p is the plane with the equation

$$z - c = f(a,b)(x - a) + g(a,b)(y - b).$$

As in the first example, the plane $\Delta_{(a,b,c)}$ through (a,b,c) will be parallel to the one through $(a,b,0)$, since f and g depend only on a and b .

We now ask when the distribution Δ has an integral manifold N through each point. Since Δ_p is never perpendicular to the (x,y) -plane, the submanifold is given locally as the graph of a function:

$$N = \{(x, y, z) : z = \alpha(x, y)\}.$$

Now the tangent space at $p = (a, b, \alpha(a, b))$ is spanned by

$$\frac{\partial}{\partial x} \Big|_p + \frac{\partial \alpha}{\partial x}(a, b) \frac{\partial}{\partial z} \Big|_p,$$

$$\frac{\partial}{\partial y} \Big|_p + \frac{\partial \alpha}{\partial y}(a, b) \frac{\partial}{\partial z} \Big|_p.$$

These tangent vectors are in Δ_p if and only if

$$f(a, b) = \frac{\partial \alpha}{\partial x}(a, b),$$

$$g(a, b) = \frac{\partial \alpha}{\partial y}(a, b).$$

So we need to find a function $\alpha: \mathbb{R}^2 \rightarrow \mathbb{R}$ with

$$(*) \quad \frac{\partial \alpha}{\partial x} = f, \quad \frac{\partial \alpha}{\partial y} = g.$$

It is well-known that this is not always possible. By using the equality of mixed partial derivatives, we find a necessary condition on f and g :

$$(**) \quad \frac{\partial f}{\partial y} = \frac{\partial g}{\partial x}.$$

In our previous example,

$$\begin{aligned} f(a, b) &= b, & \frac{\partial f}{\partial y} &= 1, \\ g(a, b) &= 0, & \frac{\partial g}{\partial x} &= 0, \end{aligned}$$

so this necessary condition is not satisfied. It is also well-known that the necessary condition $(**)$ is *sufficient* for the existence of the function α satisfying $(*)$ in a neighborhood of any point.

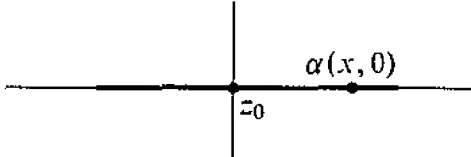

0. PROPOSITION. If $f, g: \mathbb{R}^2 \rightarrow \mathbb{R}$ satisfy

$$(**) \quad \frac{\partial f}{\partial y} = \frac{\partial g}{\partial x}$$

in a neighborhood of 0, and $z_0 \in \mathbb{R}$, then there is a function α , defined in a neighborhood of $0 \in \mathbb{R}^2$, such that

$$(*) \quad \begin{aligned} \alpha(0, 0) &= z_0 \\ \frac{\partial \alpha}{\partial x} &= f \\ \frac{\partial \alpha}{\partial y} &= g. \end{aligned}$$

PROOF. We first define $\alpha(x, 0)$ so that $\alpha(0, 0) = z_0$ and

$$(I) \quad \frac{\partial \alpha}{\partial x}(x, 0) = f(x, 0);$$

namely, we define

$$\alpha(x, 0) = z_0 + \int_0^x f(t, 0) dt.$$

Then, for each x , we define $\alpha(x, y)$ so that

$$(2) \quad \frac{\partial \alpha}{\partial y}(x, y) = g(x, y);$$

namely, we define

$$\begin{aligned} \alpha(x, y) &= \alpha(x, 0) + \int_0^y g(x, t) dt \\ &= z_0 + \int_0^x f(t, 0) dt + \int_0^y g(x, t) dt. \end{aligned}$$

This construction does not use (**), and always provide us with an α satisfying (2), $\partial\alpha/\partial y = g$. We claim that if (**) holds, then also $\partial\alpha/\partial x = f$. To prove this, consider, for each fixed x , the function

$$y \mapsto \frac{\partial \alpha}{\partial x}(x, y) - f(x, y).$$

This is 0 for $y = 0$ by (1). To prove that it equals 0 for all y , we just have to show that its derivative is 0. But its derivative at y is

$$\begin{aligned} \frac{\partial^2 \alpha}{\partial y \partial x}(x, y) - \frac{\partial f}{\partial y}(x, y) &= \frac{\partial}{\partial x} \left(\frac{\partial \alpha}{\partial y} \right)(x, y) - \frac{\partial f}{\partial y}(x, y) \\ &= \frac{\partial g}{\partial x}(x, y) - \frac{\partial f}{\partial y}(x, y) \quad \text{by (2)} \\ &= 0 \quad \text{by (**).} \quad \spadesuit \end{aligned}$$

We are now ready to look at essentially the most general case of a 2-dimensional distribution in \mathbb{R}^3 :

$$\Delta_p = \left\{ r \frac{\partial}{\partial x} \Big|_p + s \frac{\partial}{\partial y} \Big|_p + [rf(p) + sg(p)] \frac{\partial}{\partial z} \Big|_p : r, s \in \mathbb{R} \right\},$$

where $f, g: \mathbb{R}^3 \rightarrow \mathbb{R}$. Suppose that

$$N = \{(x, y, z) : z = \alpha(x, y)\}$$

is an integral manifold of Δ . The tangent space of N at $p = (a, b, \alpha(a, b))$ is spanned, once again, by

$$\begin{aligned} \frac{\partial}{\partial x} \Big|_p + \frac{\partial \alpha}{\partial x}(a, b) \frac{\partial}{\partial z} \Big|_p, \\ \frac{\partial}{\partial y} \Big|_p + \frac{\partial \alpha}{\partial y}(a, b) \frac{\partial}{\partial z} \Big|_p. \end{aligned}$$

These tangent vectors are in Δ_p if and only if

$$\begin{aligned} (*) \quad f(a, b, \alpha(a, b)) &= \frac{\partial \alpha}{\partial x}(a, b), \\ g(a, b, \alpha(a, b)) &= \frac{\partial \alpha}{\partial y}(a, b). \end{aligned}$$

In order to obtain necessary conditions for the existence of such a function α , we again use the equality of mixed partial derivatives. Thus (*) and the chain rule imply that

$$\begin{aligned} \frac{\partial^2 \alpha}{\partial y \partial x}(a, b) &= \frac{\partial f}{\partial y}(a, b, \alpha(a, b)) + \frac{\partial f}{\partial z}(a, b, \alpha(a, b)) \cdot \frac{\partial \alpha}{\partial y}(a, b) \\ &\parallel \\ \frac{\partial^2 \alpha}{\partial x \partial y}(a, b) &= \frac{\partial g}{\partial x}(a, b, \alpha(a, b)) + \frac{\partial g}{\partial z}(a, b, \alpha(a, b)) \cdot \frac{\partial \alpha}{\partial y}(a, b). \end{aligned}$$

This condition is not very useful, since it still involves the unknown function α , but we can substitute from (*) to obtain

$$\begin{aligned} \frac{\partial f}{\partial y}(a, b, \alpha(a, b)) + \frac{\partial f}{\partial z}(a, b, \alpha(a, b)) \cdot g(a, b, \alpha(a, b)) \\ = \frac{\partial g}{\partial x}(a, b, \alpha(a, b)) + \frac{\partial g}{\partial z}(a, b, \alpha(a, b)) \cdot f(a, b, \alpha(a, b)). \end{aligned}$$

Now we are looking for conditions which will be satisfied by f and g when there is an integral manifold of Δ *through every point*, which means that for each pair (a, b) these equations must hold no matter what $\alpha(a, b)$ is. Thus we obtain finally the necessary condition

$$(**) \quad \frac{\partial f}{\partial y} + \frac{\partial f}{\partial z} \cdot g = \frac{\partial g}{\partial x} + \frac{\partial g}{\partial z} \cdot f.$$

In this more general case, the necessary condition again turns out to be sufficient. In fact, there is no need to restrict ourselves to equations for a single function defined on \mathbb{R}^2 ; we can treat a system of partial differential equations for n functions on \mathbb{R}^m (i.e., a partial differential equation for a function from \mathbb{R}^m to \mathbb{R}^n). In the following theorem, we will use t to denote points in \mathbb{R}^m and x for points in \mathbb{R}^n ; so for a function $f: \mathbb{R}^m \times \mathbb{R}^n \rightarrow \mathbb{R}^k$ we use

$$\begin{aligned} \frac{\partial f}{\partial t^i} & \quad \text{for } D_i f, \\ \frac{\partial f}{\partial x^i} & \quad \text{for } D_{m+i} f. \end{aligned}$$

1. THEOREM. Let $U \times V \subset \mathbb{R}^m \times \mathbb{R}^n$ be open, where U is a neighborhood of $0 \in \mathbb{R}^m$, and let $f_i: U \times V \rightarrow \mathbb{R}^n$ be C^∞ functions, for $i = 1, \dots, m$. Then for every $x \in V$, there is at most one function

$$\alpha: W \rightarrow V,$$

defined in a neighborhood W of 0 in \mathbb{R}^m , satisfying

$$(*) \quad \begin{aligned} \alpha(0) &= x \\ \frac{\partial \alpha}{\partial t^j}(t) &= f_j(t, \alpha(t)) \quad \text{for all } t \in W. \end{aligned}$$

(More precisely, any two such functions α_1 and α_2 , defined on W_1 and W_2 , agree on the component of $W_1 \cap W_2$ which contains 0 .) Moreover, such a function exists (and is automatically C^∞) in some neighborhood W if and only if there is a neighborhood of $(0, x) \in U \times V$ on which

$$(**) \quad \frac{\partial f_j}{\partial t^i} - \frac{\partial f_i}{\partial t^j} + \sum_{k=1}^n \frac{\partial f_j}{\partial x^k} f_i^k - \sum_{k=1}^n \frac{\partial f_i}{\partial x^k} f_j^k = 0 \quad i, j = 1, \dots, m.$$

PROOF. Uniqueness will be obvious from the proof of existence. Necessity of the conditions (**) is left to the reader as a simple exercise, and we will concern ourselves with proving existence if these conditions do hold. The proof will be like that of Proposition 0, with a different twist at the end.

We first want to define $\alpha(t, 0, \dots, 0)$ so that

$$(I) \quad \begin{aligned} \alpha(0, 0, \dots, 0) &= x \\ \frac{\partial \alpha}{\partial t^1}(t, 0, \dots, 0) &= f_1(t, 0, \dots, 0, \alpha(t, 0, \dots, 0)). \end{aligned}$$

To do this, we consider the ordinary differential equation

$$\begin{aligned}\beta_1(0) &= x \\ \beta_1'(t) &= f_1(t, 0, \dots, 0, \beta_1(t)).\end{aligned}$$

This equation has a unique solution, defined for $|t| < \varepsilon_1$. Define

$$\alpha(t, 0, \dots, 0) = \beta_1(t) \quad |t| < \varepsilon_1.$$

Then (1) holds for $|t| < \varepsilon_1$.

Now for each fixed t^1 with $|t^1| < \varepsilon_1$, consider the equation

$$\begin{aligned}\beta_2(0) &= \alpha(t^1, 0, \dots, 0) \\ \beta_2'(t) &= f_2(t^1, t, 0, \dots, 0, \beta_2(t)).\end{aligned}$$

This has a unique solution for sufficiently small t . At this point the reader must refer back to Theorem 5-2, and verify the following assertion: If we choose ε_1 sufficiently small, then for $|t^1| < \varepsilon_1$ the solutions of the equations for β_2 with the initial conditions $\beta_2(0) = \alpha(t^1, 0, \dots, 0)$ will each be defined for $|t| < \varepsilon_2$ for some $\varepsilon_2 > 0$. We then define

$$\alpha(t^1, t, 0, \dots, 0) = \beta_2(t) \quad |t^1| < \varepsilon_1, |t| < \varepsilon_2.$$

Then

$$\begin{aligned}\alpha(0, 0, 0, \dots, 0) &= x \\ (2) \quad \frac{\partial \alpha}{\partial t^2}(t^1, t, 0, \dots, 0) &= f_2(t^1, t, 0, \dots, 0, \alpha(t^1, t, 0, \dots, 0)) \\ &\quad |t^1| < \varepsilon_1, |t| < \varepsilon_2.\end{aligned}$$

We claim that for each fixed t^1 with $|t^1| < \varepsilon_1$ we also have, for all t with $|t| < \varepsilon_2$,

$$(3) \quad 0 = g(t) = \frac{\partial \alpha}{\partial t^1}(t^1, t, 0, \dots, 0) - f_1(t^1, t, 0, \dots, 0, \alpha(t^1, t, 0, \dots, 0)).$$

Note first that

$$(4) \quad g(0) = 0 \quad \text{by (1).}$$

We now derive an equation for $g'(t)$. In the following, all expressions involving α are to be evaluated at $(t^1, t, 0, \dots, 0)$ and all expressions involving f_i are to be evaluated at $(t^1, t, 0, \dots, 0, \alpha(t^1, t, 0, \dots, 0))$. We have

$$g'(t) = \frac{\partial^2 \alpha}{\partial t^2 \partial t^1} - \frac{\partial f_1}{\partial t^2} - \sum_{k=1}^n \frac{\partial f_1}{\partial x^k} \frac{\partial \alpha^k}{\partial t^2},$$

and thus

$$\begin{aligned}
 (5) \quad g'(t) &= \frac{\partial}{\partial t^1} \left(\frac{\partial \alpha}{\partial t^2} \right) - \frac{\partial f_1}{\partial t^2} - \sum_{k=1}^n \frac{\partial f_1}{\partial x^k} f_2^k && \text{by (2)} \\
 &= \frac{\partial f_2}{\partial t^1} + \sum_{k=1}^n \frac{\partial f_2}{\partial x^k} \frac{\partial \alpha^k}{\partial t^1} - \frac{\partial f_1}{\partial t^2} - \sum_{k=1}^n \frac{\partial f_1}{\partial x^k} f_2^k && \text{by (2) again} \\
 &= \frac{\partial f_2}{\partial t^1} + \sum_{k=1}^n \frac{\partial f_2}{\partial x^k} [g^k(t) + f_1^k] \\
 &\quad - \frac{\partial f_1}{\partial t^2} - \sum_{k=1}^n \frac{\partial f_1}{\partial x^k} f_2^k && \text{by definition, (3)} \\
 &= \sum_{k=1}^n \frac{\partial f_2}{\partial x^k} g^k(t) && \text{by (**).}
 \end{aligned}$$

Now equation (5) is a differential equation with a unique solution for each initial condition. The solution with initial condition $g(0) = 0$, given by (4), is clearly $g(t) = 0$ for all t . So (3) is true.

It is a simple exercise to continue the definition of α until it is eventually defined on $(-\varepsilon_1, \varepsilon_1) \times \cdots \times (-\varepsilon_n, \varepsilon_n)$ and satisfies (*). ♦

Theorem 1 essentially solves for us the problem of deciding which distributions have integral manifolds. Our investigation of the problem so far illustrates one basic fact about theorems in differential geometry:

Many of the fundamental theorems of differential geometry fall into one of two classes. The first kind of theorem says that if one has a certain nice situation (e.g., a distribution with integral submanifolds through every point) then certain other conditions hold; these conditions are obtained by setting mixed partials equal, and are called “integrability conditions”. The second kind of theorem justifies this terminology, by showing that the “integrability conditions” are sufficient for recovering the nice situation.

The remaining parts of our investigation, in which we will essentially begin anew, illustrates an even more important fact about the theorems of differential geometry:

There are always incredibly concise and elegant ways to state the integrability conditions, and prove their sufficiency, without ever even mentioning partial derivatives.

LOCAL THEORY

If $f: M \rightarrow N$ is a C^∞ function, and X and Y are C^∞ vector fields on M and N , respectively, we say that X and Y are f -related if $f_{*p}(X_p) = Y_{f(p)}$ for each $p \in M$. If $g: N \rightarrow \mathbb{R}$ is a C^∞ function, then

$$\begin{aligned} Y_{f(p)}(g) &= f_{*p}X_p(g) \\ &= X_p(g \circ f), \end{aligned}$$

so

$$(Yg) \circ f = X(f \circ g).$$

Conversely, if this is true for all C^∞ functions $g: N \rightarrow \mathbb{R}$, then X and Y are f -related.

Of course, a given vector field X may not be f -related to any vector field Y , nor must a given vector field Y be f -related to any vector field on M . In one case, the latter condition is fulfilled:

2. PROPOSITION. Let $f: M \rightarrow N$ be a C^∞ function such that f is an immersion. If Y is a C^∞ vector field on N with

$$Y_{f(p)} \in f_{*p}(M_p),$$

then there is a unique C^∞ vector field X on M which is f -related to Y .

PROOF. Clearly we must define X_p to be the unique element of M_p with $Y_{f(p)} = f_{*p}X_p$. To prove that X is C^∞ , we use Theorem 2-10(2): there are coordinate systems (x, U) around $p \in M$ and (y, V) around $f(p) \in N$ such that

$$y \circ f \circ x^{-1}(a^1, \dots, a^n) = (a^1, \dots, a^n, 0, \dots, 0).$$

This is easily seen to imply that

$$f_{*p} \left(\frac{\partial}{\partial x^i} \Big|_p \right) = \frac{\partial}{\partial y^i} \Big|_{f(p)}.$$

Thus if

$$Y = \sum_{i=1}^n \alpha^i \frac{\partial}{\partial y^i},$$

where α^i are C^∞ functions, then

$$X = \sum_{i=1}^n \beta^i \frac{\partial}{\partial x^i},$$

where $\alpha^i \circ f = \beta^i$. This implies that the functions β^i are C^∞ (Problem 3). ♦

The most important property of f -relatedness for us is the following:

3. PROPOSITION. If X_i and Y_i are f -related, for $i = 1, 2$, then $[X_1, X_2]$ and $[Y_1, Y_2]$ are f -related.

PROOF. If $g: N \rightarrow \mathbb{R}$ is C^∞ , then

$$(I) \quad (Y_i g) \circ f = X_i(g \circ f) \quad i = 1, 2.$$

So

$$\begin{aligned} \{[Y_1, Y_2]g\} \circ f &= \{Y_1(Y_2 g)\} \circ f - \{Y_2(Y_1 g)\} \circ f \\ &= X_1([Y_2 g] \circ f) - X_2([Y_1 g] \circ f) \\ &\quad \text{by (I), with } g \text{ replaced by } Y_2 g \text{ and } Y_1 g, \text{ respectively} \\ &= X_1(X_2(g \circ f)) - X_2(X_1(g \circ f)) \quad \text{by (I)} \\ &= [X_1, X_2](g \circ f). \quad \diamond \end{aligned}$$

Now consider a k -dimensional distribution Δ . We will say that a vector field X belongs to Δ if $X_p \in \Delta_p$ for all p . Suppose that N is an integral manifold of Δ , and $i: N \rightarrow M$ is the inclusion map. If X and Y are two vector fields which belong to Δ , then for all $p \in N$ there are unique $\bar{X}_p, \bar{Y}_p \in N_p$ such that

$$X_p = i_* \bar{X}_p, \quad Y_p = i_* \bar{Y}_p.$$

In other words, X and \bar{X} are i -related, and Y and \bar{Y} are i -related. Proposition 2 shows that \bar{X} and \bar{Y} are C^∞ vector fields on N , and Proposition 3 then shows that $[\bar{X}, \bar{Y}]$ and $[X, Y]$ are i -related. Thus

$$i_*[\bar{X}, \bar{Y}]_p = [X, Y]_p.$$

Here $[\bar{X}, \bar{Y}]_p \in N_p$; this therefore shows that $[X, Y]_p \in \Delta_p$. Consequently, if there is an integral manifold of Δ through every point p , then $[X, Y]$ also belongs to Δ .

For a moment look back at the distribution Δ in \mathbb{R}^3 given by

$$\Delta_p = \left\{ r \frac{\partial}{\partial x} \Big|_p + s \frac{\partial}{\partial y} \Big|_p + [rf(p) + sg(p)] \frac{\partial}{\partial z} \Big|_p : r, s \in \mathbb{R} \right\}.$$

The vector fields

$$X = \frac{\partial}{\partial x} + f \frac{\partial}{\partial z}$$

$$Y = \frac{\partial}{\partial y} + g \frac{\partial}{\partial z}$$

belong to Δ . Using the formula on page 156, we see that

$$[X, Y] = \left(\frac{\partial g}{\partial x} - \frac{\partial f}{\partial y} + f \frac{\partial g}{\partial z} - g \frac{\partial f}{\partial z} \right) \cdot \frac{\partial}{\partial z}.$$

This belongs to Δ only when the expression in parentheses is 0, which is precisely the condition for Δ to have an integral manifold through every point.

In general, Δ is called **integrable** if $[X, Y]$ belongs to Δ whenever X and Y belong to Δ . This condition can be checked fairly easily:

4. **PROPOSITION.** If X_1, \dots, X_k span Δ in a neighborhood U of p , then Δ is integrable on U if and only if each $[X_i, X_j]$ is a linear combination

$$[X_i, X_j] = \sum_{\alpha=1}^k C_{ij}^{\alpha} X_{\alpha}$$

for C^{∞} functions C_{ij}^{α} .

PROOF. Such functions clearly exist if Δ is integrable, since $[X_i, X_j]_q \in \Delta_q$, which is spanned by the $X_{\alpha}(q)$. Conversely, suppose such functions exist. If X and Y belong to Δ we can clearly write

$$X = \sum_{i=1}^k f_i X_i$$

$$Y = \sum_{i=1}^k g_i X_i.$$

To prove $[X, Y]$ belongs to Δ , it obviously suffices to treat each $[f_i X_i, g_j X_j]$ separately. Since we have

$$[fX, gY] = fg[X, Y] + f(Xg)Y - g(Yf)X,$$

clearly $[fX, gY]$ belongs to Δ if X, Y and $[X, Y]$ do. ♦

We are now ready for the main theorem. It is equivalent to Theorem 1; in fact, Theorem 1 can be derived from it (Problem 7). But the proof is quite different.

5. **THEOREM (THE FROBENIUS INTEGRABILITY THEOREM; FIRST VERSION).** Let Δ be a C^{∞} integrable k -dimensional distribution on M . For every $p \in M$ there is a coordinate system (x, U) with

$$x(p) = 0$$

$$x(U) = (-\varepsilon, \varepsilon) \times \dots \times (-\varepsilon, \varepsilon),$$

such that for each a^{k+1}, \dots, a^n with all $|a^i| < \varepsilon$, the set

$$\{q \in U : x^{k+1}(q) = a^{k+1}, \dots, x^n(q) = a^n\}$$

is an integral manifold of Δ .

Any connected integral manifold of Δ restricted to U is contained in one of these sets.

PROOF. We can clearly assume that we are in \mathbb{R}^n , with $p = 0$. Moreover, we can assume that $\Delta_0 \subset \mathbb{R}^n_0$ is spanned by

$$\left. \frac{\partial}{\partial t^1} \right|_0, \dots, \left. \frac{\partial}{\partial t^k} \right|_0.$$

Let $\pi: \mathbb{R}^n \rightarrow \mathbb{R}^k$ be projection onto the first k factors. Then $\pi_*: \Delta_0 \rightarrow \mathbb{R}^k_0$ is an isomorphism. By continuity, π_* is one-one on Δ_q for q near 0. So near 0, we can choose unique

$$X_1(q), \dots, X_k(q) \in \Delta_q$$

so that

$$\pi_* X_i(q) = \left. \frac{\partial}{\partial t^i} \right|_{\pi(q)} \quad i = 1, \dots, k.$$

Then the vector fields X_i (on a neighborhood of $0 \in \mathbb{R}^n$) and $\partial/\partial t^i$ (on \mathbb{R}^k) are π -related. By Proposition 3,

$$\begin{aligned} \pi_*[X_i, X_j]_q &= \left[\left. \frac{\partial}{\partial t^i} \right|, \left. \frac{\partial}{\partial t^j} \right| \right]_{\pi(q)} \\ &= 0. \end{aligned}$$

But, $[X_i, X_j]_q \in \Delta_q$ by assumption, and π_* is one-one on Δ_q . So $[X_i, X_j] = 0$. By Theorem 5-14, there is a coordinate system x such that

$$X_i = \frac{\partial}{\partial x^i} \quad i = 1, \dots, k.$$

The sets $\{q \in U: x^{k+1}(q) = a^{k+1}, \dots, x^n(q) = a^n\}$ are clearly integral manifolds of Δ , since their tangent spaces are spanned by the $\partial/\partial x^i = X_i$ for $i = 1, \dots, k$.

If N is a connected integral manifold of Δ restricted to U , with inclusion map $i: N \rightarrow U$, consider $d(x^m \circ i)$ for $k+1 \leq m \leq n$. For any tangent vector X_q of N_q we have

$$\begin{aligned} d(x^m \circ i)(X_q) &= X_q(x^m \circ i) = i_* X_q(x^m) \\ &= 0, \end{aligned}$$

since $i_* X_q \in \Delta_q$, which is spanned by the $\partial/\partial x^j|_q$ for $j = 1, \dots, k$. Thus $d(x^m \circ i) = 0$, which implies that $x^m \circ i$ is constant on the connected manifold N . ♦

GLOBAL THEORY

In order to express the global results succinctly, we introduce the following terminology.

If M is a C^∞ manifold, a (usually disconnected) k -dimensional submanifold N of M is called a **foliation** of M if every point of M is in (some component of) N , and if around every point $p \in M$ there is a coordinate system (x, U) , with

$$x(U) = (-\varepsilon, \varepsilon) \times \cdots \times (-\varepsilon, \varepsilon),$$

such that the components of $N \cap U$ are the sets of the form

$$\{q \in U : x^{k+1}(q) = a^{k+1}, \dots, x^n(q) = a^n\} \quad |a^i| < \varepsilon.$$

Each component of N is called a **folium** or **leaf** of the foliation N . Notice that two distinct components of $N \cap U$ might belong to the same leaf of the foliation.

6. THEOREM. Let Δ be a C^∞ k -dimensional integrable distribution on M . Then M is foliated by an integral manifold of Δ (each component is called a maximal **integral manifold** of Δ).

PROOF. Using Theorem 1-2, we see that we can cover M by a sequence of coordinate systems (x_i, U_i) satisfying the conditions of Theorem 5. For such a coordinate system (x, U) , let us call each set

$$\{q \in U : x^{k+1}(q) = a^{k+1}, \dots, x^n(q) = a^n\}$$

a *slice* of U .

It is possible for a single slice S of U_i to intersect U_j in more than one slice of U_j , as shown below. But $S \cap U_j$ has at most countably many components,

and each component is contained in a single slice of U_j by Theorem 5, so $S \cap U_j$ is contained in at most countably many slices of U_j .

Given $p \in M$, choose a coordinate system (x_0, U_0) with $p \in U_0$, and let S_0 be the slice of U_0 containing p . A slice S of some U_i will be called *joined* to p if there is a sequence

$$0 = i_0, i_1, \dots, i_l = i$$

and corresponding slices

$$S_0 = S_{i_0}, S_{i_1}, \dots, S_{i_l} = S$$

with

$$S_{i_\alpha} \cap S_{i_{\alpha+1}} \neq \emptyset \quad \alpha = 0, \dots, l-1.$$

Since there are at most countably many such sequences of slices for each sequence i_0, \dots, i_l , and only countably many such sequences, there are at most countably many slices joined to p . Using Problem 3-1, we see that the union of all such slices is a submanifold of M . For $q \neq p$, the corresponding union is either equal to, or totally disjoint from, the first union. Consequently, M is foliated by the disjoint union of all such submanifolds; this disjoint union is clearly an integral manifold of Δ . ♦

[If we are allowing non-metrizable manifolds, the proof is even easier, since we do not have to find a countable number of coordinate systems for each leaf, and can merely describe the topology of the foliation as the smallest one which makes each slice an open set. In this case, however, the discussion to follow will not be valid—in fact, Appendix A describes a non-paracompact manifold which is foliated by a lower-dimensional *connected* submanifold.]

Notice that if (x, U) is a coordinate system of the sort considered in the proof of the theorem, then infinitely many slices of U may belong to the same folium.

However, *at most countably many* slices can belong to the same folium; otherwise

this folium would contain an uncountable disjoint family of open sets. This allows us to apply a proposition from Chapter 2.

7. THEOREM. Let M be a C^∞ manifold, and M_1 a folium of the foliation determined by some distribution Δ . Let P be another C^∞ manifold and $f: P \rightarrow M$ a C^∞ function with $f(P) \subset M_1$. Then f is C^∞ considered as a map into M_1 .

PROOF. According to Proposition 2-11, it suffices to show that f is continuous as a map into M_1 . Given $p \in P$, choose a coordinate system (x, U) around $f(p)$ such that the slices

$$\{q \in U : x^{k+1}(q) = a^{k+1}, \dots, x^n(q) = a^n\}$$

are integral manifolds of Δ . Now f is continuous as a map into M , so f takes

some neighborhood W of p into U ; we can choose W to be connected. For $k+1 \leq i \leq n$, if we had $x^i(f(p')) \neq a^i$ for any $p' \in W$, then $x^i \circ f$ would take on all values between a^i and $x^i(f(p'))$, by continuity. This would mean that $f(W)$ contained points of uncountably many slices, contradicting the fact that $f(W) \subset M_1$.

Consequently, $x^i(f(p')) = a^i$ for all $p' \in W$. In other words, $f(W)$ is contained in the single slice of U which contains p . This makes it clear that f is continuous as a map into M_1 . ♦

PROBLEMS

1. (a) Let $\xi = \pi: E \rightarrow B$ be an n -plane bundle, and $\xi' = \pi': E' \rightarrow B$ a k -plane bundle such that $E' \subset E$. If $i: E' \rightarrow E$ is the inclusion map, and $1_B: B \rightarrow B$ the identity map, we say that ξ' is a **subbundle** of ξ if $(i, 1_B)$ is a bundle map. Show that a k -dimensional distribution on M is just a subbundle of TM .

(b) For the case of C^∞ bundles ξ and ξ' over a C^∞ manifold M , define a C^∞ subbundle, and show that a k -dimensional distribution is C^∞ if and only if it is a C^∞ subbundle.

2. (a) In the proof of Theorem 1, check the assertion about choosing ε_1 sufficiently small.

(b) Supply the proof of the uniqueness part of the theorem.

3. (a) In the proof of Proposition 2, show that

$$f_* \left(\frac{\partial}{\partial x^i} \Big|_p \right) = \frac{\partial}{\partial y^i} \Big|_{f(p)}.$$

(b) Complete the proof of Proposition 2 by showing that if

$$Y = \sum_{i=1}^n \alpha^i \frac{\partial}{\partial y^i},$$

so that

$$X = \sum_{i=1}^n \beta^i \frac{\partial}{\partial x^i},$$

with $\alpha^i \circ f = \beta^i$, then the functions β^i are C^∞ .

4. In the proof of Proposition 4, show that the functions C_{ij}^α actually are C^∞ .

5. Let $\Delta_1, \dots, \Delta_h$ be integrable distributions on M , of dimensions d_1, \dots, d_h . Suppose that for each $p \in M$,

$$M_p = (\Delta_1)_p \oplus \cdots \oplus (\Delta_h)_p.$$

Show that there is a coordinate system (x, U) around each point, such that Δ_1 is spanned by $\partial/\partial x^1, \dots, \partial/\partial x^{d_1}$, etc.

6. Prove Theorem 1 from Theorem 5, by considering the distribution Δ in $\mathbb{R}^m \times \mathbb{R}^n$ (with coordinates t, x), defined by

$$\Delta_p = \left\{ \sum_{i=1}^m r^i \frac{\partial}{\partial t^i} \Big|_p + \sum_{k=1}^n \left(\sum_{i=1}^m r^i f_i^k(p) \right) \frac{\partial}{\partial x^k} \Big|_p : r \in \mathbb{R}^m \right\}.$$

Notice that even when the f_j do not depend on x , so that the equations are of the form

$$\frac{\partial \alpha}{\partial t^j}(t) = f_j(t),$$

with the integrability conditions

$$\frac{\partial f_j}{\partial t^i} = \frac{\partial f_i}{\partial t^j},$$

we nevertheless work in $\mathbb{R}^m \times \mathbb{R}^n$, rather than \mathbb{R}^m . This is connected with the classical technique of “introducing new independent variables”.

7. This problem outlines another method of proving Theorem 1, by reducing the partial differential equations to ordinary equations along lines through the origin. A similar technique will be very important in Chapter II.7.

(a) If we want $\alpha(ut) = \beta(u, t)$ for some function $\beta: [0, \varepsilon) \times W \rightarrow V$, show that β must satisfy the equation

$$\begin{aligned} \frac{\partial \beta}{\partial u}(u, t) &= \sum_{j=1}^m t^j \cdot f_j(ut, \beta(u, t)) \\ \beta(0, t) &= x. \end{aligned}$$

We know that we can solve such equations (we need Problem 5-5, since the equation depends on the “parameter” $t \in \mathbb{R}^m$). One has to check that one ε can be picked which works for all $t \in W$.

(b) Show that

$$\beta(u, vt) = \beta(uv, t).$$

(Show that both functions satisfy the same differential equation as functions of u , with the same initial condition.) By shrinking W , we can consequently assume that $\varepsilon = 1$.

(c) Conclude that

$$\frac{\partial \beta}{\partial t^j}(v, t) = v \cdot \frac{\partial \beta}{\partial t^j}(1, vt).$$

(d) Use the integrability condition on f to show that

$$\frac{\partial \beta}{\partial t^j}(v, t) \quad \text{and} \quad v \cdot f_j(vt, \beta(v, t))$$

satisfy the same differential equation, as functions of v . Use (c) to conclude that the two functions are equal.

(e) Define $\alpha(t) = \beta(1, t)$. Noting that $\alpha(vt) = \beta(v, t)$, show that α satisfies the desired equation.

8. This problem is for those who know something about complex analysis. Let $f: \mathbb{C} \times \mathbb{C} \rightarrow \mathbb{C}$ be complex analytic. If we denote the coordinate functions in $\mathbb{C} \times \mathbb{C}$ by $z_1, z_2 = x_1, y_1, x_2, y_2$, then $f = u + iv$ satisfies the Cauchy-Riemann equations

$$\begin{aligned} \frac{\partial u}{\partial x_i} &= \frac{\partial v}{\partial y_i} \\ \frac{\partial u}{\partial y_i} &= -\frac{\partial v}{\partial x_i} \end{aligned} \quad i = 1, 2.$$

Use Theorem 1 to prove that we can solve the equations

$$\begin{aligned} \frac{\partial \alpha^1}{\partial x} &= u(x, y, \alpha^1(x, y), \alpha^2(x, y)) = \frac{\partial \alpha^2}{\partial y} \\ \frac{\partial \alpha^2}{\partial x} &= v(x, y, \alpha^1(x, y), \alpha^2(x, y)) = -\frac{\partial \alpha^1}{\partial y} \end{aligned}$$

in a neighborhood of $0 \in \mathbb{C}$ (or of any point $z_0 \in \mathbb{C}$), and conclude that the differential equation

$$\phi'(z) = f(z, \phi(z))$$

(in which $'$ denotes the complex derivative) has a solution in a neighborhood of z_0 , with any given initial condition $\phi(z_0) = w_0$.

CHAPTER 7

DIFFERENTIAL FORMS

We turn our attention once more to tensor fields, but we will be concerned with a special kind of tensor field, the discussion of which requires some more algebraic preliminaries.

Let V be an n -dimensional vector space over \mathbb{R} . An element $T \in \mathcal{T}^k(V)$ is called **alternating** if

$$T(v_1, \dots, v_i, \dots, v_j, \dots, v_k) = 0 \quad \text{if } v_i = v_j \ (i \neq j).$$

If T is alternating, then for any v_1, \dots, v_k , we have

$$\begin{aligned} 0 &= T(v_1, \dots, v_i + v_j, \dots, v_i + v_j, \dots, v_k) \\ &= T(v_1, \dots, v_i, \dots, v_i, \dots, v_k) + T(v_1, \dots, v_i, \dots, v_j, \dots, v_k) \\ &\quad + T(v_1, \dots, v_j, \dots, v_i, \dots, v_k) + T(v_1, \dots, v_j, \dots, v_j, \dots, v_k) \\ &= 0 + T(v_1, \dots, v_i, \dots, v_j, \dots, v_k) + T(v_1, \dots, v_j, \dots, v_i, \dots, v_k) + 0. \end{aligned}$$

Therefore, T is **skew-symmetric**:

$$T(v_1, \dots, v_i, \dots, v_j, \dots, v_k) = -T(v_1, \dots, v_j, \dots, v_i, \dots, v_k).$$

Of course, if T is skew-symmetric, then T is also alternating. [This is not true in the special case of a vector space over a field where $1 + 1 = 0$; in this case, skew-symmetry is the same as symmetry, and the condition of being alternating is the stronger one.]

We will denote by $\Omega^k(V)$ the set of all alternating $T \in \mathcal{T}^k(V)$. It is clear that $\Omega^k(V) \subset \mathcal{T}^k(V)$ is a subspace of $\mathcal{T}^k(V)$. Moreover, if $f: V \rightarrow W$ is a linear transformation, then $f^*: \mathcal{T}^k(W) \rightarrow \mathcal{T}^k(V)$ preserves these subspaces— $f^*: \Omega^k(W) \rightarrow \Omega^k(V)$. Notice that $\Omega^1(V) = \mathcal{T}^1(V) = V^*$, so $\Omega^1(V)$ has dimension n . It is also convenient to set $\Omega^0(V) = \mathcal{T}^0(V) = \mathbb{R}$. At the moment it is not clear what the dimension of $\Omega^k(V)$ equals for $k > 1$, but one case is well-known. The most familiar example of an alternating T is the determinant function $\det \in \mathcal{T}^n(\mathbb{R}^n)$, considered as a function of the n rows of a matrix—we shall soon see that this function is, in a certain sense, the most general alternating function. Most discussions of the determinant begin by showing that of any two alternating n -linear functions on \mathbb{R}^n , one is a multiple of the

other; in other words, $\dim \Omega^n(\mathbb{R}^n) \leq 1$. Then one proves $\dim \Omega^n(\mathbb{R}^n) = 1$ by actually constructing the non-zero function \det (it follows, of course, that $\dim \Omega^n(V) = 1$ if V is any n -dimensional vector space). The construction of \det is usually by a messy, explicit formula, which is a special case of the definition to follow.

Let S_k denote the set of all permutations of $\{1, \dots, k\}$; an element $\sigma \in S_k$ is a function $i \mapsto \sigma(i)$. If (v_1, \dots, v_k) is a k -tuple (of any objects) we set

$$\sigma \cdot (v_1, \dots, v_k) = (v_{\sigma(1)}, \dots, v_{\sigma(k)}).$$

This definition has a built-in confusion. On the right side, the first element, for example, is the $\sigma(1)^{\text{st}}$ of the v 's on the left side; if these v 's have indices running in some order *other* than $1, \dots, k$, then the first element on the right is *not* necessarily that v whose index is $\sigma(1)$. The simplest way to figure out something like $\sigma \cdot (v_3, v_2, v_1, \dots)$ is to rename things: $v_3 = w_1, v_2 = w_2, v_1 = w_3, \dots$. Thus warned, we compute

$$\sigma \cdot (\rho \cdot (v_1, \dots, v_k)) = \sigma \cdot (v_{\rho(1)}, \dots, v_{\rho(k)})$$

by setting

$$v_{\rho(1)} = w_1, \dots, v_{\rho(k)} = w_k,$$

so that

$$\begin{aligned} \sigma \cdot (\rho \cdot (v_1, \dots, v_k)) &= \sigma \cdot (w_1, \dots, w_k) \\ &= (w_{\sigma(1)}, \dots, w_{\sigma(k)}) \\ &= (v_{\rho(\sigma(1))}, \dots, v_{\rho(\sigma(k))}) \quad \text{since } w_\alpha = v_{\rho(\alpha)}. \end{aligned}$$

Thus

$$(*) \quad \sigma \cdot (\rho \cdot (v_1, \dots, v_k)) = (\rho\sigma) \cdot (v_1, \dots, v_k).$$

Now for any $T \in \mathcal{T}^k(V)$ we define the "alternation of T "

$$\text{Alt } T = \frac{1}{k!} \sum_{\sigma \in S_k} \text{sgn } \sigma \cdot T \circ \sigma,$$

i.e.,

$$\text{Alt } T(v_1, \dots, v_k) = \frac{1}{k!} \sum_{\sigma \in S_k} \text{sgn } \sigma \cdot T(v_{\sigma(1)}, \dots, v_{\sigma(k)}),$$

where $\text{sgn } \sigma$ is $+1$ if σ is an even permutation and -1 if σ is odd.

1. PROPOSITION.

- (1) If $T \in \mathcal{T}^k(V)$, then $\text{Alt}(T) \in \Omega^k(V)$.
- (2) If $\omega \in \Omega^k(V)$, then $\text{Alt } \omega = \omega$.
- (3) If $T \in \mathcal{T}^k(V)$, then $\text{Alt}(\text{Alt}(T)) = \text{Alt}(T)$.

PROOF. Left to the reader (or see pp. 78–79 of *Calculus on Manifolds*). ♦

We now define, for $\omega \in \Omega^k(V)$ and $\eta \in \Omega^l(V)$, an element $\omega \wedge \eta \in \Omega^{k+l}(V)$, the wedge product of ω and η , by

$$\omega \wedge \eta = \frac{(k+l)!}{k!l!} \text{Alt}(\omega \otimes \eta).$$

The funny coefficient is not essential, but it makes some things work out more nicely, as we shall soon see. It is clear that

- (1) \wedge is bilinear:

$$\begin{aligned} (\omega_1 + \omega_2) \wedge \eta &= \omega_1 \wedge \eta + \omega_2 \wedge \eta \\ \omega \wedge (\eta_1 + \eta_2) &= \omega \wedge \eta_1 + \omega \wedge \eta_2 \\ a\omega \wedge \eta &= \omega \wedge a\eta = a(\omega \wedge \eta) \end{aligned}$$

- (2) $f^*(\omega \wedge \eta) = f^*\omega \wedge f^*\eta$.

Moreover, it is easy to see that

- (3) \wedge is “anti-commutative”: $\omega \wedge \eta = (-1)^{kl} \eta \wedge \omega$.

In particular, if k is odd then

$$\omega \wedge \omega = 0.$$

Finally, associativity of \wedge is proved in the following way.

2. THEOREM.

- (1) If $S \in \mathcal{T}^k(V)$ and $T \in \mathcal{T}^l(V)$ and $\text{Alt}(S) = 0$, then

$$\text{Alt}(S \otimes T) = \text{Alt}(T \otimes S) = 0.$$

- (2) $\text{Alt}(\text{Alt}(\omega \otimes \eta) \otimes \theta) = \text{Alt}(\omega \otimes \eta \otimes \theta) = \text{Alt}(\omega \otimes \text{Alt}(\eta \otimes \theta))$.

- (3) If $\omega \in \Omega^k(V)$, $\eta \in \Omega^l(V)$, $\theta \in \Omega^m(V)$, then

$$(\omega \wedge \eta) \wedge \theta = \omega \wedge (\eta \wedge \theta) = \frac{(k+l+m)!}{k!l!m!} \text{Alt}(\omega \otimes \eta \otimes \theta).$$

PROOF. (1) We have

$$\begin{aligned}
 (k+l)! \operatorname{Alt}(S \otimes T)(v_1, \dots, v_{k+l}) \\
 &= \sum_{\sigma \in S_{k+l}} \operatorname{sgn} \sigma \cdot (S \otimes T) \cdot (\sigma \cdot (v_1, \dots, v_{k+l})) \\
 &= \sum_{\sigma \in S_{k+l}} \operatorname{sgn} \sigma \cdot S(v_{\sigma(1)}, \dots, v_{\sigma(k)}) \cdot T(v_{\sigma(k+1)}, \dots, v_{\sigma(k+l)}).
 \end{aligned}$$

Now let $G \subset S_{k+l}$ consist of all σ which leave $k+1, \dots, k+l$ fixed. Then

$$\begin{aligned}
 \sum_{\sigma \in G} \operatorname{sgn} \sigma \cdot S(v_{\sigma(1)}, \dots, v_{\sigma(k)}) \cdot T(v_{\sigma(k+1)}, \dots, v_{\sigma(k+l)}) \\
 &= \left[\sum_{\sigma' \in S_k} \operatorname{sgn} \sigma' \cdot S(v_{\sigma'(1)}, \dots, v_{\sigma'(k)}) \right] \cdot T(v_{k+1}, \dots, v_{k+l}) \\
 &= 0.
 \end{aligned}$$

Suppose now that $\sigma_0 \notin G$. Let $\sigma_0 G = \{\sigma_0 \sigma' : \sigma' \in G\}$. Then

$$\begin{aligned}
 \sum_{\sigma \in \sigma_0 G} \operatorname{sgn} \sigma \cdot (S \otimes T)(\sigma \cdot (v_1, \dots, v_{k+l})) \\
 = \operatorname{sgn} \sigma_0 \cdot \sum_{\sigma' \in G} \operatorname{sgn} \sigma' \cdot (S \otimes T)(\sigma' \cdot (\sigma_0 \cdot (v_1, \dots, v_{k+l}))) \quad \text{by (*).}
 \end{aligned}$$

We have just shown that this is 0 (since $\sigma_0 \cdot (v_1, \dots, v_{k+l})$ is just some other $(k+l)$ -tuple of vectors). Notice that $G \cap \sigma_0 G = \emptyset$, for if $\sigma \in G \cap \sigma_0 G$, then $\sigma = \sigma_0 \sigma'$ for some $\sigma' \in G$, so $\sigma_0 = \sigma(\sigma')^{-1} \in G$, a contradiction. We can then continue in this way, breaking S_{k+l} up into disjoint subsets, the sum over each being 0. The relation $\operatorname{Alt}(T \otimes S) = 0$ is proved similarly.

(2) Clearly

$$\operatorname{Alt}(\operatorname{Alt}(\eta \otimes \theta) - \eta \otimes \theta) = \operatorname{Alt}(\eta \otimes \theta) - \operatorname{Alt}(\eta \otimes \theta) = 0,$$

so (1) implies that

$$\begin{aligned}
 0 &= \operatorname{Alt}(\omega \otimes [\operatorname{Alt}(\eta \otimes \theta) - \eta \otimes \theta]) \\
 &= \operatorname{Alt}(\omega \otimes \operatorname{Alt}(\eta \otimes \theta)) - \operatorname{Alt}(\omega \otimes \eta \otimes \theta);
 \end{aligned}$$

the other equality is proved similarly.

(3) We have

$$\begin{aligned}
 (\omega \wedge \eta) \wedge \theta &= \frac{(k+l+m)!}{(k+l)!m!} \operatorname{Alt}((\omega \wedge \eta) \otimes \theta) \\
 &= \frac{(k+l+m)!}{(k+l)!m!} \frac{(k+l)!}{k!l!} \operatorname{Alt}(\omega \otimes \eta \otimes \theta).
 \end{aligned}$$

The other equality is proved similarly. ♦

Notice that (2) just states that \wedge is associative even if we had omitted the factor $(k+l)!/k!l!$ in the definition. On the other hand, the factor $1/k!$ in the definition of Alt is essential—without it, we would not have $\text{Alt}(\text{Alt } T) = \text{Alt } T$, and the first equation in the proof of (2) would fail. [If we had defined $\overline{\text{Alt}}$ just like Alt , but without the factor $1/k!$, then \wedge could be defined by

$$\omega \wedge \eta = \frac{1}{k!l!} \overline{\text{Alt}}(\omega \otimes \eta).$$

This makes sense, *even over a field of finite characteristic*, because each term in the sum $\text{Alt}(\omega \otimes \eta)(v_1, \dots, v_{k+l})$ occurs $k!l!$ times (since ω and η are alternating), and $1/k!l!$ can be interpreted as meaning that these $k!l!$ terms are replaced by just one.] The factor $(k+l)!/k!l!$ has been inserted into the definition of \wedge for the following reason. If v_1, \dots, v_n is a basis of V , and ϕ_1, \dots, ϕ_n is the dual basis, then

$$\begin{aligned} \phi_1 \wedge \dots \wedge \phi_n &= \frac{(1 + \dots + 1)!}{1! \dots 1!} \text{Alt}(\phi_1 \otimes \dots \otimes \phi_n) \\ &= \sum_{\sigma \in S_n} \text{sgn } \sigma \cdot (\phi_1 \otimes \dots \otimes \phi_n) \circ \sigma. \end{aligned}$$

In particular,

$$(\phi_1 \wedge \dots \wedge \phi_n)(v_1, \dots, v_n) = 1.$$

(So if v_1, \dots, v_n is the standard basis for \mathbb{R}^n , then $\phi_1 \wedge \dots \wedge \phi_n = \det$.) A basis for $\Omega^k(V)$ can now be described.

3. THEOREM. The set of all

$$\phi_{i_1} \wedge \dots \wedge \phi_{i_k} \quad 1 \leq i_1 < \dots < i_k \leq n$$

is a basis for $\Omega^k(V)$, which therefore has dimension

$$\binom{n}{k} = \frac{n!}{k!(n-k)!}.$$

(In particular, $\Omega^k(V) = \{0\}$ for $k > n$.)

PROOF. If $\omega \in \Omega^k(V) \subset \mathcal{T}^k(V)$, we can write

$$\omega = \sum_{i_1, \dots, i_k} a_{i_1 \dots i_k} \phi_{i_1} \otimes \dots \otimes \phi_{i_k}.$$

So

$$\omega = \text{Alt}(\omega) = \sum_{i_1, \dots, i_k} a_{i_1 \dots i_k} \text{Alt}(\phi_{i_1} \otimes \dots \otimes \phi_{i_k}).$$

Each $\text{Alt}(\phi_{i_1} \otimes \dots \otimes \phi_{i_k})$ is either 0 or $= \pm(1/k!) \phi_{j_1} \wedge \dots \wedge \phi_{j_k}$ for some $j_1 < \dots < j_k$, so the elements $\phi_{j_1} \wedge \dots \wedge \phi_{j_k}$ for $j_1 < \dots < j_k$ span $\Omega^k(V)$. If

$$0 = \sum_{i_1 < \dots < i_k} a_{i_1 \dots i_k} \phi_{i_1} \wedge \dots \wedge \phi_{i_k},$$

then applying both sides to $(v_{i_1}, \dots, v_{i_k})$ gives $a_{i_1 \dots i_k} = 0$. ♦

4. COROLLARY. If $\omega_1, \dots, \omega_k \in \Omega^1(V)$, then $\omega_1, \dots, \omega_k$ are linearly independent if and only if

$$\omega_1 \wedge \dots \wedge \omega_k \neq 0.$$

PROOF. If $\omega_1, \dots, \omega_k$ are linearly independent, there is a basis $v_1, \dots, v_k, \dots, v_n$ of V such that the dual basis vectors $\phi_1, \dots, \phi_k, \dots, \phi_n$ satisfy $\phi_i = \omega_i$ for $1 \leq i \leq k$. Then $\omega_1 \wedge \dots \wedge \omega_k$ is a basis element of $\Omega^k(V)$, so it is not 0.

On the other hand, if

$$\omega_1 = a_2 \omega_2 + \dots + a_k \omega_k,$$

then

$$\omega_1 \wedge \omega_2 \wedge \dots \wedge \omega_k = (a_2 \omega_2 + \dots + a_k \omega_k) \wedge \omega_2 \wedge \dots \wedge \omega_k = 0. \quad \spadesuit$$

To abbreviate formulas, it is convenient to let I denote a typical “multi-index” (i_1, \dots, i_k) , and let ϕ_I denote $\phi_{i_1} \wedge \dots \wedge \phi_{i_k}$. Then every element of $\Omega^k(V)$ is uniquely expressible as

$$\sum_I a_I \phi_I.$$

Notice that Theorem 3 implies that every $\omega \in \Omega^k(\mathbb{R}^n)$ is a linear combination of the functions

$$(v_1, \dots, v_k) \mapsto \text{determinant of a } k \times k \text{ minor of } \begin{pmatrix} v_1 \\ \vdots \\ v_k \end{pmatrix}.$$

One more simple theorem is in order; before we proceed to apply our construction to manifolds.

5. THEOREM. Let v_1, \dots, v_n be a basis for V , let $\omega \in \Omega^n(V)$, and let

$$w_i = \sum_{j=1}^n \alpha_{ji} v_j \quad i = 1, \dots, n.$$

Then

$$\omega(w_1, \dots, w_n) = \det(\alpha_{ij}) \cdot \omega(v_1, \dots, v_n).$$

PROOF. Define $\eta \in \mathcal{T}^n(\mathbb{R}^n)$ by

$$\eta((a_{11}, \dots, a_{n1}), \dots, (a_{n1}, \dots, a_{nn})) = \omega\left(\sum_{j=1}^n a_{j1} v_j, \dots, \sum_{j=1}^n a_{jn} v_j\right).$$

Then clearly $\eta \in \Omega^n(\mathbb{R}^n)$, so $\eta = c \cdot \det$ for some $c \in \mathbb{R}$, and

$$c = \eta(e_1, \dots, e_n) = \omega(v_1, \dots, v_n). \quad \spadesuit$$

6. COROLLARY. If V is n -dimensional and $0 \neq \omega \in \Omega^n(V)$, then there is a unique orientation μ for V such that

$$[v_1, \dots, v_n] = \mu \quad \text{if and only if} \quad \omega(v_1, \dots, v_n) > 0.$$

With our new algebraic construction at hand, we are ready to apply it to vector bundles. If $\xi = \pi: E \rightarrow B$ is a vector bundle, we obtain a new bundle $\Omega^k(\xi)$ by replacing each fibre $\pi^{-1}(p)$ with $\Omega^k(\pi^{-1}(p))$. A section ω of $\Omega^k(\xi)$ is a function with $\omega(p) \in \Omega^k(\pi^{-1}(p))$ for each $p \in B$. If η is a section of $\Omega^l(\xi)$, then we can define a section $\omega \wedge \eta$ of $\Omega^{k+l}(\xi)$ by $(\omega \wedge \eta)(p) = \omega(p) \wedge \eta(p) \in \Omega^{k+l}(\pi^{-1}(p))$.

In particular, sections of $\Omega^k(TM)$, which are just alternating covariant tensor fields of order k , are called k -forms on M . A 1-form is just a covariant vector field. Since $\Omega^k(TM)$ can obviously be made into a C^∞ vector bundle, we can speak of C^∞ forms; all forms will be understood to be C^∞ forms unless the contrary is explicitly stated. Remember that covariant tensors actually map contravariantly: If $f: M \rightarrow N$ is C^∞ , and ω is a k -form on N , then $f^*\omega$ is a k -form on M . We can also define $\omega_1 + \omega_2$ and $\omega \wedge \eta$. The following properties of k -forms are obvious from the corresponding properties for $\Omega^k(V)$:

$$\begin{aligned} (\omega_1 + \omega_2) \wedge \eta &= \omega_1 \wedge \eta + \omega_2 \wedge \eta \\ \omega \wedge (\eta_1 + \eta_2) &= \omega \wedge \eta_1 + \omega \wedge \eta_2 \\ f\omega \wedge \eta &= \omega \wedge f\eta = f(\omega \wedge \eta) \\ \omega \wedge \eta &= (-1)^{kl} \eta \wedge \omega \\ f^*(\omega \wedge \eta) &= f^*\omega \wedge f^*\eta. \end{aligned}$$

If (x, U) is a coordinate system, then the $dx^i(p)$ are a basis for M_p^* , so the $dx^{i_1}(p) \wedge \cdots \wedge dx^{i_k}(p)$ ($i_1 < \cdots < i_k$) are a basis for $\Omega^k(p)$. Thus every k -form ω can be written uniquely as

$$\omega = \sum_{i_1 < \cdots < i_k} \omega_{i_1 \dots i_k} dx^{i_1} \wedge \cdots \wedge dx^{i_k}$$

or, if we denote $dx^{i_1} \wedge \cdots \wedge dx^{i_k}$ by dx^I for the multi-index $I = (i_1, \dots, i_k)$,

$$\omega = \sum_I \omega_I dx^I.$$

The problem of finding the relationship between the ω_I and the functions ω'_I when

$$\omega = \sum_I \omega_I dx^I = \sum_I \omega'_I dy^I$$

is left to the reader (Problem 16), but we will do one special case here.

7. THEOREM. If $f: M \rightarrow N$ is a C^∞ function between n -manifolds, (x, U) is a coordinate system around $p \in M$, and (y, V) a coordinate system around $q = f(p) \in N$, then

$$f^*(g dy^1 \wedge \cdots \wedge dy^n) = (g \circ f) \cdot \det \left(\frac{\partial(y^i \circ f)}{\partial x^j} \right) dx^1 \wedge \cdots \wedge dx^n.$$

PROOF. It suffices to show that

$$f^*(dy^1 \wedge \cdots \wedge dy^n) = \det \left(\frac{\partial(y^i \circ f)}{\partial x^j} \right) dx^1 \wedge \cdots \wedge dx^n.$$

Now, by Problem 4-1,

$$\begin{aligned} f^*(dy^1 \wedge \cdots \wedge dy^n)(p) & \left(\frac{\partial}{\partial x^1} \Big|_p, \dots, \frac{\partial}{\partial x^n} \Big|_p \right) \\ &= dy^1(q) \wedge \cdots \wedge dy^n(q) \left(f_* \frac{\partial}{\partial x^1} \Big|_p, \dots, f_* \frac{\partial}{\partial x^n} \Big|_p \right) \\ &= dy^1(q) \wedge \cdots \wedge dy^n(q) \left(\sum_{i=1}^n \frac{\partial(y^i \circ f)}{\partial x^1}(p) \frac{\partial}{\partial y^i} \Big|_q, \right. \\ & \quad \left. \dots, \sum_{i=1}^n \frac{\partial(y^i \circ f)}{\partial x^n}(p) \frac{\partial}{\partial y^i} \Big|_q \right) \\ &= \det \left(\frac{\partial(y^i \circ f)}{\partial x^j}(p) \right), \quad \text{by Theorem 5. } \spadesuit \end{aligned}$$

8. COROLLARY. If (x, U) and (y, V) are two coordinate systems on M and

$$g \, dy^1 \wedge \cdots \wedge dy^n = h \, dx^1 \wedge \cdots \wedge dx^n,$$

then

$$h = g \cdot \det \left(\frac{\partial y^i}{\partial x^j} \right).$$

PROOF. Apply the theorem with $f = \text{identity map}$. ♦

[This corollary shows that n -forms are the geometric objects corresponding to the “even scalar densities” defined in Problem 4-10.]

If $\xi = \pi : E \rightarrow B$ is an n -plane bundle, then a *nowhere zero* section ω of $\Omega^n(\xi)$ has a special significance: For each $p \in B$, the non-zero $\omega(p) \in \Omega^n(\pi^{-1}(p))$ determines an orientation μ_p of $\pi^{-1}(p)$ by Corollary 6. It is easy to see that the collection of orientations $\{\mu_p\}$ satisfy the “compatibility condition” set forth in Chapter 3, so that $\mu = \{\mu_p\}$ is an orientation of ξ . In particular, if there is a nowhere zero n -form ω on an n -manifold M , then M is orientable (i.e., the bundle TM is orientable). The converse also holds:

9. THEOREM. If a C^∞ manifold M is orientable, then there is an n -form ω on M which is nowhere 0.

PROOF. By Theorem 2-13 and 2-15, we can choose a cover \mathcal{O} of M by a collection of coordinate systems $\{(x, U)\}$, and a partition of unity $\{\phi_U\}$ subordinate to \mathcal{O} . Let μ be an orientation of M . For each (x, U) choose an n -form ω_U on U such that for $v_1, \dots, v_n \in M_p$, $p \in U$ we have

$$\omega_U(v_1, \dots, v_n) > 0 \quad \text{if and only if} \quad [v_1, \dots, v_n] = \mu_p.$$

Now let

$$\omega = \sum_{U \in \mathcal{O}} \phi_U \omega_U.$$

Then ω is a C^∞ n -form. Moreover, for every p , if $v_1, \dots, v_n \in M_p$ satisfy $[v_1, \dots, v_n] = \mu_p$, then *each*

$$(\phi_U \omega_U)(p)(v_1, \dots, v_n) \geq 0,$$

and strict inequality holds for at least one U . Thus $\omega(p) \neq 0$. ♦

Notice that the bundle $\Omega^n(TM)$ is 1-dimensional. We have shown that if M is orientable, then $\Omega^n(TM)$ has a nowhere 0 section, which implies that it is trivial. Conversely, of course, if the bundle $\Omega^n(TM)$ is trivial, then it certainly has a nowhere 0 section, so M is orientable. [Generally, if ξ is a k -plane bundle, then $\Omega^k(\xi)$ is trivial if and only if ξ is orientable, provided that the base space B is “paracompact” (every open cover has a locally-finite refinement).]

Just as $\Omega^0(V)$ has been introduced as another name for \mathbb{R} , a 0-form on M will just mean a function f on M (and $f \wedge \omega$ will just mean $f \cdot \omega$). For every 0-form f we have the 1-form df (recall that $df(X) = X(f)$), which in a coordinate system (x, U) is given by

$$df = \sum_{j=1}^n \frac{\partial f}{\partial x^j} dx^j.$$

If ω is a k -form

$$\omega = \sum_I \omega_I dx^I,$$

then each $d\omega_I$ is a 1-form, and we can define a $(k+1)$ -form $d\omega$, the differential of ω , by

$$\begin{aligned} d\omega &= \sum_I d\omega_I dx^I \\ &= \sum_I \sum_{\alpha=1}^n \frac{\partial \omega_I}{\partial x^\alpha} dx^\alpha \wedge dx^I. \end{aligned}$$

It turns out that this definition does not depend on the coordinate system. This can be proved in several ways. The first way is to use a brute-force computation, comparing the coefficients ω'_I in the expression

$$\omega = \sum_I \omega'_I dx^I$$

with the ω_I .

The second method is a lot sneakier. We begin by finding some properties of $d\omega$ (still defined with respect to this particular coordinate system).

10. PROPOSITION.

(1) $d(\omega_1 + \omega_2) = d\omega_1 + d\omega_2$.

(2) If ω_1 is a k -form, then

$$d(\omega_1 \wedge \omega_2) = d\omega_1 \wedge \omega_2 + (-1)^k \omega_1 \wedge d\omega_2.$$

(3) $d(d\omega) = 0$. Briefly, $d^2 = 0$.

PROOF. (1) is clear. To prove (2) we first note that because of (1) it suffices to consider only

$$\begin{aligned}\omega_1 &= f dx^I \\ \omega_2 &= g dx^J.\end{aligned}$$

Then $\omega_1 \wedge \omega_2 = fg dx^I \wedge dx^J$ and

$$\begin{aligned}d(\omega_1 \wedge \omega_2) &= d(fg) \wedge dx^I \wedge dx^J \\ &= g df \wedge dx^I \wedge dx^J + f dg \wedge dx^I \wedge dx^J \\ &= d\omega_1 \wedge \omega_2 + (-1)^k f dx^I \wedge dg \wedge dx^J \\ &= d\omega_1 \wedge \omega_2 + (-1)^k \omega_1 \wedge d\omega_2.\end{aligned}$$

(3) It clearly suffices to consider only k -forms of the form

$$\omega = f dx^I.$$

Then

$$d\omega = \sum_{\alpha=1}^n \frac{\partial f}{\partial x^\alpha} dx^\alpha \wedge dx^I$$

so

$$d(d\omega) = \sum_{\alpha=1}^n \left(\sum_{\beta=1}^n \frac{\partial^2 f}{\partial x^\beta \partial x^\alpha} dx^\beta \wedge dx^\alpha \wedge dx^I \right).$$

In this sum, the terms

$$\frac{\partial^2 f}{\partial x^\beta \partial x^\alpha} dx^\beta \wedge dx^\alpha \wedge dx^I$$

and

$$\frac{\partial^2 f}{\partial x^\alpha \partial x^\beta} dx^\alpha \wedge dx^\beta \wedge dx^I$$

cancel in pairs. ♦

We next note that these properties characterize d on U .

11. PROPOSITION. Suppose d' takes k -forms on U to $(k+1)$ -forms on U , for all k , and satisfies

- (1) $d'(\omega_1 + \omega_2) = d'\omega_1 + d'\omega_2$.
- (2) $d'(\omega_1 \wedge \omega_2) = d'\omega_1 \wedge \omega_2 + (-1)^k \omega_1 \wedge d'\omega_2$.
- (3) $d'(d'f) = 0$.
- (4) $d'f = (\text{the old}) df$.

Then $d' = d$ on U .

PROOF. It is clearly enough to show that $d'\omega = d\omega$ when $\omega = f dx^I$. Now by (2),

$$\begin{aligned} d'(f dx^I) &= d'f \wedge dx^I + f \wedge d'(dx^I) \\ &= df \wedge dx^I + f \wedge d'(dx^I) \quad \text{by (4).} \end{aligned}$$

So it suffices to show that $d'(dx^I) = 0$, where

$$\begin{aligned} dx^I &= dx^{i_1} \wedge \dots \wedge dx^{i_k} \\ &= d'x^{i_1} \wedge \dots \wedge d'x^{i_k} \quad \text{by (4).} \end{aligned}$$

We will use induction on k . Assuming it for $k - 1$ we have

$$\begin{aligned} d'(dx^I) &= d'(d'x^{i_1} \wedge \dots \wedge d'x^{i_k}) \\ &= d'(d'x^{i_1}) \wedge d'x^{i_2} \wedge \dots \wedge d'x^{i_k} \\ &\quad - d'x^{i_1} \wedge d'(d'x^{i_1} \wedge \dots \wedge d'x^{i_k}) \quad \text{by (2)} \\ &= 0 - 0, \quad \text{by (3) and the inductive hypothesis. } \spadesuit \end{aligned}$$

12. COROLLARY. There is a unique operator d from the k -forms on M to the $(k + 1)$ -forms on M , for all k , satisfying

$$\begin{aligned} d(\omega_1 + \omega_2) &= d\omega_1 + d\omega_2 \\ d(\omega_1 \wedge \omega_2) &= d\omega_1 \wedge \omega_2 + (-1)^k \omega_1 \wedge d\omega_2 \\ d^2 &= 0, \end{aligned}$$

and agreeing with the old d on functions.

PROOF. For each coordinate system (x, U) we have a unique d_U defined. Given the form ω , and $p \in M$, pick any U with $p \in U$ and define

$$d\omega(p) = d_U(\omega|U)(p). \quad \spadesuit$$

The third way of proving that the definition of d does not depend on the coordinate system is to give an invariant definition.

13. THEOREM. If ω is a k -form on M , then there is a unique $(k+1)$ -form $d\omega$ on M such that for every set of vector fields X_1, \dots, X_{k+1} we have

$$\begin{aligned}
 (*) \quad d\omega(X_1, \dots, X_{k+1}) &= \sum_{i=1}^{k+1} (-1)^{i+1} X_i(\omega(X_1, \dots, \widehat{X}_i, \dots, X_{k+1})) \\
 &\quad + \sum_{1 \leq i < j \leq k+1} (-1)^{i+j} \omega([X_i, X_j], X_1, \dots, \widehat{X}_i, \dots, \widehat{X}_j, \dots, X_{k+1}) \\
 & (= \Sigma_1 + \Sigma_2, \text{ say})
 \end{aligned}$$

where $\widehat{}$ over X_i indicates that it is omitted. This $(k+1)$ -form agrees with $d\omega$ as defined previously.

PROOF. The operator which takes (X_1, \dots, X_{k+1}) to $\Sigma_1 + \Sigma_2$ is clearly linear over \mathbb{R} . Moreover, it is actually linear over the C^∞ functions \mathcal{F} . In fact, if X_{i_0} is replaced by fX_{i_0} , then Σ_1 becomes

$$f\Sigma_1 + \sum_{i \neq i_0} (-1)^{i+1} (X_i f) \omega(X_1, \dots, \widehat{X}_i, \dots, X_{k+1}),$$

and using the formulas

$$\begin{aligned}
 [fX, Y] &= f[X, Y] - Yf \cdot X \\
 [X, fY] &= f[X, Y] + Xf \cdot Y,
 \end{aligned}$$

it is easily seen that Σ_2 becomes

$$\begin{aligned}
 f\Sigma_2 + \sum_{i < i_0} (-1)^{i+i_0} (X_i f) \omega(X_{i_0}, X_1, \dots, \widehat{X}_i, \dots, \widehat{X}_{i_0}, \dots, X_{k+1}) \\
 - \sum_{i_0 < j} (-1)^{i_0+j} (X_j f) \omega(X_{i_0}, X_1, \dots, \widehat{X}_{i_0}, \dots, \widehat{X}_j, \dots, X_{k+1});
 \end{aligned}$$

a brief inspection then shows that $\Sigma_1 + \Sigma_2$ becomes $f\Sigma_1 + f\Sigma_2$.

Theorem 4-2 shows that there is a unique covariant tensor field $d\omega$ satisfying (*). It is easy to check that $d\omega$ is alternating, so that it is a $(k+1)$ -form.

To compute $d\omega$ in a coordinate system (x, U) it clearly suffices to compute $d(f dx^I)$. Moreover, by renumbering, we might as well assume

$$\omega = f dx^1 \wedge \dots \wedge dx^k.$$

For $d\omega$, as for any form, we have

$$d\omega = \sum_{\alpha_1 < \dots < \alpha_{k+1}} d\omega(\partial/\partial x^{\alpha_1}, \dots, \partial/\partial x^{\alpha_{k+1}}) dx^{\alpha_1} \wedge \dots \wedge dx^{\alpha_{k+1}}.$$

It is clear from (*) that $d\omega(\partial/\partial x^{\alpha_1}, \dots, \partial/\partial x^{\alpha_{k+1}}) = 0$

unless some $(\alpha_1, \dots, \widehat{\alpha_i}, \dots, \alpha_{k+1})$ is a permutation of $(1, \dots, k)$.

Since the α 's are increasing, this happens only if

$$(\alpha_1, \dots, \alpha_{k+1}) = (1, \dots, k, j) \quad j > k,$$

in which case

$$d\omega(\partial/\partial x^{\alpha_1}, \dots, \partial/\partial x^{\alpha_k}, \partial/\partial x^j) = (-1)^k \frac{\partial f}{\partial x^j},$$

so

$$\begin{aligned} d\omega &= \sum_{j>k} (-1)^k \frac{\partial f}{\partial x^j} dx^1 \wedge \dots \wedge dx^k \wedge dx^j \\ &= \sum_{j>k} \frac{\partial f}{\partial x^j} dx^j \wedge dx^1 \wedge \dots \wedge dx^k \\ &= \sum_{j=1}^n \frac{\partial f}{\partial x^j} dx^j \wedge dx^1 \wedge \dots \wedge dx^k, \end{aligned}$$

which is just the old definition. ♦

This is our first real example of an invariant definition of an important tensor, and our first use of Theorem 4-2. We do not find $d\omega(p)(v_1, \dots, v_{k+1})$ directly, but first find $d\omega(X_1, \dots, X_{k+1})$, where X_i are vector fields extending v_i , and then evaluate this function at p . By some sort of magic, this turns out to be independent of the extensions X_1, \dots, X_{k+1} . This may not seem to be much of an improvement over using a coordinate system and checking that the definition is independent of the coordinate system. But we can hardly hope for anything better. After all, although $d\omega(X_1, \dots, X_{k+1})(p)$ does not depend on the values of X_i except at p , it *does* depend on the values of ω at points other than p —this must enter into our formula somehow. One other feature of our definition is common to most invariant definitions of tensors—the presence of a term involving brackets of various vector fields. This term is what makes the operator

linear over the C^∞ functions, but it disappears in computations in a coordinate system.

In the particular case where ω is a 1-form, Theorem 13 gives the following formula.

$$d\omega(X, Y) = X(\omega(Y)) - Y(\omega(X)) - \omega([X, Y])$$

This enables us to state a second version of Theorem 6-5 (The Frobenius Integrability Theorem) in terms of differential forms. Define the ring $\Omega(M)$ to be the direct sum of the rings of l -forms on M , for all l . If Δ is a k -dimensional distribution on M , then $\mathcal{I}(\Delta) \subset \Omega(M)$ will denote the subring generated by the set of all forms ω with the property that (if ω has degree l)

$$\omega(X_1, \dots, X_l) = 0 \quad \text{whenever } X_1, \dots, X_l \text{ belong to } \Delta.$$

It is clear that $\omega_1 + \omega_2 \in \mathcal{I}(\Delta)$ if $\omega_1, \omega_2 \in \mathcal{I}(\Delta)$, and that $\eta \wedge \omega \in \mathcal{I}(\Delta)$ if $\omega \in \mathcal{I}(\Delta)$ [thus, $\mathcal{I}(\Delta)$ is an ideal in the ring $\Omega(M)$]. Locally, the ideal $\mathcal{I}(\Delta)$ is generated by $n - k$ independent 1-forms $\omega^{k+1}, \dots, \omega^n$. In fact, around any point $p \in M$ we can choose a coordinate system (x, U) so that

$$\left. \frac{\partial}{\partial x^1} \right|_p, \dots, \left. \frac{\partial}{\partial x^k} \right|_p \quad \text{span } \Delta_p.$$

Then

$$dx^1(p) \wedge \dots \wedge dx^k(p) \quad \text{is non-zero on } \Delta_p.$$

By continuity, the same is true for q sufficiently close to p , which by Corollary 4 implies that $dx^1(q), \dots, dx^k(q)$ are linearly independent in Δ_q . Therefore, there are C^∞ functions f_β^α such that

$$dx^\alpha(q) = \sum_{\beta=1}^k f_\beta^\alpha(q) dx^\beta(q) \quad \text{restricted to } \Delta_q \quad \alpha = k+1, \dots, n.$$

We can therefore let

$$\omega^\alpha = dx^\alpha - \sum_{\beta=1}^k f_\beta^\alpha dx^\beta.$$

14. PROPOSITION (THE FROBENIUS INTEGRABILITY THEOREM; SECOND VERSION). A distribution Δ on M is integrable if and only if $d(\mathcal{I}(\Delta)) \subset \mathcal{I}(\Delta)$.

PROOF. Locally we can choose 1-forms $\omega^1, \dots, \omega^n$ which span M_q^* for each q such that $\omega^{k+1}, \dots, \omega^n$ generate $\mathfrak{L}(\Delta)$. Let X_1, \dots, X_n be the vector fields with

$$\omega^i(X_j) = \delta_j^i.$$

Then X_1, \dots, X_k span Δ . So Δ is integrable if and only if there are functions C_{ij}^β with

$$[X_i, X_j] = \sum_{\beta=1}^k C_{ij}^\beta X_\beta \quad i, j = 1, \dots, k.$$

Now

$$d\omega^\alpha(X_i, X_j) = X_i(\omega^\alpha(X_j)) - X_j(\omega^\alpha(X_i)) - \omega^\alpha([X_i, X_j]).$$

For $1 \leq i, j \leq k$ and $\alpha > k$, the first two terms on the right vanish. So $d\omega^\alpha(X_i, X_j) = 0$ if and only if $\omega^\alpha([X_i, X_j]) = 0$. But each $\omega^\alpha([X_i, X_j]) = 0$ if and only if each $[X_i, X_j]$ belongs to Δ (i.e., if Δ is integrable), while each $d\omega^\alpha(X_i, X_j) = 0$ if and only if $d\omega^\alpha \in \mathfrak{L}(\Delta)$. ♦

Notice that since the $\omega^i \wedge \omega^j$ ($i < j$) span $\Omega^2(M_q)$ for each q , we can always write

$$\begin{aligned} d\omega^\alpha &= \sum_{i < j} c_{ij}^\alpha \omega^i \wedge \omega^j \\ &= \sum_j \theta_j^\alpha \wedge \omega^j \quad \text{for certain forms } \theta_j^\alpha. \end{aligned}$$

If $\alpha > k$, and $i_0, j_0 \leq k$ are distinct, we have

$$\begin{aligned} 0 &= d\omega^\alpha(X_{i_0}, X_{j_0}) = \sum_j (\theta_j^\alpha \wedge \omega^j)(X_{i_0}, X_{j_0}) \\ &= \theta_{j_0}^\alpha(X_{i_0}), \end{aligned}$$

so we can write the condition $d(\mathfrak{L}(\Delta)) \subset \mathfrak{L}(\Delta)$ as

$$d\omega^\alpha = \sum_{\beta > k} \theta_\beta^\alpha \wedge \omega^\beta.$$

Once we have introduced a coordinate system (x, U) such that the slices

$$\{q \in U : x^{k+1}(q) = a^{k+1}, \dots, x^n(q) = a^n\}$$

are integral submanifolds of Δ , the forms dx^{k+1}, \dots, dx^n are a basis for $\mathfrak{L}(\Delta)$, so $\omega^{k+1}, \dots, \omega^n$ must be linear combinations of them. We therefore have the following.

15. COROLLARY. If $\omega^{k+1}, \dots, \omega^n$ are linearly independent 1-forms in a neighborhood of $p \in M$, then there are 1-forms θ_β^α ($\alpha, \beta > k$) with

$$d\omega^\alpha = \sum_\beta \theta_\beta^\alpha \wedge \omega^\beta$$

if and only if there are functions f_β^α, g^β ($\alpha, \beta > k$) with

$$\omega^\alpha = \sum_\beta f_\beta^\alpha dg^\beta.$$

Although Theorem 13 warms the heart of many an invariant lover, the cases $k > 1$ will hardly ever be used (a very significant exception occurs in the last chapter of Volume V). Problem 18 gives another invariant definition of $d\omega$, using induction on the degree of ω , which is much simpler. The reader may reflect on the difficulties which would be involved in using the definition of Theorem 13 to prove the following important property of d :

16. PROPOSITION. If $f: M \rightarrow N$ is C^∞ and ω is a k -form on N , then

$$f^*(d\omega) = d(f^*\omega).$$

PROOF. For $p \in M$, let (x, U) be a coordinate system around $f(p)$. We can assume

$$\omega = g dx^{i_1} \wedge \dots \wedge dx^{i_k}.$$

We will use induction on k . For $k = 0$ we have, tracing through some definitions,

$$\begin{aligned} f^*(dg)(X) &= dg(f_*X) = [f_*X](g) = X(g \circ f) \\ &= d(g \circ f)(X) \end{aligned}$$

(and, of course, f^*g is to be interpreted as $g \circ f$). Assuming the formula for $k - 1$, we have

$$\begin{aligned} d(f^*\omega) &= d((f^*g dx^{i_1} \wedge \dots \wedge dx^{i_{k-1}}) \wedge f^*dx^{i_k}) \\ &= d(f^*(g dx^{i_1} \wedge \dots \wedge dx^{i_{k-1}})) \wedge f^*dx^{i_k} + 0 \\ &\quad \text{since } df^*dx^{i_k} = dd(x^{i_k} \circ f) = 0 \\ &= f^*(d(g dx^{i_1} \wedge \dots \wedge dx^{i_{k-1}})) \wedge f^*dx^{i_k} \\ &\quad \text{by the inductive hypothesis} \\ &= f^*(dg \wedge dx^{i_1} \wedge \dots \wedge dx^{i_{k-1}}) \wedge f^*dx^{i_k} \\ &= f^*(dg \wedge dx^{i_1} \wedge \dots \wedge dx^{i_{k-1}} \wedge dx^{i_k}) \\ &= f^*(d\omega). \quad \spadesuit \end{aligned}$$

One property of d qualifies, by the criterion of the previous chapter, as a basic theorem of differential geometry. The relation $d^2 = 0$ is just an elegant way of stating that mixed partial derivatives are equal. There is another set of terminology for stating the same thing. A form ω is called *closed* if $d\omega = 0$ and *exact* if $\omega = d\eta$ for some form η . (The terminology “exact” is classical—differential forms used to be called simply “differentials”; a differential was then called “exact” if it actually was the differential of something. The term “closed” is based on an analogy with chains, which will be discussed in the next chapter.) Since $d^2 = 0$, every exact form is closed. In other words, $d\omega = 0$ is a necessary condition for solving $\omega = d\eta$. If ω is a 1-form

$$\omega = \sum_{i=1}^n \omega_i dx^i,$$

then the condition $d\omega = 0$, i.e.,

$$\frac{\partial \omega_i}{\partial x^j} = \frac{\partial \omega_j}{\partial x^i}$$

is necessary for solving $\omega = df$, i.e.,

$$\frac{\partial f}{\partial x^i} = \omega_i.$$

Now we know from Theorem 6-1 that these conditions are also sufficient. For 2-forms the situation is more complicated, however. If ω is a 2-form on \mathbb{R}^3 ,

$$\omega = A dy \wedge dz - B dx \wedge dz + C dx \wedge dy,$$

then

$$\omega = d(P dx + Q dy + R dz)$$

if and only if

$$\frac{\partial R}{\partial y} - \frac{\partial Q}{\partial z} = A$$

$$\frac{\partial P}{\partial z} - \frac{\partial R}{\partial x} = B$$

$$\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} = C.$$

The necessary condition, $d\omega = 0$, is

$$\frac{\partial A}{\partial x} + \frac{\partial B}{\partial y} + \frac{\partial C}{\partial z} = 0.$$

In general, we are dealing with a rather strange collection of partial differential equations (carefully selected so that we can get integrability conditions). It turns out that these necessary conditions are also sufficient: if ω is closed, then it is exact. Like our results about solutions to differential equations, this result is true only locally. The reasons for restricting ourselves to local results are now somewhat different, however. Consider the case of a closed 1-form ω on \mathbb{R}^2 :

$$\omega = f dx + g dy, \quad \text{with} \quad \frac{\partial f}{\partial y} = \frac{\partial g}{\partial x}.$$

We know how to find a function α on *all* of \mathbb{R}^2 with $\omega = d\alpha$, namely

$$\alpha(x, y) = \int_{x_0}^x f(t, y_0) dt + \int_{y_0}^y g(x, t) dt.$$

On the other hand, the situation is very different if ω is defined only on $\mathbb{R}^2 - \{0\}$. Recall that if $L \subset \mathbb{R}^2$ is $[0, \infty) \times \{0\}$, then

$$\theta: \mathbb{R}^2 - L \rightarrow \mathbb{R},$$

defined in Chapter 2, is C^∞ ; in fact,

$$(r, \theta): \mathbb{R}^2 - L \rightarrow \{r: r > 0\} \times (0, 2\pi)$$

is the inverse of the map

$$(a, b) \mapsto (a \cos b, a \sin b),$$

whose derivative at (a, b) has determinant equal to $a \neq 0$. By deleting a different ray L_1 we can define a different function θ_1 . Then $\theta_1 = \theta$ in the region A_1 and $\theta_1 = \theta + 2\pi$ in the region A_2 . Consequently $d\theta$ and $d\theta_1$ agree on their common

domain, so that together they define a 1-form ω on $\mathbb{R}^2 - \{0\}$. A computation (Problem 20) shows that

$$\omega = \frac{-y}{x^2 + y^2} dx + \frac{x}{x^2 + y^2} dy.$$

The 1-form ω is usually denoted by $d\theta$, but this is an abuse of notation, since $\omega = d\theta$ only on $\mathbb{R}^2 - L$. In fact, ω is not df for any C^1 function $f: \mathbb{R}^2 - \{0\} \rightarrow \mathbb{R}$. Indeed, if $\omega = df$, then

$$df = d\theta \quad \text{on} \quad \mathbb{R}^2 - L,$$

so $d(f - \theta) = 0$ on $\mathbb{R}^2 - L$, which implies that $\partial f / \partial x = \partial \theta / \partial x$ and $\partial f / \partial y = \partial \theta / \partial y$ and hence $f = \theta + \text{constant}$ on $\mathbb{R}^2 - L$, which is impossible. Nevertheless, $d\omega = 0$ [the two relations

$$d(d\theta) = 0 \quad \text{on} \quad \mathbb{R}^2 - L$$

$$d(d\theta_1) = 0 \quad \text{on} \quad \mathbb{R}^2 - L_1$$

clearly imply that this is so]. So ω is closed, but not exact. (It is still exact in a neighborhood of any point of $\mathbb{R}^2 - \{0\}$.)

Clearly ω is also not exact in any small region containing 0. This example shows that it is the shape of the region, rather than its size, that determines whether or not a closed form is necessarily exact.

A manifold M is called (smoothly) contractible to a point $p_0 \in M$ if there is a C^∞ function

$$H: M \times [0, 1] \rightarrow M$$

such that

$$\begin{aligned} H(p, 1) &= p \\ H(p, 0) &= p_0 \end{aligned} \quad \text{for } p \in M.$$

For example, \mathbb{R}^n is smoothly contractible to $0 \in \mathbb{R}^n$; we can define

$$H: \mathbb{R}^n \times [0, 1] \rightarrow \mathbb{R}^n$$

by

$$H(p, t) = tp.$$

More generally, $U \subset \mathbb{R}^n$ is contractible to $p_0 \in U$ if U has the property that

$p \in U$ implies $p_0 + t(p - p_0) \in U$ for $0 \leq t \leq 1$ (such a region U is called **star-shaped** with respect to p_0).

Of course, many other regions are also contractible to a point. If we think

of $[0, 1]$ as representing time, then for each time t we have a map $p \mapsto H(p, t)$ of M into itself; at time 1 this is just the identity map, and at time 0 it is the constant map.

We will show that if M is smoothly contractible to a point, then every closed form on M is exact. (By the way, this result and our investigation of the form $d\theta$ prove the intuitively obvious fact that $\mathbb{R}^2 - \{0\}$ is *not* contractible to a point; the same result holds for $\mathbb{R}^n - \{0\}$, but we will not be in a position to prove this until the next chapter.) The trick in proving our result is to analyze $M \times [0, 1]$ (for any manifold M), and pay hardly any attention at all to H .

For $t \in [0, 1]$ we define

$$i_t: M \rightarrow M \times [0, 1]$$

by

$$i_t(p) = (p, t).$$

We claim that if ω is a form on $M \times [0, 1]$ with $d\omega = 0$, then

$$i_1^* \omega - i_0^* \omega \quad \text{is exact;}$$

we will see later (and you may try to convince yourself right now) that the theorem follows trivially from this.

Consider first a 1-form ω on $M \times [0, 1]$. We will begin by working in a coordinate system on $M \times [0, 1]$. There is an obvious function t on $M \times [0, 1]$ (namely, the projection π on the second coordinate), and if (x, U) is a coordinate system on M , while π_M is the projection on M , then

$$(x^1 \circ \pi_M, \dots, x^n \circ \pi_M, t)$$

is a coordinate system on $U \times [0, 1]$. We will denote $x^i \circ \pi_M$ by \bar{x}^i , for convenience. It is easy to check (or should be) that

$$i_\alpha^* \left(\sum_{i=1}^n \omega_i d\bar{x}^i + f dt \right) = \sum_{i=1}^n \omega_i(\cdot, \alpha) dx^i,$$

where

$$\omega_i(\cdot, \alpha) \text{ denotes the function } p \mapsto \omega_i(p, \alpha).$$

Now for $\omega = \sum_{i=1}^n \omega_i d\bar{x}^i + f dt$ we have

$$d\omega = [\text{terms not involving } dt] - \sum_{i=1}^n \frac{\partial \omega_i}{\partial t} d\bar{x}^i \wedge dt + \sum_{i=1}^n \frac{\partial f}{\partial \bar{x}^i} d\bar{x}^i \wedge dt.$$

So $d\omega = 0$ implies that

$$\frac{\partial \omega_i}{\partial t} = \frac{\partial f}{\partial \bar{x}^i}.$$

Consequently,

$$\begin{aligned} \omega_i(p, 1) - \omega_i(p, 0) &= \int_0^1 \frac{\partial \omega_i}{\partial t}(p, t) dt \\ &= \int_0^1 \frac{\partial f}{\partial \bar{x}^i}(p, t) dt, \end{aligned}$$

so

$$(1) \quad \sum_{i=1}^n \omega_i(p, 1) dx^i - \sum_{i=1}^n \omega_i(p, 0) dx^i = \sum_{i=1}^n \left(\int_0^1 \frac{\partial f}{\partial \bar{x}^i}(p, t) dt \right) dx^i.$$

If we define $g: M \rightarrow \mathbb{R}$ by

$$g(p) = \int_0^1 f(p, t) dt,$$

then

$$(2) \quad \frac{\partial g}{\partial x^i}(p) = \int_0^1 \frac{\partial f}{\partial \bar{x}^i}(p, t) dt.$$

Equations (1) and (2) show that

$$i_1^* \omega - i_0^* \omega = dg.$$

Now although we seem to be using a coordinate system, the function f , and hence g also, is really independent of the coordinate system. Notice that for the tangent space of $M \times [0, 1]$ we have

$$(*) \quad (M \times [0, 1])_{(p, t)} = \ker \pi_* \oplus \ker \pi_{M*}.$$

If a vector space V is a direct sum $V = V_1 \oplus V_2$ of two subspaces, then any $\omega \in \Omega^1(V)$ can be written

$$\omega = \omega_1 + \omega_2$$

where

$$\omega_1(v_1 + v_2) = \omega(v_1)$$

$$\omega_2(v_1 + v_2) = \omega(v_2).$$

Applying this to the decomposition (*), we write the 1-form ω on $M \times [0, 1]$ as $\omega_1 + \omega_2$; there is then a unique f with $\omega_2 = f dt$.

In general, for a k -form ω , it is easy to see (Problem 22) that we can write ω uniquely as

$$\omega = \omega_1 + (dt \wedge \eta)$$

where $\omega_1(v_1, \dots, v_k) = 0$ if some $v_i \in \ker \pi_{M*}$, and η is a $(k-1)$ -form with the

analogous property. Define a $(k-1)$ -form $I\omega$ on M as follows:

$$I\omega(p)(v_1, \dots, v_{k-1}) = \int_0^1 \eta(p, t)(i_{t*}v_1, \dots, i_{t*}v_{k-1}) dt.$$

We claim that $d\omega = 0$ implies that $i_1^*\omega - i_0^*\omega = d(I\omega)$. Actually, it is easier to find a formula for $i_1^*\omega - i_0^*\omega$ that holds even when $d\omega \neq 0$.

17. THEOREM. For any k -form ω on $M \times [0, 1]$ we have

$$i_1^*\omega - i_0^*\omega = d(I\omega) + I(d\omega).$$

(Consequently, $i_1^*\omega - i_0^*\omega = d(I\omega)$ if $d\omega = 0$.)

PROOF. Since $I\omega$ is already invariantly defined, we can just as well work in a coordinate system $(\bar{x}^1, \dots, \bar{x}^n, t)$. The operator I is clearly linear, so we just have to consider two cases.

(1) $\omega = f d\bar{x}^{i_1} \wedge \dots \wedge d\bar{x}^{i_k} = f d\bar{x}^I$. Then

$$d\omega = \frac{\partial f}{\partial t} dt \wedge d\bar{x}^I;$$

it is easy to see that

$$\begin{aligned} I(d\omega)(p) &= \left(\int_0^1 \frac{\partial f}{\partial t}(p, t) dt \right) dx^I(p) \\ &= [f(p, 1) - f(p, 0)] dx^I(p) \\ &= i_1^*\omega(p) - i_0^*\omega(p). \end{aligned}$$

Since $I\omega = 0$, this proves the result in this case.

(2) $\omega = f dt \wedge d\bar{x}^{i_1} \wedge \dots \wedge d\bar{x}^{i_{k-1}} = f dt \wedge d\bar{x}^I$. Then $i_1^*\omega = i_0^*\omega = 0$. Now

$$\begin{aligned} I(d\omega)(p) &= I\left(-\sum_{\alpha=1}^n \frac{\partial f}{\partial \bar{x}^\alpha} dt \wedge d\bar{x}^\alpha \wedge d\bar{x}^I\right)(p) \\ &= -\sum_{\alpha=1}^n \left(\int_0^1 \frac{\partial f}{\partial \bar{x}^\alpha}(p, t) dt \right) dx^\alpha \wedge dx^I \end{aligned}$$

and

$$\begin{aligned} d(I\omega) &= d\left(\int_0^1 f(p, t) dt\right) dx^I \\ &= \sum_{\alpha=1}^n \frac{\partial}{\partial x^\alpha} \left(\int_0^1 f(p, t) dt \right) dx^\alpha \wedge dx^I. \end{aligned}$$

Clearly $I(d\omega) + d(I\omega) = 0$. ♦

18. COROLLARY. If M is smoothly contractible to a point $p_0 \in M$, then every closed form ω on M is exact.

PROOF. We are given $H: M \times [0, 1] \rightarrow M$ with

$$\begin{aligned} H(p, 1) &= p \\ H(p, 0) &= p_0 \end{aligned} \quad \text{for all } p \in M.$$

Thus

$$\begin{aligned} H \circ i_1: M &\rightarrow M \quad \text{is the identity} \\ H \circ i_0: M &\rightarrow M \quad \text{is the constant map } p_0. \end{aligned}$$

So

$$\begin{aligned} \omega &= (H \circ i_1)^*(\omega) = i_1^*(H^*\omega) \\ 0 &= (H \circ i_0)^*(\omega) = i_0^*(H^*\omega). \end{aligned}$$

But

$$d(H^*\omega) = H^*(d\omega) = 0,$$

so

$$\begin{aligned} \omega - 0 &= i_1^*(H^*\omega) - i_0^*(H^*\omega) \\ &= d(I(H^*\omega)) \quad \text{by the Theorem. } \blacklozenge \end{aligned}$$

Corollary 18 is called the Poincaré Lemma by most geometers, while $d^2 = 0$ is called the Poincaré Lemma by some (I don't even know whether Poincaré had anything to do with it.) In the case of a star-shaped open subset U of \mathbb{R}^n , where we have an explicit formula for H , we can find (Problem 23) an explicit formula for $I(H^*\omega)$, for every form ω on U . Since the new form is given by an integral, we can solve the system of partial differential equations $\omega = d\eta$ explicitly in terms of integrals. There are classical theorems about vector fields in \mathbb{R}^3 which can be derived from the Poincaré Lemma and its converse (Problem 27), and originally d was introduced in order to obtain a uniform generalization of all these results. Even though the Poincaré Lemma and its converse fit very nicely into our pattern for basic theorems about differential geometry, it has always been something of a mystery to me just why d turns out to be so important. An answer to this question is provided by a theorem of Palais, *Natural Operations on Differential Forms*, Trans. Amer. Math. Soc. 92 (1959), 125–141. Suppose we have any operator D from k -forms to l -forms, such that the following diagram

commutes for every C^∞ map $f: M \rightarrow N$ [it actually suffices to assume that the diagram commutes only for diffeomorphisms f].

$$\begin{array}{ccc}
 k\text{-forms on } M & \xleftarrow{f^*} & k\text{-forms on } N \\
 D \downarrow & & \downarrow D \\
 l\text{-forms on } M & \xleftarrow{f^*} & l\text{-forms on } M
 \end{array}$$

Palais' theorem says that, with few exceptions, $D = 0$. Roughly, these exceptional cases are the following. If $k = l$, then D can be a multiple of the identity map, but nothing else. If $l = k + 1$, then D can only be some multiple of d . (As a corollary, $d^2 = 0$, since d^2 makes the above diagram commute!) There is only one other case where a non-zero D exists—when k is the dimension of M and $l = 0$. In this case, D can be a multiple of “integration”, which we discuss in the next chapter.

PROBLEMS

1. Show that if we define

$$\sigma \bullet (v_1, \dots, v_k) = (v_{\sigma^{-1}(1)}, \dots, v_{\sigma^{-1}(k)}),$$

then

$$\sigma \bullet \rho \bullet (v_1, \dots, v_k) = \sigma\rho \bullet (v_1, \dots, v_k).$$

2. Let $\overline{\text{Alt}}$ be Alt without the factor $1/k!$, and define $\omega \pi \eta = \overline{\text{Alt}}(\omega \otimes \eta)$. Show that π is *not* associative. (Try $\omega, \eta \in \Omega^1(V)$ and $\theta \in \Omega^2(V)$.)

3. Let $S' \subset S_{k+l}$ be the subgroup of all σ which leave both sets $\{1, \dots, k\}$ and $\{k+1, \dots, k+l\}$ invariant. A *cross section* of S' is a subset $K \subset S_{k+l}$ containing exactly one element from each left coset of S' .

(a) Show that for any cross section K we have

$$\omega \wedge \eta(v_1, \dots, v_{k+l}) = \sum_{\sigma \in K} \text{sgn } \sigma \cdot \omega \otimes \eta(v_{\sigma(1)}, \dots, v_{\sigma(k+l)}).$$

This definition may be used even in a field of finite characteristic.

(b) Show from this definition that $\omega \wedge \eta$ is alternating, and $\omega \wedge \eta = (-1)^{kl} \eta \wedge \omega$. (Proving associativity is quite messy.)

(c) A permutation $\sigma \in S_{k+l}$ is called a *shuffle permutation* if $\sigma(1) < \sigma(2) < \dots < \sigma(k)$ and $\sigma(k+1) < \sigma(k+2) < \dots < \sigma(k+l)$. Show that the set of all shuffle permutations is a cross section of S' .

4. For $v \in V$ and $\omega \in \Omega^k(V)$, we define the contraction $v \lrcorner \omega \in \Omega^{k-1}(V)$ by

$$(v \lrcorner \omega)(v_1, \dots, v_{k-1}) = \omega(v, v_1, \dots, v_{k-1}).$$

This is sometime also called the *inner product* and the notation $i_v \omega$ is also used.

(a) Show that

$$v \lrcorner (w \lrcorner \omega) = -w \lrcorner (v \lrcorner \omega).$$

(b) Show that if v_1, \dots, v_n is a basis of V with dual basis ϕ_1, \dots, ϕ_n , then

$$v_j \lrcorner (\phi_{i_1} \wedge \dots \wedge \phi_{i_k}) = \begin{cases} 0 & j \neq \text{any } i_\alpha \\ (-1)^{\alpha-1} \phi_{i_1} \wedge \dots \wedge \widehat{\phi_{i_\alpha}} \wedge \dots \wedge \phi_{i_k} & \text{if } j = i_\alpha. \end{cases}$$

(c) Show that for $\omega_1 \in \Omega^k(V)$ and $\omega_2 \in \Omega^l(V)$ we have

$$v \lrcorner (\omega_1 \wedge \omega_2) = (v \lrcorner \omega_1) \wedge \omega_2 + (-1)^k \omega_1 \wedge (v \lrcorner \omega_2).$$

(Use (b) and linearity of everything.)

(d) Formula (c) can be used to give a definition of $\omega_1 \wedge \omega_2$ by induction on $k + l$ (which works for vector spaces over any field): If \wedge is defined for forms of degree adding up to $< k + l$, we define

$$\begin{aligned}\omega_1 \wedge \omega_2(v_1, \dots, v_{k+l}) &= [(v_1 \lrcorner \omega_1) \wedge \omega_2](v_2, \dots, v_{k+l}) \\ &\quad + (-1)^k [\omega_1 \wedge (v_1 \lrcorner \omega_2)](v_2, \dots, v_{k+l}).\end{aligned}$$

Show that with this definition $\omega_1 \wedge \omega_2$ is skew-symmetric (it is only necessary to check that interchanging v_1 and v_2 changes the sign of the right side).

(e) Prove by induction that \wedge is bilinear and that $\omega_1 \wedge \omega_2 = (-1)^{kl} \omega_2 \wedge \omega_1$.

(f) If X is a vector field on M and ω a k -form on M we define a $(k-1)$ -form $X \lrcorner \omega$ by

$$(X \lrcorner \omega)(p) = X(p) \lrcorner \omega(p).$$

Show that if ω_1 is a k -form, then

$$X \lrcorner (\omega_1 \wedge \omega_2) = (X \lrcorner \omega_1) \wedge \omega_2 + (-1)^k \omega_1 \wedge (X \lrcorner \omega_2).$$

5. Show that n functions $f_1, \dots, f_n: M \rightarrow \mathbb{R}$ form a coordinate system in a neighborhood of $p \in M$ if and only if $df_1 \wedge \dots \wedge df_n(p) \neq 0$.

6. An element $\omega \in \Omega^k(V)$ is called **decomposable** if $\omega = \phi_1 \wedge \dots \wedge \phi_k$ for some $\phi_i \in V^* = \Omega^1(V)$.

(a) If $\dim V \leq 3$, then every $\omega \in \Omega^2(V)$ is decomposable.

(b) If $\phi_i, i = 1, \dots, 4$ are independent, then $\omega = (\phi_1 \wedge \phi_2) + (\phi_3 \wedge \phi_4)$ is not decomposable. *Hint*: Look at $\omega \wedge \omega$.

7. For any $\omega \in \Omega^k(V)$, we define the **annihilator** of ω to be

$$\text{Ann}(\omega) = \{\phi \in V^*: \phi \wedge \omega = 0\}.$$

(a) Show that

$$\dim \text{Ann}(\omega) \leq k,$$

and that equality holds if and only if ω is decomposable.

(b) Every subspace of V^* is $\text{Ann}(\omega)$ for some decomposable ω , which is unique up to a multiplicative constant.

(c) If ω_1 and ω_2 are decomposable, then $\text{Ann}(\omega_1) \subset \text{Ann}(\omega_2)$ if and only if $\omega_2 = \omega_1 \wedge \eta$ for some η .

(d) If ω_i are decomposable, then $\text{Ann}(\omega_1) \cap \text{Ann}(\omega_2) = \{0\}$ if and only if $\omega_1 \wedge \omega_2 \neq 0$. In this case,

$$\text{Ann}(\omega_1) + \text{Ann}(\omega_2) = \text{Ann}(\omega_1 \wedge \omega_2).$$

(e) If V has dimension n , then any $\omega \in \Omega^{n-1}(V)$ is decomposable.

(f) Since $v_i \in V$ can be regarded as elements of V^{**} , we can consider $v_1 \wedge \dots \wedge v_k \in \Omega^k(V^*)$. Reformulate parts (a)–(d) in terms of this \wedge product.

8. (a) Let $\omega \in \Omega^2(V)$. Show that there is a basis ϕ_1, \dots, ϕ_n of V^* such that

$$\omega = (\phi_1 \wedge \phi_2) + \dots + (\phi_{2r-1} \wedge \phi_{2r}).$$

Hint: If

$$\omega = \sum_{i < j} a_{ij} \psi_i \wedge \psi_j,$$

choose ϕ_1 involving $\psi_1, \psi_3, \dots, \psi_n$ and ϕ_2 involving ψ_2, \dots, ψ_n so that

$$\omega = \phi_1 \wedge \phi_2 + \omega',$$

where ω' does not involve ψ_1 or ψ_2 .

(b) Show that the r -fold wedge product $\omega \wedge \dots \wedge \omega$ is non-zero and decomposable, and that the $(r+1)$ -fold wedge product is 0. Thus r is well-determined; it is called the **rank** of ω .

(c) If $\omega = \sum_{i < j} a_{ij} \psi_i \wedge \psi_j$, show that the rank of ω is the rank of the matrix (a_{ij}) .

9. If v_1, \dots, v_n is a basis for V and $w_i = \sum_{j=1}^n \alpha_{ji} v_j$, show that

$$\det(\alpha_{ij}) w_1^* \wedge \dots \wedge w_n^* = v_1^* \wedge \dots \wedge v_n^*.$$

10. Let $A = (a_{ij})$ be an $n \times n$ matrix. Let $1 \leq p \leq n$ be fixed, and let $q = n - p$. For $H = h_1 < \dots < h_p$ and $K = k_1 < \dots < k_q$, let

$$B^H = \det \begin{pmatrix} a_{1,h_1} & \dots & a_{1,h_p} \\ \vdots & & \vdots \\ a_{p,h_1} & \dots & a_{p,h_p} \end{pmatrix}, \quad C^K = \det \begin{pmatrix} a_{p+1,k_1} & \dots & a_{p+1,k_q} \\ \vdots & & \vdots \\ a_{n,k_1} & \dots & a_{n,k_q} \end{pmatrix}.$$

(a) If v_1, \dots, v_n is a basis of V and

$$w_i = \sum_{j=1}^n a_{ji} v_j,$$

show that

$$\begin{aligned} w_1 \wedge \dots \wedge w_p &= \sum_H B^H v_H \\ w_{p+1} \wedge \dots \wedge w_n &= \sum_K C^K v_K. \end{aligned}$$

(b) Let $H' = \{1, \dots, n\} - H$ (arranged in increasing order). Show that

$$v_H \wedge v_K = \begin{cases} 0 & K \neq H' \\ e_{H, H'} v_1 \wedge \dots \wedge v_n & K = H', \end{cases}$$

where $e_{H, H'}$ is the sign of the permutation

$$\begin{pmatrix} 1 & \dots & \dots & \dots & \dots & \dots & n \\ h_1, h_2, \dots, h_p, k_1, \dots, k_q \end{pmatrix}.$$

(c) Prove “Laplace’s expansion”

$$\det A = \sum_H e_{H, H'} B^H C^{H'}.$$

11. (Cartan’s Lemma) Let $\phi_1, \dots, \phi_k \in V^*$ be independent and suppose that $\psi_1, \dots, \psi_k \in V^*$ satisfy

$$(\phi_1 \wedge \psi_1) + \dots + (\phi_k \wedge \psi_k) = 0.$$

Then

$$\psi_i = \sum_{j=1}^k a_{ji} \phi_j, \quad \text{where } a_{ji} = a_{ij}.$$

12. In addition to forms, we can consider sections of bundles constructed from TM using Ω and other operations. For example, if $\xi = \pi: E \rightarrow B$ is a vector bundle, we can consider $\Omega^k(\xi^*)$, the bundle whose fibre at p is $\Omega^k([\pi^{-1}(p)]^*)$. Since we can regard

$$\frac{\partial}{\partial x^i} \quad \text{as an element of } (M_p)^{**},$$

any section of $\Omega^n(T^*M)$ can be written locally as

$$h \frac{\partial}{\partial x^1} \wedge \dots \wedge \frac{\partial}{\partial x^n}.$$

(a) Show that if

$$g \frac{\partial}{\partial y^1} \wedge \dots \wedge \frac{\partial}{\partial y^n} = h \frac{\partial}{\partial x^1} \wedge \dots \wedge \frac{\partial}{\partial x^n},$$

then

$$h = g \cdot \left[\det \left(\frac{\partial y^i}{\partial x^j} \right) \right]^{-1}.$$

This shows that sections of $\Omega^n(T^*M)$ are the geometric objects corresponding to the (even) relative scalars of weight -1 in Problem 4-10.

(b) Let $\mathcal{T}_l^{k[m]}(V)$ denote the vector space of all multilinear functions

$$\underbrace{V \times \cdots \times V}_k \times \underbrace{V^* \times \cdots \times V^*}_l \rightarrow \Omega^m(V).$$

Show that sections of $\mathcal{T}_l^{k[n]}(TM)$ correspond to (even) relative tensors of type $\binom{k}{l}$ and weight 1. (Notice that if v_1, \dots, v_n is a basis for V , then elements of $\Omega^n(V)$ can be represented by real numbers [times the element $v^*_1 \wedge \cdots \wedge v^*_n$].)

(c) If $\mathcal{T}_{l[m]}^k(V)$ is defined similarly, except that $\Omega^m(V)$ is replaced by $\Omega^m(V^*)$, show that sections of $\mathcal{T}_{l[m]}^k(TM)$ correspond to (even) relative tensors of type $\binom{k}{l}$ and weight -1 .

(d) Show that the covariant relative tensor of type $\binom{0}{n}$ and weight 1 defined in Problem 4-10, with components $\varepsilon^{i_1 \dots i_n}$, corresponds to the map

$$\underbrace{V^* \times \cdots \times V^*}_n \rightarrow \Omega^n(V)$$

given by $(\phi_1, \dots, \phi_n) \mapsto \phi_1 \wedge \cdots \wedge \phi_n$. Interpret the relative tensor with components $\varepsilon_{i_1 \dots i_n}$ similarly.

(e) Suppose $\Omega^{n;w}(V)$ denotes all functions $\eta: V \times \cdots \times V \rightarrow \mathbb{R}$ which are of the form

$$\eta(v_1, \dots, v_n) = [\omega(v_1, \dots, v_n)]^w \quad w \text{ an integer}$$

for some $\omega \in \Omega^n(V)$. Let $\mathcal{T}_l^{k[n;w]}(V)$ be defined like $\mathcal{T}_l^{k[n]}$, except that $\Omega^n(V)$ is replaced by $\Omega^{n;w}(V)$. Show that sections of $\mathcal{T}_l^{k[n;w]}(TM)$ correspond to (even) relative tensors of type $\binom{k}{l}$ and weight w . Similarly for $\mathcal{T}_{l[n;w]}^k$.

(f) For those who know about tensor products $V \otimes W$ and exterior algebras $\Lambda^k(V)$, these results can all be restated. We can identify $\mathcal{T}_l^k(V)$ with

$$\bigotimes^k V^* \otimes \bigotimes^l V = \underbrace{V^* \otimes \cdots \otimes V^*}_k \otimes \underbrace{V \otimes \cdots \otimes V}_l.$$

Since $\Omega^m(V) \approx \Lambda^m(V^*) \approx [\Lambda^m(V)]^*$, we can identify

$$\begin{aligned} \mathcal{T}_l^{k[m]}(V) & \text{ with } \bigotimes^k V^* \otimes \bigotimes^l V \otimes \Lambda^m(V) \\ \mathcal{T}_{l[m]}^k(V) & \text{ with } \bigotimes^k V^* \otimes \bigotimes^l V \otimes \Lambda^m(V^*). \end{aligned}$$

Consider, more generally,

$$\begin{aligned}\mathcal{T}_l^{k[m;w]}(V) &= \bigotimes^k V^* \otimes \bigotimes^l V \otimes \bigotimes^w \Lambda^m(V) \\ \mathcal{T}_{l[m;w]}^k(V) &= \bigotimes^k V^* \otimes \bigotimes^l V \otimes \bigotimes^w \Lambda^m(V^*).\end{aligned}$$

Noting that $\Lambda^n(V) \otimes \cdots \otimes \Lambda^n(V)$ is always 1-dimensional, show that sections of $\mathcal{T}_l^{k[n;w]}(TM)$ and $\mathcal{T}_{l[n;w]}^k(TM)$ correspond to (even) relative tensors of type $\binom{k}{l}$ and weight w and $-w$, respectively.

13. (a) If V has dimension n and $A: V \rightarrow V$ is a linear transformation, then the map $A^*: \Omega^n(V) \rightarrow \Omega^n(V)$ must be multiplication by some constant c . Show that $c = \det A$. (This may be used as a definition of $\det A$.)

(b) Conclude that $\det AB = (\det A)(\det B)$.

14. Recall that the characteristic polynomial of $A: V \rightarrow V$ is

$$\begin{aligned}\chi(\lambda) &= \det(\lambda I - A) \\ &= \lambda^n - (\text{trace } A)\lambda^{n-1} + \cdots + (-1)^n \det A \\ &= \lambda^n - c_1\lambda^{n-1} + c_2\lambda^{n-2} + \cdots + (-1)^n c_n.\end{aligned}$$

(a) Show that $c_k = \text{trace of } A^*: \Omega^k(V) \rightarrow \Omega^k(V)$.

(b) Conclude that $c_k(AB) = c_k(BA)$.

(c) Let $\delta_{i_1 \dots i_k}^{j_1 \dots j_k}$ be as defined in Problem 4-5(xiii). If $A: V \rightarrow V$ has a matrix (a_i^j) (with respect to some basis), show that

$$c_k(A) = \frac{1}{k!} \sum_{\substack{i_1, \dots, i_k \\ j_1, \dots, j_k}} a_{i_1}^{j_1} a_{i_2}^{j_2} \cdots a_{i_k}^{j_k} \delta_{j_1 \dots j_k}^{i_1 \dots i_k}.$$

Thus, if δ is as defined on page 130, and A is a tensor of type $\binom{1}{1}$, then the function $p \mapsto c_k(A(p))$ can be defined as a $(2k)$ -fold contraction of

$$\underbrace{A \otimes \cdots \otimes A}_{k \text{ times}} \otimes \delta.$$

15. Let $P(X_{ij})$ be a polynomial in n^2 variables. For every $n \times n$ matrix $A = (a_{ij})$ we then have a number $P(a_{ij})$. Call P invariant if $P(A) = P(BAB^{-1})$ for all A and all invertible B . This problem outlines a proof that any invariant P is a polynomial in the polynomials c_1, \dots, c_n defined in Problem 14. We will

need the algebraic result that any symmetric polynomial $Q(y_1, \dots, y_n)$ in the n variables y_1, \dots, y_n can be written as a polynomial in $\sigma_1, \dots, \sigma_n$, where σ_i is the i^{th} elementary symmetric polynomial of y_1, \dots, y_n . Recall that the σ_i can be defined by the equation

$$\prod_{i=1}^n (y - y_i) = y^n - \sigma_1 y^{n-1} + \dots + (-1)^n \sigma_n.$$

Thus, they are the coefficients, up to sign, of the polynomial with roots y_1, \dots, y_n . Since the eigenvalues $\lambda_1, \dots, \lambda_n$ of a matrix A are, by definition, the roots of the polynomial $\chi(\lambda)$, it follows that

$$c_i(A) = \sigma_i(\lambda_1, \dots, \lambda_n).$$

We will first consider matrices A over the complex numbers \mathbb{C} (the coefficients of P may also be complex).

(a) Define $Q(y_1, \dots, y_n)$ to be $P(A)$ where A is the diagonal matrix

$$\begin{pmatrix} y_1 & & 0 \\ & \ddots & \\ 0 & & y_n \end{pmatrix}.$$

Then there is a polynomial R such that

$$Q(y_1, \dots, y_n) = R(\sigma_1(y_1, \dots, y_n), \dots, \sigma_n(y_1, \dots, y_n)).$$

The polynomial R has real coefficients if P does.

(b) $P(A) = R(c_1(A), \dots, c_n(A))$ for all diagonalizable A .

(c) The discriminant $D(A)$ is defined as $\prod_{i \neq j} (\lambda_i - \lambda_j)^2$, where λ_i are the eigenvalues of A . Show that $D(A)$ can be written as a polynomial in the entries of A .

(d) Show that $P(A) = R(c_1(A), \dots, c_n(A))$ whenever $D(A) \neq 0$. Conclude, by continuity, that the equation holds for all matrices A over \mathbb{C} . (This last conclusion follows even if \mathbb{C} is replaced by some other field, since the set where $D \neq 0$ is Zariski-dense; this is “the principle of irrelevance of algebraic inequalities”, compare pg. V.375.)

Now suppose that the coefficients of P are real and that $P(A) = P(BAB^{-1})$ for all real A and real invertible B .

(e) The same equation holds for complex A and complex invertible B . (Regard the equation as n^2 polynomial equations in the a_{ij} and b_{ij} .)

16. (a) Let v_1, \dots, v_n be a basis for V , and let $w_1, \dots, w_k \in V$ be given by

$$w_i = \sum_{j=1}^n \alpha_{ji} v_j.$$

For $\omega \in \Omega^k(V)$ show that

$$\omega(w_1, \dots, w_k) = \sum_{I=i_1 < \dots < i_k} \alpha_I \omega(v_{i_1}, \dots, v_{i_k}),$$

where α_I is the determinant of the $k \times k$ submatrix of (α_{ij}) obtained by selecting rows i_1, \dots, i_k .

(b) Generalize Theorem 7 and Corollary 8 to k -forms.

(c) Check directly from (b) that the definition of d does not depend on the coordinate system.

17. Show that $d(\sum_{i < j} \alpha_{ij} dx^i \wedge dx^j) = 0$ if and only if

$$\frac{\partial \alpha_{ij}}{\partial x^k} - \frac{\partial \alpha_{ik}}{\partial x^j} + \frac{\partial \alpha_{jk}}{\partial x^i} = 0 \quad \text{for all } i < j < k.$$

18. In Problem 5-14 we defined $L_X A$ for any tensor field A .

(a) Show that if ω is a k -form, then so is $L_X \omega$.

(b) Show that

$$L_X(\omega_1 \wedge \omega_2) = L_X \omega_1 \wedge \omega_2 + \omega_1 \wedge L_X \omega_2.$$

(c) Using 5-14(e), show that

$$\begin{aligned} X(\omega(X_1, \dots, X_k)) &= L_X(\omega(X_1, \dots, X_k)) \\ &= L_X \omega(X_1, \dots, X_k) \\ &\quad + \sum_{i=1}^k (-1)^{i+1} \omega([X, X_i], X_1, \dots, \widehat{X_i}, \dots, X_k). \end{aligned}$$

(d) Deduce the following two expressions:

$$\begin{aligned} d\omega(X_1, \dots, X_{k+1}) &= \sum_{i=1}^{k+1} (-1)^{i+1} L_{X_i} \omega(X_1, \dots, \widehat{X_i}, \dots, X_{k+1}) \\ &\quad + \sum_{i < j} (-1)^{i+j+1} \omega([X_i, X_j], X_1, \dots, \widehat{X_i}, \dots, \widehat{X_j}, \dots, X_{k+1}) \end{aligned}$$

$$\begin{aligned}
d\omega(X_1, \dots, X_{k+1}) \\
&= \frac{1}{2} \sum_{i=1}^{k+1} (-1)^{i+1} \{X_i(\omega(X_1, \dots, \widehat{X}_i, \dots, X_{k+1})) \\
&\quad + L_{X_i} \omega(X_1, \dots, \widehat{X}_i, \dots, X_{k+1})\}
\end{aligned}$$

(e) Show that

$$X \lrcorner d\omega = L_X \omega - d(X \lrcorner \omega),$$

i.e.,

$$d\omega(X_1, \dots, X_{k+1}) = (L_{X_1} \omega)(X_2, \dots, X_{k+1}) - d(X_1 \lrcorner \omega)(X_2, \dots, X_{k+1}).$$

(This may be used to give an inductive definition of d .)

(f) Using (e), show that $d(L_X \omega) = L_X(d\omega)$.

19. Let a_{ij} be n^2 functions on \mathbb{R}^n with $a_{ij} = a_{ji}$. Show that in order for there to be functions u_1, \dots, u_n in a neighborhood of any point in \mathbb{R}^n with

$$a_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x^j} + \frac{\partial u_j}{\partial x^i} \right)$$

it is necessary and sufficient that

$$\frac{\partial^2 a_{ij}}{\partial x^k \partial x^l} - \frac{\partial^2 a_{ik}}{\partial x^j \partial x^l} = \frac{\partial^2 a_{lj}}{\partial x^k \partial x^i} - \frac{\partial^2 a_{lk}}{\partial x^j \partial x^i} \quad \text{for all } i, j, k, l.$$

Hint: First set up partial differential equations for the functions $f_{jk} = \partial u_j / \partial x^k - \partial u_k / \partial x^j$, and use Theorem 6-1.

20. Compute that

$${}^{\text{“}}d\theta{}^{\text{”}} = \frac{x dy - y dx}{x^2 + y^2}.$$

(At most places $\theta = \arctan y/x$ [+ a constant].)

21. (a) If ω is a 1-form $f dx$ on $[0, 1]$ with $f(0) = f(1)$, show that there is a unique number λ such that $\omega - \lambda dx = dg$ for some function g with $g(0) = g(1)$.

Hint: Integrate the equation $\omega - \lambda dx = dg$ on $[0, 1]$ to find λ .

(b) Let $i: S^1 \rightarrow \mathbb{R}^2 - \{0\}$ be the inclusion, and let $\sigma' = i^*(d\theta)$. If $c: [0, 1] \rightarrow S^1$ is

$$c(x) = (\cos 2\pi x, \sin 2\pi x),$$

show that

$$c^*(\sigma') = 2\pi dx.$$

(c) If ω is a closed 1-form on S^1 show that there is a unique number λ such that $\omega - \lambda \sigma'$ is exact.

22. (a) Show that every $\omega \in \Omega^k(V_1 \oplus V_2)$ can be written as a sum of forms $\omega_1 \wedge \omega_2$ where ω_1 has degree α and ω_2 has degree $\beta = k - \alpha$ and

$$\omega_1(v_1, \dots, v_\alpha) = 0 \quad \text{if some } v_i \in V_2$$

$$\omega_2(v_1, \dots, v_\beta) = 0 \quad \text{if some } v_i \in V_1.$$

(b) If $\dim V_2 = 1$, and $0 \neq \lambda \in V_2^*$, then ω can be written uniquely as $\omega_1 + (\omega_2 \wedge \lambda)$, where ω_1 is a k -form and ω_2 is a $(k - 1)$ -form such that

$$\omega_1(v_1, \dots, v_k) = 0 \quad \text{if some } v_i \in V_2$$

$$\omega_2(v_1, \dots, v_{k-1}) = 0 \quad \text{if some } v_i \in V_2.$$

23. Let $U \subset \mathbb{R}^n$ be an open set star-shaped with respect to 0, and define $H: U \times [0, 1] \rightarrow U$ by $H(p, t) = tp$. If

$$\omega = \sum_{i_1 < \dots < i_k} \omega_{i_1 \dots i_k} dx^{i_1} \wedge \dots \wedge dx^{i_k}$$

on U , show that

$$I(H^*\omega)$$

$$= \sum_{i_1 < \dots < i_k} \sum_{\alpha=1}^k (-1)^{\alpha-1} \left(\int_0^1 t^{k-1} \omega_{i_1 \dots i_k}(tx) dt \right) x^{i_\alpha} dx^{i_1} \wedge \dots \wedge \widehat{dx^{i_\alpha}} \wedge \dots \wedge dx^{i_k}.$$

24. (a) Let $U \subset \mathbb{R}^2$ be a bounded open set such that $\mathbb{R}^2 - U$ is connected. Show that U is diffeomorphic to \mathbb{R}^2 , and hence smoothly contractible to a point. (The converse is proved in Problem 8-9.) *Hint*: Obtain U as an increasing union of sets, the k^{th} set being a finite union of squares containing the set of points in U whose distance from boundary U is $\leq 1/k$.

(b) Find a bounded open set $U \subset \mathbb{R}^3$ such that $\mathbb{R}^3 - U$ is connected, but U is not contractible to a point.

25. Let $U \subset \mathbb{R}^n$ be an open set star-shaped with respect to 0. Is U homeomorphic to \mathbb{R}^n ? (It would certainly appear so, but the “obvious” proof does not work, since the length of rays from 0 to the boundary of the set could vary discontinuously.)

26. Let $\langle \cdot, \cdot \rangle$ be the usual inner product on \mathbb{R}^n ,

$$\langle a, b \rangle = \sum_{i=1}^n a^i b^i.$$

(a) If $v_1, \dots, v_{n-1} \in \mathbb{R}^n$, show that there is a unique vector $v_1 \times \dots \times v_{n-1} \in \mathbb{R}^n$ with

$$\langle v_1 \times \dots \times v_{n-1}, w \rangle = \det \begin{pmatrix} w \\ v_1 \\ \vdots \\ v_{n-1} \end{pmatrix} \text{ for all } w \in \mathbb{R}^n.$$

(b) Show that $v_1 \times \dots \times v_{n-1} \in \Omega^{n-1}(\mathbb{R}^n)$, and express it in terms of the e^*_i , using the expansion of a matrix by minors.

(c) For \mathbb{R}^3 show that

$$v \times w = (v^2 w^3 - v^3 w^2, v^3 w^1 - v^1 w^3, v^1 w^2 - v^2 w^1).$$

(First find all $e_i \times e_j$.)

27. (a) If $f: \mathbb{R}^n \rightarrow \mathbb{R}$, define a vector field $\text{grad } f$, the **gradient** of f , on \mathbb{R}^n by

$$\text{grad } f = \sum_{i=1}^n \frac{\partial f}{\partial x^i} \cdot \frac{\partial}{\partial x^i} = \sum_{i=1}^n D_i f \cdot \frac{\partial}{\partial x^i}.$$

Introducing the formal symbolism

$$\nabla = \sum_{i=1}^n D_i \frac{\partial}{\partial x^i},$$

we can write $\text{grad } f = \nabla f$. If $(\text{grad } f)(p) = w_p$, show that

$$D_v f(p) = \langle v, w \rangle,$$

where $D_v f(p)$ denotes the directional derivative in the direction v at p (or simply $v_p(f)$, if we regard $v_p \in \mathbb{R}^n_p$). Conclude that $\nabla f(p)$ is the direction in which f is changing fastest at p .

(b) If $X = \sum_{i=1}^n a^i \partial/\partial x^i$ is a vector field on \mathbb{R}^n , we define the **divergence** of X as

$$\text{div } X = \sum_{i=1}^n \frac{\partial a^i}{\partial x^i}.$$

(Symbolically, we can write $\text{div } X = \langle \nabla, X \rangle$.) We also define, for $n = 3$,

$$\begin{aligned} \text{curl } X (= \nabla \times X) \\ = \left(\frac{\partial a^3}{\partial x^2} - \frac{\partial a^2}{\partial x^3} \right) \frac{\partial}{\partial x^1} + \left(\frac{\partial a^1}{\partial x^3} - \frac{\partial a^3}{\partial x^1} \right) \frac{\partial}{\partial x^2} + \left(\frac{\partial a^2}{\partial x^1} - \frac{\partial a^1}{\partial x^2} \right) \frac{\partial}{\partial x^3}. \end{aligned}$$

Define forms

$$\begin{aligned} \omega_X &= a^1 dx + a^2 dy + a^3 dz \\ \eta_X &= a^1 dy \wedge dz + a^2 dz \wedge dx + a^3 dx \wedge dy. \end{aligned}$$

Show that

$$\begin{aligned} df &= \omega_{\text{grad } f} \\ d(\omega_X) &= \eta_{\text{curl } X} \\ d(\eta_X) &= (\text{div } X) dx \wedge dy \wedge dz. \end{aligned}$$

(c) Conclude that

$$\begin{aligned} \text{curl grad } f &= 0 \\ \text{div curl } X &= 0. \end{aligned}$$

(d) If X is a vector field on a star-shaped open set $U \subset \mathbb{R}^n$ and $\text{curl } X = 0$, then $X = \text{grad } f$ for some function $f: U \rightarrow \mathbb{R}$. Similarly, if $\text{div } X = 0$, then $X = \text{curl } Y$ for some vector field Y on U .

CHAPTER 8

INTEGRATION

The basic concept of this chapter generalizes line and surface integrals, which first arose from very physical considerations. Suppose, for example, that $c: [0, 1] \rightarrow \mathbb{R}^2$ is a curve and $\omega = f dx + g dy$ is a 1-form on \mathbb{R}^2 (where $f, g: \mathbb{R}^2 \rightarrow \mathbb{R}$, and x and y denote the coordinate functions on \mathbb{R}^2). If we choose a partition $0 = t_0 < \cdots < t_n = 1$ of $[0, 1]$, then we can divide the curve c into n pieces, the i^{th} piece going from $c(t_{i-1})$ to $c(t_i)$. When the differences $t_i - t_{i-1}$ are small, each such piece is approximately a straight segment, with

horizontal projection $c^1(t_i) - c^1(t_{i-1})$ and vertical projection $c^2(t_i) - c^2(t_{i-1})$. We can choose points $c(\xi_i)$ on each piece by choosing points $\xi_i \in [t_{i-1}, t_i]$. For each partition P and each such choice $\xi = (\xi_1, \dots, \xi_n)$, consider the sum

$$S(P, \xi) = \sum_{i=1}^n f(c(\xi_i)) [c^1(t_i) - c^1(t_{i-1})] + g(c(\xi_i)) [c^2(t_i) - c^2(t_{i-1})].$$

If these sums approach a limit as the “mesh” $\|P\|$ of P approaches 0, that is, as the maximum of $t_i - t_{i-1}$ approaches 0, then the limit is denoted by

$$\int_c f dx + g dy.$$

(This is a complicated limit. To be precise, if $\|P\| = \max_i \{t_i - t_{i-1}\}$, then the equation

$$\lim_{\|P\| \rightarrow 0} S(P, \xi) = \int_c f dx + g dy$$

means: for all $\varepsilon > 0$, there is a $\delta > 0$ such that for all partitions P with $\|P\| < \delta$, we have

$$\left| S(P, \xi) - \int_c f dx + g dy \right| < \varepsilon$$

for all choices ξ for P .)

The limit which we have just defined is called a “line integral”; it has a natural physical interpretation. If we consider a “force field” on \mathbb{R}^2 , described by the vector field

then $S(P, \xi)$ is the “work” involved in moving a unit mass along the curve c in the case where c is actually a straight line between t_{i-1} and t_i and f and g are constant along these straight line segments; the limit is the natural definition of the work done in the general case. (In classical terminology, the differential $f dx + g dy$ would be described as the work done by the force field on an “infinitely small” displacement with components dx, dy ; the integral is the “sum” of these infinitely small displacements.)

Before worrying about how to compute this limit, consider the special case where

In this case, $c^1(t_i) - c^1(t_{i-1}) = t_i - t_{i-1}$, while $c^2(t_i) - c^2(t_{i-1}) = 0$, so

$$S(P, \xi) = \sum_{i=1}^n f(\xi_i, y_0)(t_i - t_{i-1}).$$

These sums approach

$$\int_c f dx + g dy = \int_0^1 f(x, y_0) dx.$$

On the other hand, if

then $c^1(t_i) - c^1(t_{i-1}) = (b - a)(t_i - t_{i-1})$, so

$$S(P, \xi) = (b - a) \cdot \sum_{i=1}^n f(\xi_i b + (1 - \xi_i)a, y_0)(t_i - t_{i-1}).$$

These sums approach

$$(b - a) \int_0^1 f(xb + (1 - x)a, y_0) dx = \int_a^b f(x, y_0) dx.$$

In general, for any curve c , we have, by the mean value theorem,

$$\begin{aligned} c^1(t_i) - c^1(t_{i-1}) &= c^{1'}(\alpha_i)(t_i - t_{i-1}) & \alpha_i &\in [t_{i-1}, t_i] \\ c^2(t_i) - c^2(t_{i-1}) &= c^{2'}(\beta_i)(t_i - t_{i-1}) & \beta_i &\in [t_{i-1}, t_i]. \end{aligned}$$

So

$$S(P, \xi) = \sum_{i=1}^n \{f(c(\xi_i))c^{1'}(\alpha_i) + g(c(\xi_i))c^{2'}(\beta_i)\} (t_i - t_{i-1}).$$

A somewhat messy argument (Problem 1) shows that these sums approach what it looks like they should approach, namely

$$\int_0^1 [f(c(t))c^{1'}(t) + g(c(t))c^{2'}(t)] dt.$$

Physicists' notation (or abuse thereof) makes it easy to remember this result. The components c^1, c^2 of c are denoted simply by x and y [i.e., x denotes

$x \circ c$ and y denotes $y \circ c$; this is indicated classically by saying “let $x = x(t)$, $y = y(t)$ ”. The above integral is then written

$$\int_c f dx + g dy = \int_0^1 \left[f(x, y) \frac{dx}{dt} + g(x, y) \frac{dy}{dt} \right] dt.$$

In preference to this physical interpretation of “line integrals”, we can introduce a more geometrical interpretation. Recall that $dc/dt(\xi_i)$ denotes the

tangent vector of c at time ξ_i . Then the sums

$$\begin{aligned} (*) \quad & \sum_{i=1}^n \omega(c(\xi_i)) \left(\frac{dc}{dt}(\xi_i) \right) \cdot (t_i - t_{i-1}) \\ &= \sum_{i=1}^n [f(c(\xi_i))c^1(\xi_i) + g(c(\xi_i))c^2(\xi_i)] \cdot (t_i - t_{i-1}) \end{aligned}$$

clearly also approach

$$\int_0^1 [f(c(t))c^1(t) + g(c(t))c^2(t)] dt.$$

Consider the special case where c goes with constant velocity on each (t_{i-1}, t_i) .

If we choose any $\xi_i \in (t_{i-1}, t_i)$, then

$$\begin{aligned} \text{length of } \frac{dc}{dt}(\xi_i) &= \text{the constant speed on } (t_{i-1}, t_i) \\ &= \frac{\text{length of the segment from } c(t_{i-1}) \text{ to } c(t_i)}{t_i - t_{i-1}}, \end{aligned}$$

so

$$\left[\text{length of } \frac{dc}{dt}(\xi_i) \right] \cdot (t_i - t_{i-1}) = \text{length of segment from } c(t_{i-1}) \text{ to } c(t_i).$$

In this case,

$$\sum_{i=1}^n \left[\text{length of } \frac{dc}{dt}(\xi_i) \right] \cdot (t_i - t_{i-1})$$

is the length of c , and the limit of such sums, for a general c , can be used as a definition of the length of c . The line integral

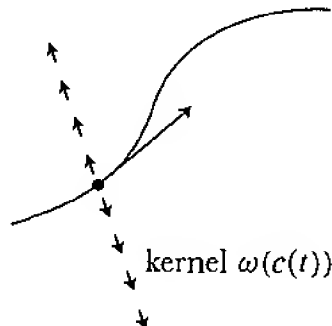

$$\int_c \omega = \text{limit of the sums } (*)$$

can be thought of as the “length” of c , when our ruler is changing continuously in a way specified by ω : Notice that the restriction of $\omega(c(t))$ to the 1-dimensional subspace of $\mathbb{R}^2_{c(t)}$ spanned by dc/dt is a constant times “signed length”. The natural way to specify a continuously changing length along c is to specify a length on its tangent vectors; this is the modern counterpart of the classical conception, whereby the curve c is divided into infinitely small parts, the infinitely small piece at $c(t)$, with components dx, dy , having length $f(c(t)) dx + g(c(t)) dy$.

Before pushing this geometrical interpretation too far, we should note that there is no 1-form ω on \mathbb{R}^2 such that

$$\int_c \omega = \text{length of } c \quad \text{for all curves } c.$$

It is true that for a given one-one curve c we can produce a form ω which works for c ; we choose $\omega(c(t)) \in \Omega^1(\mathbb{R}^2_{c(t)})$ so that

$$\omega(c(t)) \left(\frac{dc}{dt} \right) = 1,$$

(choosing the kernel of ω arbitrarily), and then extend ω to \mathbb{R}^2 . But if c is

not one-one this may be impossible; for example, in the situation shown below,

there is no element of $\Omega^1(\mathbb{R}^2_{c(t)})$ which has the value 1 on all three vectors. In general, given any ω on \mathbb{R}^2 which is everywhere non-zero, the subspaces $\Delta_p = \ker \omega(p)$ form a 1-dimensional distribution on \mathbb{R}^2 ; any curve contained in an integral submanifold of Δ will have “length” 0. Later we will see a way of circumventing this difficulty, if we are interested in obtaining the ordinary length of a curve. For the present, we note that the sums (*), used to define this generalized “length”, make sense even if c is a curve in a manifold M (where there is no notion of “length”), and ω is a 1-form on M , so we can define $\int_c \omega$ as the limit of these sums.

One property of line integrals should be mentioned now, because it is obvious with our original definition and merely true for our new definition. If $p: [0, 1] \rightarrow [0, 1]$ is a one-one increasing function from $[0, 1]$ onto $[0, 1]$, then the curve $c \circ p: [0, 1] \rightarrow M$ is called a **reparameterization** of c —it has exactly the same image as c , but transverses it at a different rate. Every sum $S(P, \xi)$ for c is clearly equal to a sum $S(P', \xi')$ for $c \circ p$, and conversely, so it is clear from our first definition that for a curve $c: [0, 1] \rightarrow \mathbb{R}^2$ we have

$$\int_c \omega = \int_{c \circ p} \omega$$

(“the integral of ω over c is independent of the parameterization”). This is no longer so clear when we consider the sums (*) for a curve $c: [0, 1] \rightarrow M$, nor is it clear even for a curve $c: [0, 1] \rightarrow \mathbb{R}^2$, but in this case we can proceed right to the integral these sums approach, namely

$$\int_0^1 [f(c(t))c^1'(t) + g(c(t))c^2'(t)] dt.$$

The result then follows from a calculation: the substitution $t = p(u)$ gives

$$\begin{aligned} & \int_0^1 [f(c(t))c'(t) + g(c(t))c^2'(t)] dt \\ &= \int_{p^{-1}(0)}^{p^{-1}(1)} [f(c(p(u)))c'(p(u)) + g(c(p(u)))c^2'(p(u))] p'(u) du \\ &= \int_0^1 [f(c \circ p(u))(c \circ p)'(u) + g(c \circ p(u))(c \circ p)^2'(u)] du. \end{aligned}$$

For a curve in \mathbb{R}^n , and a 1-form $\omega = \sum_{i=1}^n \omega_i dx^i$, there is a similar calculation; for a general manifold M , we can introduce a coordinate system for our calculations if $c([0, 1])$ lies in one coordinate system, or break c up into several pieces otherwise. We are being a bit sloppy about all this because we are about to introduce yet a third definition, which will eventually become our formal choice. Consider once again the case of a 1-form on \mathbb{R}^2 , where

$$\int_c \omega = \int_0^1 [f(c(t))c'(t) + g(c(t))c^2'(t)] dt.$$

Notice that if t is the standard coordinate system on \mathbb{R} , then for the map $c: [0, 1] \rightarrow \mathbb{R}^2$ we have

$$\begin{aligned} c^*(f dx + g dy) &= (f \circ c)c^*(dx) + (g \circ c)c^*(dy) \\ &= (f \circ c)d(x \circ c) + (g \circ c)d(y \circ c) \\ &= (f \circ c)c' dt + (g \circ c)c^2' dt, \end{aligned}$$

so that formally we just integrate $c^*(f dx + g dy)$; to be precise, we write $c^*(f dx + g dy) = h dt$ (in the unique possible way), and take the integral of h on $[0, 1]$.

Everything we have said for curves $c: [0, 1] \rightarrow \mathbb{R}^n$ could be generalized to functions $c: [0, 1]^2 \rightarrow \mathbb{R}^n$. If x and y are the coordinate functions on \mathbb{R}^2 , let

$$\begin{aligned} \frac{\partial c}{\partial x} &= c_* \left(\frac{\partial}{\partial x} \right) \\ \frac{\partial c}{\partial y} &= c_* \left(\frac{\partial}{\partial y} \right). \end{aligned}$$

For a pair of partitions $s_0 < \dots < s_m$ and $t_0 < \dots < t_n$ of $[0, 1]$, if we choose

$\xi_{ij} \in [s_{i-1}, s_i] \times [t_{j-1}, t_j]$ and ω is a 2-form on \mathbb{R}^n , then

$$\omega(c(\xi_{ij})) \left(\frac{\partial c}{\partial x}(\xi_{ij}), \frac{\partial c}{\partial y}(\xi_{ij}) \right) (s_i - s_{i-1})(t_j - t_{j-1})$$

is a “generalized area” of the parallelogram spanned by

$$\frac{\partial c}{\partial x}(\xi_{ij}), \quad \frac{\partial c}{\partial y}(\xi_{ij}).$$

The limit of sums of these terms can be thought of as a “generalized area” of c . To make a long story short, we now proceed with the formal definitions.

A C^∞ function $c: [0, 1]^k \rightarrow M$ is called a **singular k -cube** in M (the word “singular” indicates that c is not necessarily one-one). We will let $[0, 1]^0 = \mathbb{R}^0 = 0 \in \mathbb{R}$, so that a singular 0-cube c is determined by the one point $c(0) \in M$. The inclusion map of $[0, 1]^k$ in \mathbb{R}^k will be denoted by $I^k: [0, 1]^k \rightarrow \mathbb{R}^k$; it is called the **standard k -cube**.

If ω is a k -form on $[0, 1]^k$, and x^1, \dots, x^k are the coordinate functions, then ω can be written uniquely as

$$\omega = f dx^1 \wedge \dots \wedge dx^k.$$

We define

$$\int_{[0,1]^k} \omega \quad \text{to be} \quad \int_{[0,1]^k} f \quad \left(\begin{array}{l} = \int_{[0,1]^k} f(x^1, \dots, x^k) dx^1 \dots dx^k \\ \text{in classical notation, which modern} \\ \text{notation attempts to mimic as far} \\ \text{as logic permits} \end{array} \right).$$

If ω is a k -form on M , and c is a singular k -cube in M , we define

$$\int_c \omega = \int_{[0,1]^k} c^* \omega,$$

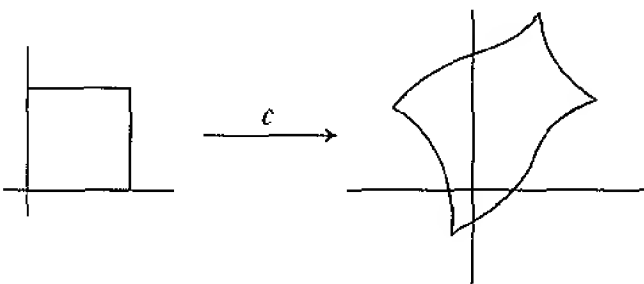

where the right hand side has just been defined. For $k = 0$, we have a special definition: a 0-form is a function f , and for a singular 0-cube c we define

$$\int_c f = f(c(0)).$$

1. PROPOSITION. Let $c: [0, 1]^n \rightarrow \mathbb{R}^n$ be a one-one singular n -cube with $\det c' \geq 0$ on $[0, 1]^n$. Let ω be the n -form

$$\omega = f dx^1 \wedge \cdots \wedge dx^n.$$

Then

$$\int_c \omega = \int_{c([0,1]^n)} f.$$

PROOF. By definition,

$$\begin{aligned} \int_c \omega &= \int_{[0,1]^n} c^*(\omega) \\ &= \int_{[0,1]^n} (f \circ c)(\det c') dx^1 \wedge \cdots \wedge dx^n \quad \text{by Theorem 7-7} \\ &= \int_{[0,1]^n} (f \circ c)|\det c'| dx^1 \wedge \cdots \wedge dx^n \quad \text{by assumption} \\ &= \int_{c([0,1]^n)} f \quad \text{by the change of variable formula. } \spadesuit \end{aligned}$$

2. COROLLARY. Let $p: [0, 1]^k \rightarrow [0, 1]^k$ be one-one onto with $\det p' \geq 0$, let c be a singular k -cube in M and let ω be a k -form on M . Then

$$\int_c \omega = \int_{c \circ p} \omega.$$

PROOF. We have

$$\begin{aligned} \int_{c \circ p} \omega &= \int_{[0,1]^k} (c \circ p)^* \omega = \int_{[0,1]^k} p^*(c^* \omega) \\ &= \int_{[0,1]^k} c^*(\omega) \quad \text{by the Proposition, since } p \text{ is onto} \\ &= \int_c \omega. \quad \spadesuit \end{aligned}$$

The map $c \circ p: [0, 1]^k \rightarrow M$ is called a **reparameterization** of c if $p: [0, 1]^k \rightarrow [0, 1]^k$ is a C^∞ one-one onto map with $\det p' \neq 0$ everywhere (so that p^{-1} is also C^∞); it is called **orientation preserving** or **orientation reversing** depending on whether $\det p' > 0$ or $\det p' < 0$ everywhere. The corollary thus shows independence of parameterization, provided it is orientation preserving; an orientation reversing reparameterization clearly changes the sign of the integral. Notice that there would be no such result if we tried to define the integral over c of a C^∞ function $f: M \rightarrow \mathbb{R}$ by the formula

$$\int_{[0,1]^k} f \circ c.$$

For example, if $c: [0, 1] \rightarrow M$ then

$$\int_0^1 f(c(t)) dt \quad \text{is generally} \quad \neq \int_0^1 f(c(p(t))) dt.$$

From a formal point of view, differential forms are the things we integrate because they transform correctly (i.e., in accordance with Theorem 7-7, so that the change of variable formula will pop up); functions on a manifold cannot be integrated (we can integrate a function f on the manifold \mathbb{R}^k only because it gives us a form $f dx^1 \wedge \cdots \wedge dx^k$).

Our definition of the integral of a k -form ω over a singular k -cube c can immediately be generalized. A k -chain is simply a formal (finite) sum of singular k -cubes multiplied by integers, e.g.,

$$1c_1 - 2c_2 + 3c_3.$$

The k -chain $1c_1 = 1 \cdot c_1$ will also be denoted simply by c_1 . We add k -chains, and multiply them by integers, purely formally, e.g.,

$$2(c_1 + 3c_4) + (-2)(c_1 + c_3 + c_2) = -2c_2 - 2c_3 + 6c_4.$$

Moreover, we define the integral of ω over a k -chain $c = \sum_i a_i c_i$ in the obvious way:

$$\int_{\sum_i a_i c_i} \omega = \sum_i a_i \int_{c_i} \omega.$$

The reason for introducing k -chains is that to every k -chain c (which may be just a singular k -cube) we wish to associate a $(k-1)$ -chain ∂c , which is called the **boundary** of c , and which is supposed to be the sum of the various singular

$(k - 1)$ -cubes around the boundary of each singular k -cube in c . In practice, it

is convenient to modify this idea. The boundary of I^2 , for example, will not be the sum of the four singular 1-cubes indicated below on the left, but the sum,

with the indicated coefficients, of the four singular 1-cubes shown on the right. (Notice that this will not change the integral of a 1-form over ∂I^2 .) For each i with $1 \leq i \leq n$ we first define two singular $(n - 1)$ -cubes $I_{(i,0)}^n$ and $I_{(i,1)}^n$ (the $(i, 0)$ -face and $(i, 1)$ -face of I^n) as follows: If $x \in [0, 1]^{n-1}$, then

$$\begin{aligned} I_{(i,0)}^n(x) &= I^n(x^1, \dots, x^{i-1}, 0, x^i, \dots, x^{n-1}) \\ &= (x^1, \dots, x^{i-1}, 0, x^i, \dots, x^{n-1}), \\ I_{(i,1)}^n(x) &= I^n(x^1, \dots, x^{i-1}, 1, x^i, \dots, x^{n-1}) \\ &= (x^1, \dots, x^{i-1}, 1, x^i, \dots, x^{n-1}). \end{aligned}$$

The (i, α) -face of a singular n -cube c is defined by

$$c_{(i,\alpha)} = c \circ (I^n_{(i,\alpha)}).$$

Now we define

$$\partial c = \sum_{i=1}^n \sum_{\alpha=0,1} (-1)^{i+\alpha} c_{(i,\alpha)}.$$

Finally, the boundary of an n -chain $\sum_i a_i c_i$ is defined by

$$\partial \left(\sum_i a_i c_i \right) = \sum_i a_i \partial(c_i).$$

These definitions all make sense only for $n \geq 1$. For the case of a 0-cube $c: [0, 1]^0 \rightarrow M$, which we will usually simply identify with the point $P = c(0)$, we define ∂c to be the number $1 \in \mathbb{R}$, and for a 0-chain $\sum_i a_i c_i$ we define

$$\partial \left(\sum_i a_i c_i \right) = \sum_i a_i \partial(c_i) = \sum_i a_i.$$

Notice that for a 1-cube $c: [0, 1] \rightarrow M$ we have

$$\partial c = c_{(1,1)} - c_{(1,0)},$$

so

$$\partial(\partial c) = 1 - 1 = 0.$$

We also have, for a singular 2-cube $c: [0, 1]^2 \rightarrow M$,

$$\begin{aligned} \partial c &= c_{(1,1)} - c_{(2,1)} - c_{(1,0)} + c_{(2,0)}, \\ \partial(\partial c) &= (R - Q) - (R - S) \\ &\quad - (S - P) + (Q - P) \\ &= 0. \end{aligned}$$

From a picture it can be checked that this also happens for a singular 3-cube, a good exercise because this involves figuring out just what the boundary of a 3-cube looks like. In general, we have:

3. PROPOSITION. If c is any n -chain in M , then $\partial(\partial c) = 0$. Briefly, $\partial^2 = 0$.

PROOF. Let $i \leq j \leq n-1$, and consider $(I_{(i,\alpha)}^n)_{(j,\beta)}$. For $x \in [0, 1]^{n-2}$, we have, from the definition

$$\begin{aligned} (I_{(i,\alpha)}^n)_{(j,\beta)}(x) &= I_{(i,\alpha)}^n(I_{(j,\beta)}^{n-1}(x)) \\ &= I_{(i,\alpha)}^n(x^1, \dots, x^{j-1}, \beta, x^j, \dots, x^{n-2}) \\ &= I^n(x^1, \dots, x^{i-1}, \alpha, x^i, \dots, x^{j-1}, \beta, x^j, \dots, x^{n-2}). \end{aligned}$$

Similarly,

$$\begin{aligned} (I_{(j+1,\beta)}^n)_{(i,\alpha)} &= I_{(j+1,\beta)}^n(I_{(i,\alpha)}^{n-1}(x)) \\ &= I_{(j+1,\beta)}^n(x^1, \dots, x^{i-1}, \alpha, x^i, \dots, x^{n-2}) \\ &= I^n(x^1, \dots, x^{i-1}, \alpha, x^i, \dots, x^{j-1}, \beta, x^j, \dots, x^{n-2}). \end{aligned}$$

Thus $(I_{(i,\alpha)}^n)_{(j,\beta)} = (I_{(j+1,\beta)}^n)_{(i,\alpha)}$ for $i \leq j \leq n-1$. It follows easily for any singular n -cube c that $(c_{(i,\alpha)})_{(j,\beta)} = (c_{(j+1,\beta)})_{(i,\alpha)}$ for $i \leq j \leq n-1$. Now

$$\begin{aligned} \partial(\partial c) &= \partial \left(\sum_{i=1}^n \sum_{\alpha=0,1} (-1)^{i+\alpha} c_{(i,\alpha)} \right) \\ &= \sum_{i=1}^n \sum_{\alpha=0,1} \sum_{j=1}^{n-1} \sum_{\beta=0,1} (-1)^{i+\alpha+j+\beta} (c_{(i,\alpha)})_{(j,\beta)}. \end{aligned}$$

In this sum, $(c_{(i,\alpha)})_{(j,\beta)}$ and $(c_{(j+1,\beta)})_{(i,\alpha)}$ occur with opposite signs. Therefore all terms cancel in pairs, and $\partial(\partial c) = 0$. Since the theorem is true for singular n -cubes, it is clearly also true for singular n -chains. ♦

Notice that for some n -chains c we have not only $\partial(\partial c) = 0$, but even $\partial c = 0$. For example, this is the case if $c = c_1 - c_2$, where c_1 and c_2 are two 1-cubes

with $c_1(0) = c_2(0)$ and $c_1(1) = c_2(1)$. If c is just a singular 1-cube itself, then

$\partial c = 0$ precisely when $c(0) = c(1)$, i.e., when c is a “closed” curve. In general,

any k -chain c is called closed if $\partial c = 0$.

Recall that a differential form ω with $d\omega = 0$ is also called “closed”; this terminology has been purposely chosen to parallel the terminology for chains (on the other hand, a chain of the form ∂c is not described, reciprocally, by the classical term of “exact”, but is simply called “a boundary”). This parallel terminology was not chosen merely because of the formal similarities between d and ∂ , expressed by the relations $d^2 = 0$ and $\partial^2 = 0$. The connection between forms and chains goes much deeper than that. For example, we have seen that on $\mathbb{R}^2 - \{0\}$ there is a 1-form “ $d\theta$ ” which is closed but not exact. There is also a 1-chain c which is closed but not a boundary, namely, a closed curve encircling

the point 0 once. Although it is intuitively clear that c is not the boundary of a 2-chain in $\mathbb{R}^2 - \{0\}$, the simplest proof uses the theorem which establishes the connection between forms, chains, d , and ∂ .

4. THEOREM (STOKES' THEOREM). If ω is a $(k-1)$ -form on M and c is a k -chain in M , then

$$\int_c d\omega = \int_{\partial c} \omega.$$

PROOF. Most of the proof involves the special case where ω is a $(k-1)$ -form on \mathbb{R}^k and $c = I^k$. In this case, ω is a sum of $(k-1)$ -forms of the type

$$f dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^k,$$

and it suffices to prove the theorem for each of these. We now compute. First, a little notation translation shows that

$$\begin{aligned} \int_{[0,1]^{k-1}} I_{(j,\alpha)}^k (f dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^k) \\ = \begin{cases} 0 & \text{if } j \neq i \\ \int_{[0,1]^k} f(x^1, \dots, \alpha, \dots, x^k) dx^1 \dots dx^k & \text{if } j = i. \end{cases} \end{aligned}$$

Therefore

$$\begin{aligned} \int_{\partial I^k} f dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^k \\ = \sum_{j=1}^k \sum_{\alpha=0,1} (-1)^{j+\alpha} \int_{[0,1]^{k-1}} I_{(j,\alpha)}^k (f dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^k) \\ = (-1)^{i+1} \int_{[0,1]^k} f(x^1, \dots, 1, \dots, x^k) dx^1 \dots dx^k \\ + (-1)^i \int_{[0,1]^k} f(x^1, \dots, 0, \dots, x^k) dx^1 \dots dx^k. \end{aligned}$$

On the other hand,

$$\begin{aligned}
 \int_{I^k} d(f dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^k) \\
 &= \int_{[0,1]^k} D_i f dx^i \wedge dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^k \\
 &= (-1)^{i-1} \int_{[0,1]^k} D_i f.
 \end{aligned}$$

By Fubini's theorem and the fundamental theorem of calculus we have

$$\begin{aligned}
 \int_{I^k} d(f dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^k) \\
 &= (-1)^{i-1} \int_0^1 \cdots \left(\int_0^1 D_i f(x^1, \dots, x^k) dx^i \right) dx^1 \cdots \widehat{dx^i} \cdots dx^k \\
 &= (-1)^{i-1} \int_0^1 \cdots \int_0^1 \left[f(x^1, \dots, 1, \dots, x^k) \right. \\
 &\quad \left. - f(x^1, \dots, 0, \dots, x^k) \right] dx^1 \cdots \widehat{dx^i} \cdots dx^k \\
 &= (-1)^{i-1} \int_{[0,1]^k} f(x^1, \dots, 1, \dots, x^k) dx^1 \cdots dx^k \\
 &\quad + (-1)^i \int_{[0,1]^k} f(x^1, \dots, 0, \dots, x^k) dx^1 \cdots dx^k.
 \end{aligned}$$

Thus

$$\int_{I^k} d\omega = \int_{\partial I^k} \omega.$$

For an arbitrary singular k -cube, chasing through the definitions shows that

$$\int_{\partial c} \omega = \int_{\partial I^k} c^* \omega.$$

Therefore

$$\int_c d\omega = \int_{I^k} c^*(d\omega) = \int_{I^k} d(c^*\omega) = \int_{\partial I^k} c^*\omega = \int_{\partial c} \omega.$$

The theorem clearly follows for k -chains also. ♦

Notice that Stokes' Theorem not only uses the fundamental theorem of calculus, but actually becomes that theorem when $c = I^1$ and $\omega = f$.

As an application of Stokes' Theorem, we show that the curve $c: [0, 1] \rightarrow \mathbb{R}^2 - \{0\}$ defined by

$$c(t) = (\cos 2\pi t, \sin 2\pi t),$$

although closed, is not ∂c^2 for any 2-chain c^2 . If we did have $c = \partial c^2$, then we would have

$$\int_c d\theta = \int_{\partial c^2} d\theta = \int_{c^2} d(d\theta) = \int_{c^2} 0 = 0.$$

But a straightforward computation (which will be good for the soul) shows that

$$\int_c d\theta = \int_c \frac{-y}{x^2 + y^2} dx + \frac{x}{x^2 + y^2} dy = 2\pi.$$

[There is also a non-computational argument, using the fact that “ $d\theta$ ” really is $d\theta$ for $\theta: \mathbb{R}^2 - ([0, \infty) \times \{0\}) \rightarrow \mathbb{R}$: We have

$$\int_{c|[\varepsilon, 1-\varepsilon]} d\theta = \theta(1-\varepsilon) - \theta(\varepsilon),$$

and $\theta(1-\varepsilon) - \theta(\varepsilon) \rightarrow 2\pi$ as $\varepsilon \rightarrow 0$.]

Although we used this calculation to show that c is not a boundary, we could just as well have used it to show that $\omega = “d\theta”$ is not exact. For, if we had $\omega = df$ for some C^∞ function $f: \mathbb{R}^2 - \{0\} \rightarrow \mathbb{R}$, then we would have

$$2\pi = \int_c \omega = \int_c df = \int_{\partial c} f = \int_0 f = 0.$$

We were previously able to give a simpler argument to show that “ $d\theta$ ” is not exact, but Stokes' Theorem is the tool which will enable us to deal with forms on $\mathbb{R}^n - \{0\}$. For example, we will eventually obtain a 2-form ω on $\mathbb{R}^3 - \{0\}$,

$$\omega = \frac{x dy \wedge dz - y dx \wedge dz + z dx \wedge dy}{(x^2 + y^2 + z^2)^{3/2}}$$

which is closed but not exact. For the moment we are keeping the origin of ω a secret, but a straightforward calculation shows that $d\omega = 0$. To prove that ω is not exact we will want to integrate it over a 2-chain which “fills up” the 2-sphere $S^2 \subset \mathbb{R}^3 - \{0\}$. There are lots of ways of doing this, but they all turn out to give the same result. In fact, we first want to describe a way of integrating n -forms over n -manifolds. This is possible only when M is orientable; the reason will be clear from the next result, which is basic for our definition.

5. THEOREM. Let M be an n -manifold with an orientation μ , and let $c_1, c_2 : [0, 1]^n \rightarrow M$ be two singular n -cubes which can be extended to be diffeomorphisms in a neighborhood of $[0, 1]^n$. Assume that c_1 and c_2 are both *orientation preserving* (with respect to the orientation μ on M , and the usual orientation on \mathbb{R}^n). If ω is an n -form on M such that

$$\text{support } \omega \subset c_1([0, 1]^n) \cap c_2([0, 1]^n),$$

then

$$\int_{c_1} \omega = \int_{c_2} \omega.$$

PROOF. We want to use Corollary 2, and write

$$\int_{c_2} \omega = \int_{c_2 \circ (c_2^{-1} \circ c_1)} \omega = \int_{c_1} \omega.$$

The only problem is that $c_2^{-1} \circ c_1$ is not defined on all of $[0, 1]^n$ (it does satisfy $\det(c_2^{-1} \circ c_1)' \geq 0$, since c_1 and c_2 are both orientation preserving). However, a glance at the proof of Corollary 2 will show that the result still follows, because of the fact that $\text{support } \omega \subset c_1([0, 1]^n) \cap c_2([0, 1]^n)$. ♦

The common number $\int_c \omega$, for singular n -cubes $c : [0, 1]^n \rightarrow M$ with $\text{support } \omega \subset c([0, 1]^n)$ and c orientation preserving, will be denoted by

$$\int_M \omega.$$

If ω is an arbitrary n -form on M , then there is a cover \mathcal{O} of M by open sets U , each contained in some $c([0, 1]^n)$, where c is a singular n -cube of this sort; if Φ is a partition of unity subordinate to this cover, then

$$\int_M \phi \cdot \omega$$

is defined for each $\phi \in \Phi$. We wish to define

$$\int_M \omega = \sum_{\phi \in \Phi} \int_M \phi \cdot \omega.$$

We will adopt this definition only when ω has compact support, in which case the sum is actually finite, since support ω can intersect only finitely many of the sets $\{p : \phi(p) \neq 0\}$, which form a locally finite collection. If we have another partition of unity Ψ (subordinate to a cover \mathcal{O}'), then

$$\sum_{\phi \in \Phi} \int_M \phi \cdot \omega = \sum_{\phi \in \Phi} \int_M \sum_{\psi \in \Psi} \psi \cdot \phi \cdot \omega = \sum_{\phi \in \Phi} \sum_{\psi \in \Psi} \int_M \psi \cdot \phi \cdot \omega;$$

these sums are all finite, and the last sum can clearly also be written as

$$\sum_{\psi \in \Psi} \sum_{\phi \in \Phi} \int_M \phi \cdot \psi \cdot \omega = \sum_{\psi \in \Psi} \int_M \psi \cdot \omega,$$

so that our definition does not depend on the partition. (We really should denote this sum by

$$\int_{(M, \mu)} \omega;$$

for the orientation $-\mu$ of M we clearly have

$$\int_{(M, -\mu)} \omega = - \int_{(M, \mu)} \omega.$$

However, we usually omit explicit mention of μ .)

With minor modifications we can define $\int_M \omega$ even if M is an n -manifold-with-boundary. If $M \subset \mathbb{R}^n$ is an n -dimensional manifold-with-boundary and $f: M \rightarrow \mathbb{R}$ has compact support, then

$$\int_M f dx^1 \wedge \cdots \wedge dx^n = \int_M f.$$

where the right hand side denotes the ordinary integral. This is a simple consequence of Proposition 1. Likewise, if $f: M^n \rightarrow N^n$ is a diffeomorphism onto, and ω is an n -form with compact support on N , then

$$\int_M f^* \omega = \begin{cases} \int_N \omega & \text{if } f \text{ is orientation preserving} \\ - \int_N \omega & \text{if } f \text{ is orientation reversing.} \end{cases}$$

Although n -forms can be integrated only over orientable manifolds, there is a way of discussing integration on non-orientable manifolds. Suppose that ω is a function on M such that for each $p \in M$ we have

$$\omega(p) = |\eta_p| \quad \text{for some } \eta_p \in \Omega^n(M_p),$$

i.e., for any n vectors $v_1, \dots, v_n \in M_p$ we have

$$\omega(p)(v_1, \dots, v_n) = |\eta_p(v_1, \dots, v_n)| \geq 0.$$

Such a function ω is called a **volume element**—on each vector space it determines a way of measuring n -dimensional volume (not signed volume). If (x, U) is a coordinate system, then on U we can write

$$\omega = f |dx^1 \wedge \dots \wedge dx^n| \quad \text{for } f \geq 0;$$

we call ω a C^∞ volume element if f is C^∞ . One way of obtaining a volume element is to begin with an n -form η and then define $\omega(p) = |\eta(p)|$. However, not every volume element arises in this way—the form η_p may not vary continuously with p . For example, consider the Möbius strip M , imbedded in \mathbb{R}^3 . Since M_p can be considered as a subspace of \mathbb{R}^3_p , we can define

$$\omega(p)(v_p, w_p) = \text{area of parallelogram spanned by } v \text{ and } w.$$

It is not hard to see that ω is a volume element; locally, ω is of the form $\omega = |\eta|$ for an n -form η . But this cannot be true on all of M , since there is no n -form η on M which is everywhere non-zero.

Theorem 7-7 has an obvious modification for volume elements:

7-7'. THEOREM. If $f: M \rightarrow N$ is a C^∞ function between n -manifolds, (x, U) is a coordinate system around $p \in M$, and (y, V) a coordinate system around $q = f(p) \in N$, then for non-negative $g: V \rightarrow \mathbb{R}$ we have

$$f^*(g |dy^1 \wedge \dots \wedge dy^n|) = (g \circ f) \cdot \left| \det \left(\frac{\partial(y^i \circ f)}{\partial x^j} \right) \right| \cdot |dx^1 \wedge \dots \wedge dx^n|.$$

PROOF. Go through the proof of Theorem 7-7, putting in absolute value signs in the right place. ♦

7-8'. COROLLARY. If (x, U) and (y, V) are two coordinate systems on M and

$$g |dy^1 \wedge \cdots \wedge dy^n| = h |dx^1 \wedge \cdots \wedge dx^n| \quad g, h \geq 0$$

then

$$h = g \cdot \left| \det \left(\frac{\partial y^i}{\partial x^j} \right) \right|.$$

[This corollary shows that volume elements are the geometric objects corresponding to the "odd scalar densities" defined in Problem 4-10.]

It is now an easy matter to integrate a volume element ω over any manifold. First we define

$$\int_{[0,1]^n} \omega = \int_{[0,1]^n} f \quad \text{for } \omega = f |dx^1 \wedge \cdots \wedge dx^n|, \quad f \geq 0.$$

Then for an n -chain $c: [0, 1]^n \rightarrow M$ we define

$$\int_c \omega = \int_{[0,1]^n} c^* \omega.$$

Theorem 7-7' shows that Proposition 1 holds for a volume element $\omega = f |dx^1 \wedge \cdots \wedge dx^n|$ even if $\det c'$ is not ≥ 0 . Thus Corollary 2 holds for volume elements even if $\det p'$ is not ≥ 0 . From this we conclude that Theorem 5 holds for volume elements ω on any manifold M , without assuming c_1, c_2 orientation preserving (or even that M is orientable). Consequently we can define $\int_M \omega$ for any volume element ω with compact support.

Of course, when M is orientable these considerations are unnecessary. For, there is a nowhere zero n -form η on M , and consequently any volume element ω can be written

$$\omega = f |\eta|, \quad f \geq 0.$$

If we choose an orientation μ for M such that $\omega(v_1, \dots, v_n) > 0$ for v_1, \dots, v_n positively oriented, then we can define

$$\int_M \omega = \int_{(M, \mu)} f \eta.$$

Volume elements will be important later, but for the remainder of this chapter we are concerned only with integrating forms over oriented manifolds. In fact, our main result about integrals of forms over manifolds, an analogue of Stokes' Theorem about the integral of forms over chains, does not work for volume elements.

Recall from Problem 3-16 that if M is a manifold-with-boundary, and $p \in \partial M$, then certain vectors $v \in M_p$ can be distinguished by the fact that for any coordinate system $x: U \rightarrow \mathbb{H}^n$ around p , the vector $x_*(v) \in \mathbb{H}^n_{f(p)}$ points “outwards”. We call such vectors $v \in M_p$ “outward pointing”. If M has an

orientation μ , we define the induced orientation $\partial\mu$ for ∂M by the condition that $[v_1, \dots, v_{n-1}] \in (\partial\mu)_p$ if and only if $[w, v_1, \dots, v_{n-1}] \in \mu_p$ for every outward pointing $w \in M_p$. If μ is the usual orientation of \mathbb{H}^n , then for $p = (a, 0) \in \mathbb{H}^n$ we have

$$\begin{aligned}\mu_p &= [(e_1)_p, \dots, (e_n)_p] = (-1)^{n-1}[(e_n)_p, (e_1)_p, \dots, (e_{n-1})_p] \\ &= (-1)^n[(-e_n)_p, (e_1)_p, \dots, (e_{n-1})_p].\end{aligned}$$

Since $(-e_n)_p$ is an outward pointing vector, this shows that the induced orientation on $\mathbb{R}^{n-1} \times \{0\} = \partial\mathbb{H}^n$ is $(-1)^n$ times the usual one. The reason for this choice is the following. Let c be an orientation preserving singular n -cube in (M, μ) such that $\partial M \cap c([0, 1]^n) = c_{(n,0)}([0, 1]^{n-1})$. Then $c_{(n,0)}: [0, 1]^{n-1} \rightarrow$

$(\partial M, \partial\mu)$ is orientation preserving for even n , and orientation reversing for odd n . If ω is an $(n-1)$ -form on M whose support is contained in the interior

of the image of c (this interior contains points in the image of $c_{(n,0)}$), it follows that

$$\int_{c_{(n,0)}} \omega = (-1)^n \int_{\partial M} \omega.$$

But $c_{(n,0)}$ appears with coefficient $(-1)^n$ in ∂c . So

$$(*) \quad \int_{\partial c} \omega = \int_{(-1)^n c_{(n,0)}} \omega = (-1)^n \int_{c_{(n,0)}} \omega = \int_{\partial M} \omega.$$

If it were not for this choice of $\partial\mu$ we would have some unpleasant minus signs in the following theorem.

6. THEOREM (STOKES' THEOREM). If M is an oriented n -dimensional manifold-with-boundary, and ∂M is given the induced orientation, and ω is an $(n-1)$ -form on M with compact support, then

$$\int_M d\omega = \int_{\partial M} \omega.$$

PROOF. Suppose first that there is an orientation preserving singular n -cube c in $M - \partial M$ such that $\text{support } \omega \subset \text{interior of image } c$. Then

$$\begin{aligned} \int_M d\omega &= \int_c d\omega = \int_{\partial c} \omega && \text{by Theorem 4} \\ &= 0 && \text{since support } \omega \subset \text{interior of image } c, \end{aligned}$$

while we clearly have

$$\int_{\partial M} \omega = 0.$$

Suppose next that there is an orientation preserving singular n -cube c in M such that $\partial M \cap c([0, 1]^n) = c_{(n,0)}([0, 1]^{n-1})$, and $\text{support } \omega \subset \text{interior of image } c$. Then once again

$$\int_M d\omega = \int_c d\omega = \int_{\partial c} \omega = \int_{\partial M} \omega \quad \text{by } (*).$$

In general, there is an open cover \mathcal{O} of M and a partition of unity Φ subordinate to \mathcal{O} such that for each $\phi \in \Phi$ the form $\phi \cdot \omega$ is one of the two sorts already considered. We have

$$0 = d(1) = d\left(\sum_{\phi \in \Phi} \phi\right) = \sum_{\phi \in \Phi} d\phi,$$

so

$$\sum_{\phi \in \Phi} d\phi \wedge \omega = 0.$$

Since ω has compact support, this is really a finite sum, and we conclude that

$$\sum_{\phi \in \Phi} \int_M d\phi \wedge \omega = 0.$$

Therefore

$$\begin{aligned} \int_M d\omega &= \sum_{\phi \in \Phi} \int_M \phi \cdot d\omega = \sum_{\phi \in \Phi} \int_M d\phi \wedge \omega + \phi \cdot d\omega \\ &= \sum_{\phi \in \Phi} \int_M d(\phi \cdot \omega) = \sum_{\phi \in \Phi} \int_{\partial M} \phi \cdot \omega = \int_{\partial M} \omega. \quad \spadesuit \end{aligned}$$

One of the simplest applications of Stokes' Theorem occurs when the oriented n -manifold (M, μ) is compact (so that every form has compact support) and $\partial M = \emptyset$. In this case, if η is any $(n-1)$ -form, then

$$\int_M d\eta = \int_{\partial M} \eta = 0.$$

Therefore we can find an n -form ω on M which is *not* exact (even though it must be closed, because all $(n+1)$ -forms on M are 0), simply by finding an ω with

$$\int_M \omega \neq 0.$$

Such a form ω always exists. Indeed we have seen that there is a form ω such that for $v_1, \dots, v_n \in M_p$ we have

$$(*) \quad \omega(v_1, \dots, v_n) > 0 \quad \text{if } [v_1, \dots, v_n] = \mu_p.$$

If $c: [0, 1]^n \rightarrow (M, \mu)$ is orientation preserving, then the form $c^*\omega$ on $[0, 1]^n$ is clearly

$$g \, dx^1 \wedge \dots \wedge dx^n \quad \text{for some } g > 0 \text{ on } [0, 1]^n,$$

so $\int_c \omega > 0$. It follows that $\int_M \omega > 0$. There is, moreover, no need to choose a form ω with (*) holding everywhere—we can allow the $>$ sign to be replaced by \geq . Thus we can even obtain a non-exact n -form on M which has support contained in a coordinate neighborhood.

This seemingly minor result already proves a theorem: a compact oriented manifold is not smoothly contractible to a point. As we have already emphasized, it is the “shape” of M , rather than its “size”, which determines whether or not every closed form on M is exact. Roughly speaking, we can obtain more information about the shape of M by analyzing more closely the extent to which closed forms are not necessarily exact. In particular, we would now like to ask just how many non-exact n -forms there are on a compact oriented n -manifold M . Naturally, if ω is not exact, then the same is true for $\omega + d\eta$ for any $(n-1)$ -form η , so we really want to consider ω and $\omega + d\eta$ as equivalent. There is, of course, a standard way of doing this, by considering quotient spaces. We will apply this construction not only to n -forms, but to forms of any degree.

For each k , the collection $Z^k(M)$ of all closed k -forms on M is a vector space. The space $B^k(M)$ of all exact k -forms is a subspace (since $d^2 = 0$), so we can form the quotient vector space

$$H^k(M) = Z^k(M)/B^k(M);$$

this vector space $H^k(M)$ is called the k -dimensional de Rham cohomology vector space of M . [*de Rham's Theorem* states that this vector space is isomorphic to a certain vector space defined purely in terms of the topology of M (for any space M), called the “ k -dimensional cohomology group of M with real coefficients”; the notation Z^k , B^k is chosen to correspond to the notation used in algebraic topology, where these groups are defined.]

An element of $H^k(M)$ is an equivalence class $[\omega]$ of a closed k -form ω , two closed k -forms ω_1 and ω_2 being equivalent if and only if their difference is exact. In terms of these vector spaces, the Poincaré Lemma says that $H^k(\mathbb{R}^n) = 0$ (the vector space containing only 0) if $k > 0$, or more generally, $H^k(M) = 0$ if M is contractible and $k > 0$.

To compute $H^0(M)$ we note first that $B^0(M) = 0$ (there are no non-zero exact 0-forms, since there are no non-zero (-1) -forms for them to be the differential of). So $H^0(M)$ is the same as the vector space of all C^∞ functions $f: M \rightarrow \mathbb{R}$ with $df = 0$. If M is connected, the condition $df = 0$ implies that f is constant, so $H^0(M) \approx \mathbb{R}$. (In general, the dimension of $H^0(M)$ is the number of components of M .)

Aside from these trivial remarks, we presently know only one other fact about $H^k(M)$ —if M is compact and oriented, then $H^n(M)$ has dimension ≥ 1 . The further study of $H^k(M)$ requires a careful look at spheres and Euclidean space.

On $S^{n-1} \subset \mathbb{R}^n - \{0\}$ there is a natural choice of an $(n-1)$ -form σ' with $\int_{S^{n-1}} \sigma' > 0$: for $(v_1)_p, \dots, (v_{n-1})_p \in S^{n-1}_p$, we define

$$\sigma'(p)((v_1)_p, \dots, (v_{n-1})_p) = \det \begin{pmatrix} p \\ v_1 \\ \vdots \\ v_{n-1} \end{pmatrix}.$$

Clearly this is > 0 if $(v_1)_p, \dots, (v_{n-1})_p$ is a positively oriented basis. In fact, we defined the orientation of S^{n-1} in precisely this way—this orientation is just the induced orientation when S^{n-1} is considered as the boundary of the unit ball $\{p \in \mathbb{R}^n : |p| \leq 1\}$ with the usual orientation. Using the expansion of a determinant by minors along the top row we see that σ' is the restriction to S^{n-1} of the form σ on \mathbb{R}^n defined by

$$\sigma = \sum_{i=1}^n (-1)^{i-1} x^i dx^1 \wedge \dots \wedge \widehat{dx^i} \wedge \dots \wedge dx^n.$$

The form σ' on S^{n-1} will now be used to find an $(n-1)$ -form on $\mathbb{R}^n - \{0\}$ which is closed but not exact (thus showing that $H^{n-1}(\mathbb{R}^n - \{0\}) \neq 0$). Consider the map $r: \mathbb{R}^n - \{0\} \rightarrow S^{n-1}$ defined by

$$r(p) = \frac{p}{|p|} = \frac{p}{v(p)}.$$

Clearly $r(p) = p$ if $p \in S^{n-1}$; otherwise said, if $i: S^{n-1} \rightarrow \mathbb{R}^n - \{0\}$ is the inclusion, then

$$r \circ i = \text{identity of } S^{n-1}.$$

(In general, if $A \subset X$ and $r: X \rightarrow A$ satisfies $r(a) = a$ for $a \in A$, then r is called a **retraction** of X onto A .)

Clearly, $r^*\sigma'$ is closed:

$$d(r^*\sigma') = r^*d\sigma' = 0.$$

However, it is not exact, for if $r^*\sigma' = d\eta$, then

$$\sigma' = i^*r^*\sigma' = di^*\eta;$$

but we know that σ' is not exact.

It is a worthwhile exercise to compute by brute force that

$$\text{for } n = 2, \quad r^*\sigma' = \frac{x dy - y dx}{x^2 + y^2} = \frac{x dy - y dx}{v^2} = d\theta$$

$$\begin{aligned} \text{for } n = 3, \quad r^*\sigma' &= \frac{x dy \wedge dz - y dx \wedge dz + z dx \wedge dy}{(x^2 + y^2 + z^2)^{3/2}} \\ &= \frac{1}{v^3} [x dy \wedge dz - y dx \wedge dz + z dx \wedge dy]. \end{aligned}$$

Since we will actually need to know $r^*\sigma'$ in general, we evaluate it in another way:

7. LEMMA. If σ is the form on \mathbb{R}^n defined by

$$\sigma = \sum_{i=1}^n (-1)^{i-1} x^i dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^n,$$

and σ' is the restriction $i^*\sigma$ of σ to S^{n-1} , then

$$(*) \quad r^*\sigma'(p) = \frac{\sigma(p)}{|p|^n}.$$

So

$$r^*\sigma' = \frac{1}{v^n} \sum_{i=1}^n (-1)^{i-1} x^i dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^n.$$

PROOF. At any point $p \in \mathbb{R}^n - \{0\}$, the tangent space \mathbb{R}_p^n is spanned by p_p and the vectors v_p in the tangent space of the sphere $S^{n-1}(|p|)$ of radius $|p|$. So it suffices to check that both sides of $(*)$ give the same result when applied to $n-1$ vectors each of which is one of these two sorts. Now p_p is the tangent vector of a curve γ lying along the straight line through 0 and p ; this curve is taken to the single point $r(p)$ by r , so $r_*(p_p) = 0$. On the other hand,

$$\sigma(p)(p_p, (v_1)_p, \dots, (v_{n-2})_p) = \det \begin{pmatrix} p \\ p \\ v_1 \\ \vdots \\ v_{n-2} \end{pmatrix} = 0.$$

So it suffices to apply both sides of $(*)$ to vectors in the tangent space of $S^{n-1}(|p|)$. Thus (Problem 15), it suffices to show that for such vectors v_p we have

$$r_*(v_p) = \frac{1}{|p|} v_{r(p)}.$$

But this is almost obvious, since the vector v_p is the tangent vector of a circle γ lying in $S^{n-1}(|p|)$, and the curve $r \circ \gamma$ lies in S^{n-1} and goes $1/|p|$ as far in the same time. ♦

8. COROLLARY (INTEGRATION IN "POLAR COORDINATES"). Let $f: B \rightarrow \mathbb{R}$, where

$$B = \{p \in \mathbb{R}^n : |p| \leq 1\},$$

and define $g: S^{n-1} \rightarrow \mathbb{R}$ by

$$g(p) = \int_0^1 u^{n-1} f(u \cdot p) du.$$

Then

$$\int_B f = \int_B f dx^1 \wedge \cdots \wedge dx^n = \int_{S^{n-1}} g \sigma'.$$

PROOF. Consider $S^{n-1} \times [0, 1]$ and the two projections

$$\pi_1: S^{n-1} \times [0, 1] \rightarrow S^{n-1}$$

$$\pi_2: S^{n-1} \times [0, 1] \rightarrow [0, 1].$$

Let us use the abbreviation

$$\sigma' \wedge dt = \pi_1^* \sigma' \wedge \pi_2^* dt.$$

If (y, U) is a coordinate system on S^{n-1} , with a corresponding coordinate system $(\bar{y}, t) = (y \circ \pi_1, \pi_2)$ on $S^{n-1} \times [0, 1]$, and $\sigma' = \alpha dy^1 \wedge \cdots \wedge dy^{n-1}$, then clearly

$$\sigma' \wedge dt = \bar{\alpha} \circ \pi_1 d\bar{y}^1 \wedge \cdots \wedge d\bar{y}^{n-1} \wedge dt.$$

From this it is easy to see that if we define $h: S^{n-1} \times [0, 1] \rightarrow \mathbb{R}$ by

$$h(p, u) = u^{n-1} f(u \cdot p),$$

then

$$\int_{S^{n-1}} g \sigma' = (-1)^{n-1} \int_{S^{n-1} \times [0, 1]} h \sigma' \wedge dt.$$

Now we can define a diffeomorphism $\phi: B - \{0\} \rightarrow S^{n-1} \times (0, 1]$ by

$$\phi(p) = (r(p), v(p)) = (p/|p|, |p|).$$

Then

$$\begin{aligned}
 \phi^*(\sigma' \wedge dt) &= \phi^*(\pi_1^*\sigma' \wedge \pi_2^*dt) \\
 &= \phi^*\pi_1^*\sigma' \wedge \phi^*\pi_2^*dt \\
 &= (\pi_1 \circ \phi)^*\sigma' \wedge (\pi_2 \circ \phi)^*dt \\
 &= r^*\sigma' \wedge v^*dt \\
 &= \frac{1}{v^n} \left(\sum_{i=1}^n (-1)^{i-1} x^i dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^n \right) \wedge \sum_{i=1}^n \frac{x^i}{v} dx^i \\
 &= \frac{(-1)^{n-1}}{v^{n+1}} \sum_{i=1}^n (x^i)^2 dx^1 \wedge \cdots \wedge dx^n \\
 &= \frac{(-1)^{n-1}}{v^{n-1}} dx^1 \wedge \cdots \wedge dx^n.
 \end{aligned}$$

Hence

$$\begin{aligned}
 \phi^*(h\sigma' \wedge dt) &= (h \circ \phi)\phi^*(\sigma' \wedge dt) \\
 &= v^{n-1} f \cdot \frac{(-1)^{n-1}}{v^{n-1}} dx^1 \wedge \cdots \wedge dx^n \\
 &= (-1)^{n-1} f dx^1 \wedge \cdots \wedge dx^n.
 \end{aligned}$$

So,

$$\begin{aligned}
 \int_B f dx^1 \wedge \cdots \wedge dx^n &= (-1)^{n-1} \int_{B-\{0\}} \phi^*(h\sigma' \wedge dt) \\
 &= (-1)^{n-1} \int_{S^{n-1} \times (0,1]} h\sigma' \wedge dt \\
 &= \int_{S^{n-1}} g\sigma'.
 \end{aligned}$$

(This last step requires some justification, which should be supplied by the reader, since the forms involved do not have compact support on the manifolds $B - \{0\}$ and $S^{n-1} \times (0, 1]$ where they are defined.) ♦

We are about ready to compute $H^k(M)$ in a few more cases. We are going to reduce our calculations to calculations within coordinate neighborhoods, which are submanifolds of M , but not compact. It is therefore necessary to introduce another collection of vector spaces, which are interesting in their own right.

The de Rham cohomology vector spaces with compact supports $H_c^k(M)$ are defined as

$$H_c^k(M) = Z_c^k(M) / B_c^k(M),$$

where $Z_c^k(M)$ is the vector space of closed k -forms with compact support, and $B_c^k(M)$ is the vector space of all k -forms $d\eta$ where η is a $(k-1)$ -form with compact support. Of course, if M is compact, then $H_c^k(M) = H^k(M)$. Notice that $B_c^k(M)$ is *not* the same as the set of all exact k -forms with compact support. For example, on \mathbb{R}^n , if $f \geq 0$ is a function with compact support, and $f > 0$ at some point, then

$$\omega = f dx^1 \wedge \cdots \wedge dx^n$$

is exact (every closed form on \mathbb{R}^n is) and has compact support, but ω is not $d\eta$ for any form η with compact support. Indeed, if $\omega = d\eta$ where η has compact support, then by Stokes' Theorem

$$\int_{\mathbb{R}^n} \omega = \int_{\mathbb{R}^n} d\eta = \int_{\partial\mathbb{R}^n} \eta = 0.$$

This example shows that $H_c^n(\mathbb{R}^n) \neq 0$, and a similar argument shows that if M is any orientable manifold, then $H_c^n(M) \neq 0$. We are now going to show that for any connected orientable manifold M we actually have

$$H_c^n(M) \approx \mathbb{R}.$$

This means that if we choose a fixed ω with $\int_M \omega \neq 0$, then for any n -form ω' with compact support there is a real number a such that $\omega' - a\omega$ is exact. The number a can be described easily: if

$$\omega' - a\omega = d\eta,$$

then

$$\int_M \omega' - \int_M a\omega = \int_M d\eta = 0,$$

so

$$a = \int_M \omega' / \int_M \omega;$$

the problem, of course, is showing that η exists. Notice that the assertion that $H_c^n(M) \approx \mathbb{R}$ is equivalent to the assertion that

$$[\omega] \mapsto \int_M \omega$$

is an isomorphism of $H_c^n(M)$ with \mathbb{R} , i.e., to the assertion that a closed form ω with compact support is the differential of another form with compact support if $\int_M \omega = 0$.

9. THEOREM. If M is a connected orientable n -manifold, then $H_c^n(M) \approx \mathbb{R}$.

PROOF. We will establish the theorem in three steps:

- (1) The theorem is true for $M = \mathbb{R}$.
- (2) If the theorem is true for $(n-1)$ -manifolds, in particular for S^{n-1} , then it is true for \mathbb{R}^n .
- (3) If the theorem is true for \mathbb{R}^n , then it is true for any connected oriented n -manifold.

Step 1. Let ω be a 1-form on \mathbb{R} with compact support such that $\int_{\mathbb{R}} \omega = 0$. There is some function f (not necessarily with compact support) such that $\omega = df$. Since support ω is compact, $df = 0$ outside some interval $[-N, N]$, so f is a

constant c_1 on $(-\infty, -N)$ and a constant c_2 on (N, ∞) . Moreover,

$$0 = \int_{\mathbb{R}} \omega = \int_{\mathbb{R}} df = \int_{\mathbb{R}} f'(t) dt = c_2 - c_1.$$

Therefore $c_1 = c_2 = c$ and we have

$$\omega = d(f - c)$$

where $f - c$ has compact support.

Step 2. Let $\omega = f dx^1 \wedge \cdots \wedge dx^n$ be an n -form with compact support on \mathbb{R}^n such that $\int_{\mathbb{R}^n} \omega = 0$. For simplicity assume that support $\omega \subset \{p \in \mathbb{R}^n : |p| < 1\}$. We know that there is an $(n-1)$ -form η on \mathbb{R}^n such that $\omega = d\eta$. In fact, from Problem 7-23, we have an explicit formula for η ,

$$\eta(p) = \sum_{i=1}^n (-1)^{i-1} \left(\int_0^1 t^{n-1} f(t \cdot p) dt \right) x^i dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^n.$$

Using the substitution $u = |p|t$ this becomes

$$\begin{aligned}\eta(p) &= \left(\int_0^{|p|} u^{n-1} f\left(u \cdot \frac{p}{|p|}\right) du \right) \frac{1}{|p|^n} \\ &\quad \times \sum_{i=1}^n (-1)^{i-1} x^i dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^n \\ &= \left(\int_0^{|p|} u^{n-1} f\left(u \cdot \frac{p}{|p|}\right) du \right) \cdot r^* \sigma'(p) \quad \text{by Lemma 7.}\end{aligned}$$

Define $g: S^{n-1} \rightarrow \mathbb{R}$ by

$$g(p) = \int_0^1 u^{n-1} f(u \cdot p) du.$$

On the set $A = \{p \in \mathbb{R}^n : |p| > 1\}$ we have $f = 0$, so on A we have

$$\eta(p) = \left(\int_0^1 u^{n-1} f\left(u \cdot \frac{p}{|p|}\right) du \right) \cdot r^* \sigma'(p),$$

or

$$\eta = (g \circ r) \cdot r^* \sigma' = r^*(g\sigma').$$

Moreover, by Corollary 8 we have for the $(n-1)$ -form $g\sigma'$ on S^{n-1} ,

$$\begin{aligned}\int_{S^{n-1}} g\sigma' &= \int_B f dx^1 \wedge \cdots \wedge dx^n \\ &= \int_{\mathbb{R}^n} \omega = 0.\end{aligned}$$

Thus, by the hypothesis for *Step 2*,

$$g\sigma' = d\lambda \quad \text{for some } (n-2)\text{-form } \lambda \text{ on } S^{n-1}.$$

Hence

$$\eta = r^*(d\lambda) = d(r^*\lambda).$$

Let $h: \mathbb{R}^n \rightarrow [0, 1]$ be any C^∞ function with $h = 1$ on A and $h = 0$ in a neighborhood of 0. Then $hr^*\lambda$ is a C^∞ form on \mathbb{R}^n and

$$\omega = d\eta = d(\eta - d(hr^*\lambda)):$$

the form $\eta - d(hr^*\lambda)$ has compact support, since on A we have

$$\eta - d(hr^*\lambda) = \eta - d(r^*\lambda) = 0.$$

Step 3. Choose an n -form ω such that $\int_M \omega \neq 0$ and ω has compact support contained in an open set $U \subset M$, with U diffeomorphic to \mathbb{R}^n . If ω' is any other n -form with compact support, we want to show that there is a number c and a form η with compact support such that

$$\omega' = c\omega + d\eta.$$

Using a partition of unity, we can write

$$\omega' = \phi_1 \omega' + \cdots + \phi_k \omega'$$

where each $\phi_i \omega'$ has compact support contained in some open set $U_i \subset M$ with U_i diffeomorphic to \mathbb{R}^n . It obviously suffices to find c_i and η_i with $\phi_i \omega' = c_i \omega + d\eta_i$, for each i . In other words, we can assume ω' has support contained in some open $V \subset M$ which is diffeomorphic to \mathbb{R}^n .

Using the connectedness of M , it is easy to see that there is a sequence of open sets

$$U = V_1, \dots, V_r = V$$

diffeomorphic to \mathbb{R}^n , with $V_i \cap V_{i+1} \neq \emptyset$. Choose forms ω_i with support $\omega_i \subset$

$V_i \cap V_{i+1}$ and $\int_{V_i} \omega_i \neq 0$. Since we are assuming the theorem for \mathbb{R}^n we have

$$\begin{aligned} \omega_1 - c_1 \omega &= d\eta_1 \\ \omega_2 - c_2 \omega_1 &= d\eta_2 \\ &\vdots \\ \omega' - c_r \omega_{r-1} &= d\eta_r, \end{aligned}$$

where all η_i have compact support ($\subset V_i$). From this we clearly obtain the desired result. ♦

The method used in the last step can be used to derive another result.

10. THEOREM. If M is any connected non-orientable n -manifold, then $H_c^n(M) = 0$.

PROOF. Choose an n -form ω with compact support contained in an open set U diffeomorphic to \mathbb{R}^n , such that $\int_U \omega \neq 0$ (this integral makes sense, since U is orientable). It obviously suffices to show that $\omega = d\eta$ for some form η with compact support. Consider a sequence

$$U = V_1, \dots, V_r = V$$

of coordinate systems (V_i, x_i) where each $x_i \circ x_{i+1}^{-1}$ is orientation preserving. Choose the forms ω_i in *Step 3* so that, using the orientation of V_i which makes $x_i: V_i \rightarrow \mathbb{R}^n$ orientation preserving, we have $\int_{V_i} \omega_i > 0$; then also $\int_{V_{i+1}} \omega_i > 0$. Consequently, the numbers

$$c_i = \int_{V_i} \omega_i \bigg/ \int_{V_i} \omega_{i-1} \quad \text{are positive.}$$

It follows that

$$\omega_i = c\omega + d\eta \quad \text{where } c > 0.$$

Now if M is unorientable, there is such a sequence where $V_r = V_1$ but $x_r \circ x_1^{-1}$ is orientation reversing. Taking $\omega' = -\omega$, we have

$$-\omega = c\omega + d\eta \quad \text{for } c > 0$$

so

$$(-c - 1)\omega = d\eta \quad \text{for } -c - 1 \neq 0. \quad \spadesuit$$

We can also compute $H^n(M)$ for non-compact M .

11. THEOREM. If M is a connected non-compact n -manifold (orientable or not), then $H^n(M) = 0$.

PROOF. Consider first an n -form ω with support contained in a coordinate neighborhood U which is diffeomorphic to \mathbb{R}^n . Since M is not compact, there is an infinite sequence

$$U = U_1, U_2, U_3, U_4, \dots$$

of such coordinate neighborhoods such that $U_i \cap U_{i+1} \neq \emptyset$, and such that the sequence is eventually in the complement of any compact set.

Now choose n -forms ω_i with compact support contained in $U_i \cap U_{i+1}$, such that $\int_{U_i} \omega_i \neq 0$. There are constants c_i and forms η_i with compact support $\subset U_i$ such that

$$\begin{aligned}\omega &= c_1 \omega_1 + d\eta_1 \\ \omega_i &= c_{i+1} \omega_{i+1} + d\eta_{i+1} \quad i \geq 1.\end{aligned}$$

Then

$$\begin{aligned}\omega &= d\eta_1 + c_1 \omega_1 \\ &= d\eta_1 + c_1 d\eta_2 + c_1 c_2 \omega_2 \\ &= d\eta_1 + c_1 d\eta_2 + c_1 c_2 d\eta_3 + c_1 c_2 c_3 \omega_3 \\ &= \dots\end{aligned}$$

Since any point $p \in M$ is eventually in the complement of the U_i 's, we have

$$\omega = d\eta_1 + c_1 d\eta_2 + c_1 c_2 d\eta_3 + c_1 c_2 c_3 d\eta_4 + \dots,$$

where the right side makes sense since the U_i are eventually outside of any compact set.

Now it can be shown (Problem 20) that there is actually such a sequence U_1, U_2, U_3, \dots whose union is all of M (repetitions are allowed, and U_i may intersect several U_j for $j < i$, but the sequence is still eventually outside of any compact set). The cover $\mathcal{O} = \{U_i\}$ is then locally finite. Let $\{\phi_{U_i}\}$ be a partition of unity subordinate to \mathcal{O} . If ω is an n -form on M , then for each U_i we have seen that

$$\phi_{U_i} \omega = d\eta_i \quad \text{where } \eta_i \text{ has support contained in } U_i \cup U_{i+1} \cup U_{i+2} \cup \dots.$$

Hence

$$\omega = \sum_{i=1}^{\infty} \phi_{U_i} \omega = \sum_{i=1}^{\infty} d\eta_i = d \left(\sum_{i=1}^{\infty} \eta_i \right). \quad \spadesuit$$

SUMMARY OF RESULTS

(1) For \mathbb{R}^n we have

$$H^k(\mathbb{R}^n) \approx \begin{cases} \mathbb{R} & k = 0 \\ 0 & k > 0. \end{cases}$$

(2) If M is a connected n -manifold, then

$$\begin{aligned} H^0(M) &\approx \mathbb{R} \\ H_c^n(M) &\approx \begin{cases} \mathbb{R} & \text{if } M \text{ is orientable} \\ 0 & \text{if } M \text{ is non-orientable} \end{cases} \\ H^n(M) &\approx \begin{cases} H_c^n & \text{if } M \text{ is compact} \\ 0 & \text{if } M \text{ is not compact.} \end{cases} \end{aligned}$$

We also know that $H^{n-1}(\mathbb{R}^n - \{0\}) \neq 0$, but we have not listed this result, since we will eventually improve it. In order to proceed further with our computations we need to examine the behavior of the de Rham cohomology vector spaces under C^∞ maps $f: M \rightarrow N$. If ω is a closed k -form on N , then $f^*\omega$ is also closed ($df^*\omega = f^*d\omega = 0$), so f^* takes $Z^k(N)$ to $Z^k(M)$. On the other hand, f^* also takes $B^k(N)$ to $B^k(M)$, since $f^*(d\eta) = d(f^*\eta)$. This shows that f^* induces a map

$$Z^k(N)/B^k(N) \rightarrow Z^k(M)/B^k(M),$$

also denoted by f^* :

$$f^*: H^k(N) \rightarrow H^k(M).$$

For example, consider the case $k = 0$. If N is connected, then $H^0(N)$ is just the collection of constant functions $c: N \rightarrow \mathbb{R}$. Then $f^*(c) = c \circ f$ is also a constant function. If M is connected, then $f^*: H^0(N) \rightarrow H^0(M)$ is just the identity map under the natural identification of $H^0(N)$ and $H^0(M)$ with \mathbb{R} . If M is disconnected, with components M_α , $\alpha \in A$, then $H^0(M)$ is isomorphic to the direct sum

$$\bigoplus_{\alpha \in A} \mathbb{R}_\alpha, \quad \text{where each } \mathbb{R}_\alpha \approx \mathbb{R};$$

the map f^* takes $c \in \mathbb{R}$ into the element of $\bigoplus \mathbb{R}_\alpha$ with α^{th} component equal to c . If N is also disconnected, with components N_β , $\beta \in B$, then

$$f^*: \bigoplus_{\beta \in B} \mathbb{R}_\beta \rightarrow \bigoplus_{\alpha \in A} \mathbb{R}_\alpha$$

takes the element $\{c_\beta\}$ of $\bigoplus_{\beta \in B} \mathbb{R}_\beta$ to $\{c'_\alpha\}$, where $c'_\alpha = c_\beta$ when $f(M_\alpha) \subset N_\beta$.

A more interesting case, and the only one we are presently in a position to look at, is the map

$$f^*: H^n(N) \rightarrow H^n(M)$$

when M and N are both compact connected oriented n -manifolds. There is no natural way to make $H^n(M)$ isomorphic to \mathbb{R} , so we really want to compare

$$\int_M f^* \omega \quad \text{and} \quad \int_N \omega$$

for ω an n -form on N . Choose one ω_0 with $\int_N \omega_0 \neq 0$. Then there is some number a such that

$$\int_M f^* \omega_0 = a \cdot \int_N \omega_0.$$

Since $\omega \mapsto \int_M \omega$ is an isomorphism of $H^n(M)$ and \mathbb{R} (and similarly for N) it follows that for *every* form ω we have

$$\int_M f^* \omega = a \cdot \int_N \omega.$$

The number $a = \deg f$, which depends only on f , is called the **degree** of f . If M and N are not compact, but f is proper (the inverse image of any compact set is compact), then we have a map

$$f^*: H_c^n(N) \rightarrow H_c^n(M)$$

and a number $\deg f$, such that

$$\int_M f^* \omega = (\deg f) \int_N \omega$$

for all forms ω on N with compact support. Until one sees the proof of the next theorem, it is almost unbelievable that this number is *always an integer*.

12. THEOREM. Let $f: M \rightarrow N$ be a proper map between two connected oriented n -manifolds (M, μ) and (N, ν) . Let $q \in N$ be a regular value of f . For each $p \in f^{-1}(q)$, let

$$\text{sign}_p f = \begin{cases} 1 & \text{if } f_{*p}: M_p \rightarrow N_q \text{ is orientation preserving} \\ & \text{(using the orientations } \mu_p \text{ for } M_p \text{ and } \nu_q \text{ for } N_q) \\ -1 & \text{if } f_{*p} \text{ is orientation reversing.} \end{cases}$$

Then

$$\deg f = \sum_{p \in f^{-1}(q)} \text{sign}_p f \quad (= 0 \text{ if } f^{-1}(q) = \emptyset).$$

PROOF. Notice first that regular values exist, by Sard's Theorem. Moreover, $f^{-1}(q)$ is finite, since it is compact and consists of isolated points, so the sum above is a finite sum.

Let $f^{-1}(q) = \{p_1, \dots, p_k\}$. Choose coordinate systems (U_i, x_i) around p_i such that all points in U_i are regular values of f , and the U_i are disjoint. We want to choose a coordinate system (V, y) around q such that $f^{-1}(V) = U_1 \cup \dots \cup U_k$. To do this, first choose a compact neighborhood W of q , and let

$W' \subset M$ be the compact set

$$W' = f^{-1}(W) - (U_1 \cup \dots \cup U_k).$$

Then $f(W')$ is a closed set which does not contain q . We can therefore choose $V \subset W - f(W')$. This ensures that $f^{-1}(V) \subset U_1 \cup \dots \cup U_k$. Finally, redefine U_i to be $U_i \cap f^{-1}(V)$.

Now choose ω on N to be $\omega = g dy^1 \wedge \dots \wedge dy^n$ where $g \geq 0$ has compact support contained in V . Then support $f^*\omega \subset U_1 \cup \dots \cup U_k$. So

$$\int_M f^*\omega = \sum_{i=1}^k \int_{U_i} f^*\omega.$$

Since f is a diffeomorphism from each U_i to V we have

$$\begin{aligned} \int_{U_i} f^*\omega &= \int_V \omega \quad \text{if } f \text{ is orientation preserving} \\ &= - \int_V \omega \quad \text{if } f \text{ is orientation reversing.} \end{aligned}$$

Since f is orientation preserving [or reversing] precisely when $\text{sign}_p f = 1$ [or -1] this proves the theorem. ♦

As an immediate application of the theorem, we compute the degree of the “antipodal map” $A: S^n \rightarrow S^n$ defined by $A(p) = -p$. We have already seen that A is orientation preserving or reversing at all points, depending on whether n is odd or even. Since $A^{-1}(p)$ consists of just one point, we conclude that

$$\deg A = (-1)^{n-1}.$$

We can draw an interesting conclusion from this result, but we need to introduce another important concept first. Two functions $f, g: M \rightarrow N$ between two C^∞ manifolds are called (smoothly) homotopic if there is a smooth function

$$H: M \times [0, 1] \rightarrow N$$

with

$$\begin{aligned} H(p, 0) &= f(p) \\ H(p, 1) &= g(p) \end{aligned} \quad \text{for all } p \in M;$$

the map H is called a (smooth) homotopy between f and g . Notice that M is smoothly contractible to a point $p_0 \in M$ if and only if the identity map of M is homotopic to the constant map p_0 . Recall that for every k -form ω on $M \times [0, 1]$ we defined a $(k-1)$ -form $I\omega$ on M such that

$$i_1^* \omega - i_0^* \omega = d(I\omega) + I(d\omega).$$

We used this fact to show that all closed forms on a smoothly contractible manifold are exact. We can now prove a more general result.

13. THEOREM. If $f, g: M \rightarrow N$ are smoothly homotopic, then the maps

$$f^*: H^k(N) \rightarrow H^k(M)$$

$$g^*: H^k(N) \rightarrow H^k(M)$$

are equal, $f^* = g^*$.

PROOF. By assumption, there is a smooth map $H: M \times [0, 1] \rightarrow N$ with

$$f = H \circ i_0$$

$$g = H \circ i_1.$$

Any element of $H^k(N)$ is the equivalence class $[\omega]$ of some closed k -form ω on N . Then

$$\begin{aligned} g^* \omega - f^* \omega &= (H \circ i_1)^* \omega - (H \circ i_0)^* \omega \\ &= i_1^*(H^* \omega) - i_0^*(H^* \omega) \\ &= d(IH^* \omega) + I(dH^* \omega) \\ &= d(IH^* \omega) + 0. \end{aligned}$$

But this means that $g^*([\omega]) = f^*([\omega])$. ♦

14. COROLLARY. If M and N are compact oriented n -manifolds and the maps $f, g: M \rightarrow N$ are homotopic, then $\deg f = \deg g$.

15. COROLLARY. If n is even, then there does not exist a nowhere zero vector field on S^n .

PROOF. We have already seen that the degree of the antipodal map $A: S^n \rightarrow S^n$ is $(-1)^{n-1}$. Since the identity map has degree 1, A is not homotopic to the identity for n even. But if there is a nowhere zero vector field on S^n , then we can construct a homotopy between A and the identity map as follows. For each p , there is a unique great semi-circle γ_p from p to $A(p) = -p$ whose tangent vector at p is a multiple of $X(p)$. Define

$$H(p, t) = \gamma_p(t). \quad \spadesuit$$

For n odd we can explicitly construct a nowhere zero vector field on S^n . For $p = (x_1, \dots, x_{n+1}) \in S^n$ we define

$$X(p) = (-x_1, x_2, -x_3, x_4, \dots, -x_{n+1}, x_n);$$

this is perpendicular to $p = (x_1, x_2, \dots, x_{n+1})$, and therefore in S^n_p . (On S^1 this gives the standard picture.) The vector field on S^n can then be used to give

a homotopy between A and the identity map.

For another application of Theorem 13, consider the retraction

$$r: \mathbb{R}^n - \{0\} \rightarrow S^{n-1} \quad r(p) = p/|p|.$$

If $i: S^{n-1} \rightarrow \mathbb{R}^n - \{0\}$ is the inclusion, then

$$r \circ i: S^{n-1} \rightarrow S^{n-1} \text{ is the identity } 1 \text{ of } S^{n-1}.$$

The map

$$i \circ r: \mathbb{R}^n - \{0\} \rightarrow \mathbb{R}^n - \{0\} \quad i \circ r(p) = p/|p|$$

is, of course, not the identity, but it is homotopic to the identity; we can define the homotopy H by

$$H(p, t) = tp + (1 - t)r(p) \in \mathbb{R}^n - \{0\}.$$

A retraction with this property is called a **deformation retraction**. Whenever r is a deformation retraction, the maps $(r \circ i)^*$ and $(i \circ r)^*$ are the identity. Thus, for the case of $S^{n-1} \subset \mathbb{R}^n - \{0\}$, we have

$$\begin{aligned} H^k(S^{n-1}) &\xrightarrow{r^*} H^k(\mathbb{R}^n - \{0\}) \\ H^k(\mathbb{R}^n - \{0\}) &\xrightarrow{i^*} H^k(S^{n-1}) \end{aligned}$$

and

$$\begin{aligned} r^* \circ i^* &= (i \circ r)^* = \text{identity of } H^k(\mathbb{R}^n - \{0\}) \\ i^* \circ r^* &= (r \circ i)^* = \text{identity of } H^k(S^{n-1}). \end{aligned}$$

So i^* and r^* are inverses of each other. Thus

$$H^k(S^{n-1}) \approx H^k(\mathbb{R}^n - \{0\}) \quad \text{for all } k.$$

In particular, we have $H^{n-1}(\mathbb{R}^n - \{0\}) \approx \mathbb{R}$. A generator of $H^{n-1}(\mathbb{R}^n - \{0\})$ is the closed form $r^*\sigma'$.

We are now going to compute $H^k(\mathbb{R}^n - \{0\})$ for all k . We need one further observation. The manifold

$$M \times \{0\} \subset M \times \mathbb{R}^l$$

is clearly a deformation retraction of $M \times \mathbb{R}^l$. So $H^k(M) \approx H^k(M \times \mathbb{R}^l)$ for all l .

16. THEOREM. For $0 < k < n - 1$ we have $H^k(\mathbb{R}^n - \{0\}) = H^k(S^{n-1}) = 0$.

PROOF. Induction on n . The first case where there is anything to prove is $n = 3$. We claim $H^1(\mathbb{R}^3 - \{0\}) = 0$.

Let ω be a closed 1-form on \mathbb{R}^3 . Let A and B be the open sets

$$A = \mathbb{R}^3 - \{(0, 0) \times (-\infty, 0]\}$$

$$B = \mathbb{R}^3 - \{(0, 0) \times [0, \infty)\}.$$

Since A and B are both star-shaped (with respect to the points $(0, 0, 1)$ and $(0, 0, -1)$, respectively), there are 0-forms f_A and f_B on A and B with

$$\omega = df_A \quad \text{on } A$$

$$\omega = df_B \quad \text{on } B.$$

Now

$$d(f_A - f_B) = 0 \quad \text{on } A \cap B,$$

and

$$A \cap B = [\mathbb{R}^2 - \{0\}] \times \mathbb{R},$$

so clearly $f_A - f_B$ is a constant c on $A \cap B$. Thus ω is exact, for

$$\omega = d(f_A - c) \quad \text{on } A$$

$$\omega = d(f_B) \quad \text{on } B$$

and $f_A - c = f_B$ on $A \cap B$.

If ω is a closed 1-form on \mathbb{R}^4 , there is a similar argument, using

$$A = \mathbb{R}^4 - \{(0, 0, 0) \times (-\infty, 0]\}$$

$$B = \mathbb{R}^4 - \{(0, 0, 0) \times [0, \infty)\}.$$

If ω is a closed 2-form on \mathbb{R}^4 , then we obtain 1-forms η_A and η_B with

$$\omega = d\eta_A \quad \text{on } A$$

$$\omega = d\eta_B \quad \text{on } B.$$

Now

$$d(\eta_A - \eta_B) = 0 \quad \text{on } A \cap B$$

and

$$H^1(A \cap B) = H^1([\mathbb{R}^3 - \{0\}] \times \mathbb{R}) \approx H^1(\mathbb{R}^3 - \{0\}) = 0.$$

So $\eta_A - \eta_B = d\lambda$ for some 0-form λ on $A \cap B$. Unlike the previous case, we cannot simply consider $\eta_A - d\lambda$, since this is not defined on A . To circumvent this difficulty, note that there is a partition of unity $\{\phi_A, \phi_B\}$ for the cover $\{A, B\}$ of $\mathbb{R}^3 - \{0\}$:

$$\begin{aligned} \phi_A + \phi_B &= 1 \\ d\phi_A + d\phi_B &= 0 \\ \text{support } \phi_A &\subset A \\ \text{support } \phi_B &\subset B. \end{aligned}$$

Now, if

$$\phi_B \lambda \quad \text{denotes} \quad \begin{cases} \phi_B \lambda & \text{on } A \cap B \\ 0 & \text{on } A - (A \cap B), \end{cases}$$

and similarly for $\phi_A \lambda$, then

$$\begin{aligned} \phi_B \lambda &\text{ is a } C^\infty \text{ form on } A \\ \phi_A \lambda &\text{ is a } C^\infty \text{ form on } B. \end{aligned}$$

On $A \cap B$ we have

$$\begin{aligned} \eta_A - d(\phi_B \lambda) &= \eta_A - \phi_B d\lambda - d\phi_B \wedge \lambda \\ &= \eta_A + (\phi_A - 1) d\lambda + d\phi_A \wedge \lambda \\ &= \eta_A - d\lambda + d(\phi_A \lambda) \\ &= \eta_B + d(\phi_A \lambda). \end{aligned}$$

So we can define a C^∞ form on $\mathbb{R}^n - \{0\} = A \cup B$ by letting it be $\eta_A - d(\phi_B \lambda)$ on A , and $\eta_B + d(\phi_A \lambda)$ on B . Clearly,

$$\begin{aligned} \omega &= d\eta_A = d(\eta_A - d(\phi_B \lambda)) \quad \text{on } A \\ &= d\eta_B = d(\eta_B + d(\phi_A \lambda)) \quad \text{on } B, \end{aligned}$$

so ω is exact.

The general inductive step is similar. ♦

We end this chapter with one more calculation, which we will need in Chapter 11.

17. THEOREM. For $0 \leq k < n$ we have $H_c^k(\mathbb{R}^n) = 0$.

PROOF. The proof that $H_c^0(\mathbb{R}^n) = 0$ is left to the reader.

Let ω be a k -form on \mathbb{R}^n with compact support, $0 < k < n$. We know that $\omega = d\eta$ for some $(k-1)$ -form η on \mathbb{R}^n . Let B be a closed ball containing support ω . Then on $A = \mathbb{R}^n - B$ we have $d\eta = 0$. Since A is diffeomorphic to

$\mathbb{R}^n - \{0\}$ and $k-1 < n-1$ we have from Theorem 16 that

$$\eta = d\lambda \quad \text{for some } (k-2)\text{-form } \lambda \text{ on } A.$$

Let $f: \mathbb{R}^n \rightarrow [0, 1]$ be a C^∞ function with $f = 0$ in a neighborhood of B and $f = 1$ on $\mathbb{R}^n - 2B$, where $2B$ denotes the ball of twice the radius of B . Then $d(f\lambda)$ makes sense on all of \mathbb{R}^n and

$$\omega = d\eta = d(\eta - d(f\lambda));$$

the form $\eta - d(f\lambda)$ clearly has compact support contained in $2B$. ♦

PROBLEMS

1. *The Riemann integral versus the Darboux integral.* Let $f : [a, b] \rightarrow \mathbb{R}$ be bounded. For a partition $P = \{t_0 < \cdots < t_n\}$ of $[a, b]$, let $m_i = m_i(f)$ be the inf of f on $[t_{i-1}, t_i]$ and define $M_i = M_i(f)$ similarly. A *choice* for P is an n -tuple $\xi = (\xi_1, \dots, \xi_n)$ with $\xi_i \in [t_{i-1}, t_i]$. We define the “lower sum”, “upper sum”, and “Riemann sum” for a partition P and choice ξ by

$$L(f, P) = \sum_{i=1}^n m_i(f) \cdot (t_i - t_{i-1})$$

$$U(f, P) = \sum_{i=1}^n M_i(f) \cdot (t_i - t_{i-1})$$

$$S(f, P, \xi) = \sum_{i=1}^n f(\xi_i)(t_i - t_{i-1}).$$

Clearly $L(f, P) \leq S(f, P, \xi) \leq U(f, P)$. We call f **Darboux integrable** if the sup of all $L(f, P)$ equals the inf of all $U(f, P)$; this sup or inf is called the **Darboux integral** of f on $[a, b]$. We call f **Riemann integrable** if

$$\lim_{\|P\| \rightarrow 0} S(f, P, \xi) \text{ exists;}$$

the limit is called the **Riemann integral** of f on $[a, b]$.

(a) We can define $S(f, P, \xi)$ even if f is not bounded. Show however, that $\lim_{\|P\| \rightarrow 0} S(f, P, \xi)$ cannot exist if f is unbounded.

(b) If f is continuous on $[a, b]$, then f is Riemann and Darboux integrable on $[a, b]$, and the two integrals are equal. (Use uniform continuity of f on $[a, b]$.)

(c) If f is Riemann integrable on $[a, b]$, then f is Darboux integrable on $[a, b]$ and the two integrals are equal.

(d) Let $m \leq f \leq M$ on $[a, b]$. Let $P = \{s_0 < \cdots < s_m\}$ and $Q = \{t_0 < \cdots < t_n\}$ be two partitions of $[a, b]$. For each $i = 1, \dots, n$, let

$e_i = \text{length of } [t_{i-1}, t_i]$

– sum of lengths of all $[s_{\alpha-1}, s_\alpha]$ which are contained in $[t_{i-1}, t_i]$.

Show that, if M_i denotes the sup of f on $[t_{i-1}, t_i]$, then

$$\begin{aligned} U(f, P) &\leq U(f, Q) + \sum_{i=1}^n (M - M_i) e_i \\ &\leq U(f, Q) + (M - m) \sum_{i=1}^n e_i. \end{aligned}$$

There is a similar result for lower sums.

(e) Show that $\sum_{i=1}^n e_i \rightarrow 0$ as $\|P\| \rightarrow 0$, and deduce Darboux's Theorem:

$$\begin{aligned} \lim_{\|P\| \rightarrow 0} U(f, P) &= \inf \{U(f, Q) : Q \text{ a partition of } [a, b]\} \\ \lim_{\|P\| \rightarrow 0} L(f, P) &= \sup \{L(f, Q) : Q \text{ a partition of } [a, b]\}. \end{aligned}$$

(f) If f is Darboux integrable on $[a, b]$, then f is Riemann integrable on $[a, b]$.

(g) (Osgood's Theorem). Let f and g be integrable on $[a, b]$. Show that for choices ξ, ξ' for P ,

$$\lim_{\|P\| \rightarrow 0} \sum_{i=1}^n f(\xi_i) g(\xi'_i) (t_i - t_{i-1}) = \int_a^b f g.$$

Hint: If $|g| \leq M$ on $[a, b]$, then $|f(\xi'_i)g(\xi'_i) - f(\xi_i)g(\xi'_i)| \leq M|f(\xi'_i) - f(\xi_i)|$.

(h) Show that $\int_c f dx + g dy$, defined as a limit of sums, equals

$$\int_a^b [f(c(t))c^{1'}(t) + g(c(t))c^{2'}(t)] dt.$$

2. Compute $\int_c d\theta = \int_{[0,1]} c^* d\theta$, where $c(t) = (\cos 2\pi t, \sin 2\pi t)$ on $[0, 1]$.

3. For n an integer, and $R > 0$, let $c_{R,n} : [0, 1] \rightarrow \mathbb{R}^2 - \{0\}$ be defined by

$$c_{R,n}(t) = (R \cos 2n\pi t, R \sin 2n\pi t).$$

(a) Show that there is a singular 2-cube $c : [0, 1]^2 \rightarrow \mathbb{R}^2 - \{0\}$ such that $c_{R_1,n} - c_{R_2,n} = \partial c$.

(b) If $c : [0, 1] \rightarrow \mathbb{R}^2 - \{0\}$ is any curve with $c(0) = c(1)$, show that there is some n such that $c - c_{1,n}$ is a boundary in $\mathbb{R}^2 - \{0\}$.

(c) Show that n is unique. It is called the **winding number** of c around 0.

4. Let $f: \mathbb{C} \rightarrow \mathbb{C}$ be a polynomial, $f(z) = z^n + a_1 z^{n-1} + \cdots + a_n$, where $n \geq 1$. Define $c_{R,f}: [0, 1] \rightarrow \mathbb{C}$ by $c_{R,f} = f \circ c_{R,1}$.

(a) Show that if R is large enough, then $c_{R,f} - c_{R,n}$ is the boundary of a chain in $\mathbb{C} - \{0\}$. *Hint:* Note that $c_{R^n,n}(t) = [c_{R,1}(t)]^n$, and write

$$f(z) = z^n \left(1 + \frac{a_1}{z} + \cdots + \frac{a_n}{z^n} \right).$$

(b) Show that $f(z) = 0$ for some $z \in \mathbb{C}$ ("Fundamental Theorem of Algebra"). *Hint:* If $f(z) \neq 0$ for all z with $|z| \leq R$, then $c_{R,f} - c_{0,f}$ is a boundary.

5. Some approaches to integration use singular simplexes instead of singular cubes. Although Stokes' Theorem becomes more complicated, there are some advantages in using singular simplexes, as indicated in the next Problem.

Let $\Delta_n \subset \mathbb{R}^n$ be the set of all $x \in \mathbb{R}^n$ such that

$$0 \leq x^i \leq 1, \quad \sum_{i=1}^n x^i \leq 1.$$

A singular n -simplex in M is a C^∞ function $c: \Delta_n \rightarrow M$, and an n -chain is a formal sum of singular n -simplexes. As before, let $I^n: \Delta_n \rightarrow \mathbb{R}^n$ be the inclusion map. Define $\partial_i: \Delta_{n-1} \rightarrow \Delta_n$ by

$$\begin{aligned} \partial_0(x) &= ([1 - \sum_{i=1}^{n-1} x^i], x^1, \dots, x^{n-1}) \\ \partial_i(x) &= (x^1, \dots, x^{i-1}, 0, x^i, \dots, x^{n-1}) \quad 0 < i \leq n, \end{aligned}$$

and for singular n -simplexes c , define $\partial_i c = c \circ \partial_i$. Then we define

$$\partial c = \sum_{i=0}^n (-1)^i \partial_i c.$$

- Describe geometrically the images $\partial_i(\Delta_{n-1})$ in Δ_n .
- Show that $\partial^2 = 0$.

(c) Show that if $\omega = f dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^n$ is an $(n-1)$ -form on \mathbb{R}^n , then

$$\int_{I^n} d\omega = \int_{\partial I^n} \omega.$$

(Imitate the proof for cubes.)

(d) Define $\int_c \omega$ for any k -chain c in M and k -form ω on M , and prove that

$$\int_c d\omega = \int_{\partial c} \omega$$

for any $(k-1)$ -form ω .

6. Every $x \in \Delta_{k+1}$ can be written as tx' , for $0 \leq t \leq 1$, and $x' \in \partial_0(\Delta_k)$.

Moreover, x' is unique except when $t = 0$. For any singular k -simplex $c: \Delta_k \rightarrow \mathbb{R}^n$, define $\bar{c}: \Delta_{k+1} \rightarrow \mathbb{R}^n$ by

$$\bar{c}(x) = t \cdot c(x').$$

We then define \bar{c} for chains c in the obvious way.

(a) Show that $\partial c = 0$ implies that $c = \partial \bar{c}$.

(b) Let $c: [0, 1] \rightarrow \mathbb{R}^2$ be a closed curve. Show that c is *not* the boundary of any sum σ of singular 2-cubes. *Hint:* If $\partial \sigma = \sum_i a_i c_i$, what can be said about $\sum_i a_i$?

(c) Show that we do have $c = \partial \sigma + c'$ where c' is *degenerate*, that is, $c'([0, 1])$ is a point.

(d) If $c_1(0) = c_2(0)$ and $c_1(1) = c_2(1)$, show that $c_1 - c_2$ is a boundary, using either simplexes or cubes.

7. Let ω be a 1-form on a manifold M . Suppose that $\int_c \omega = 0$ for every closed curve c in M . Show that ω is exact. *Hint:* If we do have $\omega = df$, then for any curve c we have

$$\int_c \omega = f(c(1)) - f(c(0)).$$

8. A manifold M is called **simply-connected** if M is connected and if every smooth map $f: S^1 \rightarrow M$ is smoothly contractible to a point. [Actually, any space M (not necessarily a manifold) is called simply-connected if it is connected and any continuous $f: S^1 \rightarrow M$ is (continuously) contractible to a point. It is not hard to show that for a manifold we may insert “smooth” at both places.]

(a) If M is smoothly contractible to a point, then M is simply-connected.

(b) S^1 is not simply-connected.

(c) S^n is simply-connected for $n > 1$. *Hint:* Show that a smooth $f: S^1 \rightarrow S^n$ is not onto.

(d) If M is simply-connected and $p \in M$, then any smooth map $f: S^1 \rightarrow M$ is smoothly contractible to p .

(e) If $M = U \cup V$ where U and V are simply-connected open subsets with $U \cap V$ connected, then M is simply-connected. (This gives another proof that S^n is simply-connected for $n > 1$.) *Hint:* Given $f: S^1 \rightarrow M$, partition S^1 into a finite number of intervals each of which is taken into either U or V .

(f) If M is simply-connected, then $H^1(M) = 0$. (See Problem 7.)

9. (a) Let $U \subset \mathbb{R}^2$ be a bounded open set such that $\mathbb{R}^2 - U$ is not connected. Show that U is not smoothly contractible to a point. (Converse of

Problem 7-24.) *Hint:* If p is in a bounded component of $\mathbb{R}^2 - U$, show that there is a curve in U which “surrounds” p .

(b) A bounded connected open set $U \subset \mathbb{R}^2$ is smoothly contractible to a point if and only if it is simply-connected.

(c) This is false for open subsets of \mathbb{R}^3 .

10. Let ω be an n -form on an oriented manifold M^n . Let Φ and Ψ be two partitions of unity by functions with compact support, and suppose that

$$\sum_{\phi \in \Phi} \int_M \phi \cdot |\omega| < \infty.$$

(a) This implies that $\sum_{\phi \in \Phi} \int_M \phi \cdot \omega$ converges absolutely.

(b) Show that

$$\sum_{\phi \in \Phi} \int_M \phi \cdot \omega = \sum_{\phi \in \Phi} \sum_{\psi \in \Psi} \int_M \psi \cdot \phi \cdot \omega,$$

and show the same result with ω replaced by $|\omega|$. (Note that for each ϕ , there are only finitely many ψ which are non-zero on support ϕ .)

(c) Show that $\sum_{\psi \in \Psi} \int_M \psi \cdot |\omega| < \infty$, and that

$$\sum_{\phi \in \Phi} \int_M \phi \cdot \omega = \sum_{\psi \in \Psi} \int_M \psi \cdot \omega.$$

We define this common sum to be $\int_M \omega$.

(d) Let $A_n \subset (n, n+1)$ be closed sets. Let $f: \mathbb{R} \rightarrow \mathbb{R}$ be a C^∞ function with $\int_{A_n} f = (-1)^n/n$ and support $f \subset \bigcup_n A_n$. Find two partitions of unity Φ and Ψ such that $\sum_{\phi \in \Phi} \int_{\mathbb{R}} \phi \cdot f dx$ and $\sum_{\psi \in \Psi} \int_{\mathbb{R}} \psi \cdot f dx$ converge absolutely to different values.

11. Following Problem 7-12, define geometric objects corresponding to odd relative tensors of type $\binom{k}{l}$ and weight w (w any real number).

12. (a) Let M be $\{(x, y) \in \mathbb{R}^2 : |(x, y)| < 1\}$, together with a proper portion

of its boundary, and let $\omega = x dy$. Show that

$$\int_M d\omega \neq \int_{\partial M} \omega,$$

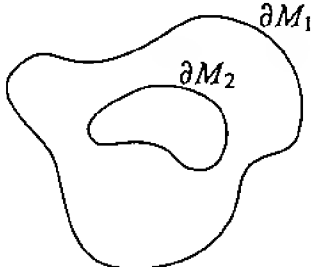

even though both sides make sense, using Problem 10. (No computations needed—note that equality would hold if we had the entire boundary.)

(b) Similarly, find a counterexample to Stokes' Theorem when $M = (0, 1)$ and ω is a 0-form whose support is not compact.

(c) Examine a partition of unity for $(0, 1)$ by functions with compact support to see just why the proof of Stokes' Theorem breaks down in this case.

13. Suppose M is a compact orientable n -manifold (with no boundary), and θ is an $(n-1)$ -form on M . Show that $d\theta$ is 0 at some point.

14. Let $M_1, M_2 \subset \mathbb{R}^n$ be compact n -dimensional manifolds-with-boundary with $M_2 \subset M_1 - \partial M_1$. Show that for any closed $(n-1)$ -form ω on M_1 ,

$$\int_{\partial M_1} \omega = \int_{\partial M_2} \omega.$$

15. Account for the factor $1/|p|^n$ in Lemma 7 (we have $r_*(v_p) = (1/|p|)v_{r(p)}$, but this only accounts for a factor of $1/|p|^{n-1}$, since there are $n-1$ vectors v_1, \dots, v_{n-1}).

16. Use the formula for r^*dx^i (Problem 4-1) to compute $r^*\sigma'$. (Note that

$$r^*\sigma' = r^*i^*\sigma = (i \circ r)^*\sigma;$$

the map $i \circ r: \mathbb{R}^n - \{0\} \rightarrow \mathbb{R}^n - \{0\}$ is just r , considered as a map into $\mathbb{R}^n - \{0\}$.)

17. (a) Let M^n and N^m be oriented manifolds, and let ω and η be an n -form and an m -form with compact support, on M and N , respectively. We will orient $M \times N$ by agreeing that $v_1, \dots, v_n, w_1, \dots, w_m$ is positively oriented in $(M \times N)_{(p,q)} \approx M_p \oplus N_q$ if v_1, \dots, v_n and w_1, \dots, w_m are positively oriented in M_p and N_q , respectively. If $\pi_i: M \times N \rightarrow M$ or N is projection on the i^{th} factor, show that

$$\int_{M \times N} \pi_1^* \omega \wedge \pi_2^* \eta = \int_M \omega \cdot \int_N \eta.$$

(b) If $h: M \times N \rightarrow \mathbb{R}$ is C^∞ , then

$$\int_{M \times N} h \pi_1^* \omega \wedge \pi_2^* \eta = \int_M g \omega,$$

where

$$g(p) = \int_N h(p, \cdot) \eta, \quad h(p, \cdot) = q \mapsto h(p, q).$$

(c) Every $(m+n)$ -form on $M \times N$ is $h \pi_1^* \omega \wedge \pi_2^* \eta$ for some ω and η .

18. (a) Let $p \in \mathbb{R}^n - \{0\}$. Let $w_1, \dots, w_{n-2} \in \mathbb{R}^n_p$ and let $v \in \mathbb{R}^n_p$ be $(\lambda p)_p$ for some $\lambda \in \mathbb{R}$. Show that

$$r^* \sigma'(v, w_1, \dots, w_{n-2}) = 0.$$

(b) Let $M \subset \mathbb{R}^n - \{0\}$ be a compact $(n-1)$ -manifold-with-boundary which is the union of segments of rays through 0. Show that $\int_M r^* \sigma' = 0$.

(c) Let $M \subset \mathbb{R}^n - \{0\}$ be a compact $(n-1)$ -manifold-with-boundary which intersects every ray through 0 at most once, and let $C(M) = \{\lambda p : p \in M, \lambda \geq 0\}$.

Show that

$$\int_M r^* \sigma' = \int_{C(M) \cap S^2} r^* \sigma'.$$

The latter integral is the measure of the solid angle subtended by M . For this reason we often denote $r^* \sigma'$ by $d\Theta_n$.

19. For all $(x, y, z) \in \mathbb{R}^3$ except those with $x = 0, y = 0, z \in (-\infty, 0]$, we define $\phi(x, y, z)$ to be the angle between the positive z -axis and the ray from 0 through (x, y, z) .

- (a) $\phi(x, y, z) = \arctan(\sqrt{x^2 + y^2}/z)$ (with appropriate conventions).
- (b) If $v(p) = |p|$, and θ is considered as a function on \mathbb{R}^3 , $\theta(x, y, z) = \arctan y/x$, then (v, θ, ϕ) is a coordinate system on the set of all points (x, y, z) in \mathbb{R}^3 except those with $y = 0$, $x \in [0, \infty)$ or with $x = 0$, $y = 0$, $z \in (-\infty, 0]$.
- (c) If v is a longitudinal unit tangent vector on the sphere $S^2(r)$ of radius r , then $d\phi(v) = 1$. If w points along a meridian through $p = (x, y, z) \in S^2(r)$,

then

$$d\theta(w_p) = \frac{1}{\sqrt{x^2 + y^2}}.$$

- (d) If θ and ϕ are taken to mean the restrictions of θ and ϕ to [certain portions of] S^2 , then

$$\sigma' = h d\theta \wedge d\phi,$$

where $h: S^2 \rightarrow \mathbb{R}$ is

$$h(x, y, z) = -\sqrt{x^2 + y^2} \quad (\text{the minus sign comes from the orientation}).$$

- (e) Conclude that

$$\sigma' = d(-\cos \phi d\theta).$$

(f) Let $r_2: \mathbb{R}^2 - \{0\} \rightarrow S^1$ be the retraction, so that $d\theta = r_2^* i^* \sigma$, for the form σ on \mathbb{R}^2 . Show that

$$r_2^* d\theta = d\theta.$$

If $\pi: \mathbb{R}^3 \rightarrow \mathbb{R}^2$ is the projection, then the form $d\theta$ on [part of] \mathbb{R}^3 is just $\pi^* d\theta$, for the form $d\theta$ on [part of] \mathbb{R}^2 . Use this to show that

$$r^* d\theta = d\theta.$$

(g) Also prove this directly by using the result in part (c), and the fact that $r_*(v_p) = v_{r(p)}/|p|$ for v tangent to $S^2(|p|)$.

(h) Conclude that

$$\begin{aligned} d\Theta_3 &= r^* \sigma' = d(-\cos(\phi \circ r) d\theta) \\ &= d(-\cos \phi d\theta). \end{aligned}$$

(i) Similarly, express $d\Theta_n$ on $\mathbb{R}^n - \{0\}$ in terms of $d\Theta_{n-1}$ on $\mathbb{R}^{n-1} - \{0\}$.

20. Prove that a connected manifold is the union $U_1 \cup U_2 \cup U_3 \cup \dots$, where the U_i are coordinate neighborhoods, with $U_i \cap U_j \neq \emptyset$, and the sequence is eventually outside of any compact set.

21. Let $f: M^n \rightarrow N^n$ be a proper map between oriented n -manifolds such that $f_*: M_p \rightarrow N_{f(p)}$ is orientation preserving whenever p is a regular point. Show that if N is connected, then either f is onto N , or else all points are critical points of f .

22. (a) Show that a polynomial map $f: \mathbb{C} \rightarrow \mathbb{C}$, given by $f(z) = z^n + a_1 z^{n-1} + \dots + a_n$, is proper ($n \geq 1$).

(b) Let $f'(z) = nz^{n-1} + (n-1)a_1 z^{n-2} + \dots + a_{n-1}$. Show that we have $f'(z) = \lim_{w \rightarrow 0} [f(z+w) - f(z)]/w$, where w varies over complex numbers.

(c) Write $f(x+iy) = u(x, y) + iv(x, y)$ for real-valued functions u and v . Show that

$$\begin{aligned} f'(x+iy) &= \frac{\partial u}{\partial x}(x, y) + i \frac{\partial v}{\partial x}(x, y) \\ &= \frac{\partial v}{\partial y}(x, y) - i \frac{\partial u}{\partial y}(x, y). \end{aligned}$$

Hint: Choose w to be a real h , and then to be ih .

(d) Conclude that

$$|f'(x+iy)|^2 = \det Df(x, y),$$

where f' is defined in part (b), while Df is the linear transformation defined for any differentiable $f: \mathbb{R}^2 \rightarrow \mathbb{R}^2$.

(e) Using Problem 21, give another proof of the Fundamental Theorem of Algebra.

(f) There is a still simpler argument, not using Problem 21 (which relies on many theorems of this chapter). Show directly that if $f: M \rightarrow N$ is proper, then the number of points in $f^{-1}(a)$ is a locally constant function on the set of regular values of f . Show that this set is connected for a polynomial $f: \mathbb{C} \rightarrow \mathbb{C}$, and conclude that f takes on all values.

23. Let $M^{n-1} \subset \mathbb{R}^n$ be a compact oriented manifold. For $p \in \mathbb{R}^n - M$, choose an $(n-1)$ -sphere Σ around p such that all points inside Σ are in $\mathbb{R}^n - M$. Let $r_p: \mathbb{R}^n - \{p\} \rightarrow \Sigma$ be the obvious retraction. Define the winding number $w(p)$ of M around p to be the degree of $r_p|_M$.

(a) Show that this definition agrees with that in Problem 3.

(b) Show that this definition does not depend on the choice of Σ .

(c) Show that w is constant in a neighborhood of p . Conclude that w is constant on each component of $\mathbb{R}^n - M$.

(d) Suppose M contains a portion A of an $(n-1)$ -plane. Let p and q be points

close to this plane, but on opposite sides. Show that $w(q) = w(p) \pm 1$. (Show that $r_q|M$ is homotopic to a map which equals $r_p|M$ on $M - A$ and which does not take any point of A onto the point x in the figure.)

(e) Show that, in general, if M is orientable, then $\mathbb{R}^n - M$ has at least 2 components. The next few Problems show how to prove the same result even if M is not orientable. More precise conclusions are drawn in Chapter 11.

24. Let M and N be compact n -manifolds, and let $f, g: M \rightarrow N$ be smoothly homotopic, by a smooth homotopy $H: M \times [0, 1] \rightarrow N$.

(a) Let $q \in N$ be a regular value of H . Let $\#f^{-1}(q)$ denote the (finite) number of points in $f^{-1}(q)$. Show that

$$\#f^{-1}(q) \equiv \#g^{-1}(q) \pmod{2}.$$

Hint: $H^{-1}(q)$ is a compact 1-manifold-with-boundary. The number of points in its boundary is clearly even. (This is one place where we use the stronger form of Sard's Theorem.)

(b) Show, more generally, that this result holds so long as q is a regular value of both f and g .

25. For two maps $f, g: M \rightarrow N$ we will write $f \simeq g$ to indicate that f is smoothly homotopic to g .

(a) If $f \simeq g$, then there is a smooth homotopy $H': M \times [0, 1] \rightarrow N$ such that

$$H'(p, t) = f(p) \quad \text{for } t \text{ in a neighborhood of } 0,$$

$$H'(p, t) = g(p) \quad \text{for } t \text{ in a neighborhood of } 1.$$

(b) \simeq is an equivalence relation.

26. If f is smoothly homotopic to g by a smooth homotopy H such that $p \mapsto H(p, t)$ is a diffeomorphism for each t , we say that f is **smoothly isotopic** to g .

(a) Being smoothly isotopic is an equivalence relation.

(b) Let $\phi: \mathbb{R}^n \rightarrow \mathbb{R}$ be a C^∞ function which is positive on the interior of the unit ball, and 0 elsewhere. For $p \in S^{n-1}$, let $H: \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ satisfy

$$\frac{\partial H(t, x)}{\partial t} = \phi(H(t, x)) \cdot p$$

$$H(0, x) = x.$$

(Each solution is defined for all t , by Theorem 5-6.) Show that each $x \mapsto H(t, x)$ is a diffeomorphism, which is smoothly isotopic to the identity, and leaves all points outside the unit ball fixed.

- (c) Show that by choosing suitable p and t we can make $H(t, 0)$ be any point in the interior of the unit ball.
- (d) If M is connected and $p, q \in M$, then there is a diffeomorphism $f: M \rightarrow M$ such that $f(p) = q$ and f is smoothly isotopic to the identity.
- (e) Use part (d) to give an alternate proof of *Step 3* of Theorem 9.
- (f) If M and N are compact n -manifolds, and $f: M \rightarrow N$, then for regular values $q_1, q_2 \in N$ we have

$$\#f^{-1}(q_1) \equiv \#f^{-1}(q_2) \pmod{2}$$

(where $\#f^{-1}(q)$ is defined in Problem 24). This number is called the mod 2 degree of f .

- (g) By replacing “degree” with “mod 2 degree” in Problem 23, show that if $M \subset \mathbb{R}^n$ is a compact $(n-1)$ -manifold, then $\mathbb{R}^n - M$ has at least 2 components.

27. Let $\{X^t\}$ be a C^∞ family of C^∞ vector fields on a compact manifold M . (To be more precise, suppose X is a C^∞ vector field on $M \times [0, 1]$; then $X^t(p)$ will denote $\pi_{M*} X_{(p,t)}$.) From the addendum to Chapter 5, and the argument which was used in the proof of Theorem 5-6, it follows that there is a C^∞ family $\{\phi_t\}$ of diffeomorphisms of M [not necessarily a 1-parameter group], with $\phi_0 = \text{identity}$, which is generated by $\{X^t\}$, i.e., for any C^∞ function $f: M \rightarrow \mathbb{R}$ we have

$$(X^t f)(p) = \lim_{h \rightarrow 0} \frac{f(\phi_{t+h}(p)) - f(\phi_t(p))}{h}.$$

For a family ω_t of k -forms on M we define the k -form

$$\dot{\omega}_t = \lim_{h \rightarrow 0} \frac{\omega_{t+h} - \omega_t}{h}.$$

- (a) Show that for $\eta(t) = \phi_t^* \omega_t$ we have

$$\dot{\eta}_t = \phi_t^*(L_{X^t} \omega_t + \dot{\omega}_t).$$

- (b) Let ω_0 and ω_1 be nowhere zero n -forms on a compact oriented n -manifold M , and define

$$\omega_t = (1-t)\omega_0 + t\omega_1.$$

Show that the family ϕ_t of diffeomorphisms generated by $\{X^t\}$ satisfies

$$\phi_t^* \omega_t = \omega_0 \quad \text{for all } t$$

if and only if

$$L_{X^t} \omega_t = \omega_0 - \omega_1.$$

(c) Using Problem 7-18, show that this holds if and only if

$$d(X^t \lrcorner \omega_t) = \omega_0 - \omega_1.$$

(d) Suppose that $\int_M \omega_0 = \int_M \omega_1$, so that $\omega_0 - \omega_1 = d\lambda$ for some λ . Show that there is a diffeomorphism $f_1: M \rightarrow M$ such that $\omega_0 = f_1^* \omega_1$.

28. Let $f: M^k \rightarrow \mathbb{R}^n$ and $g: N^l \rightarrow \mathbb{R}^n$ be C^∞ maps, where M and N are compact oriented manifolds, $n = k + l + 1$, and $f(M) \cap g(N) = \emptyset$. Define

$$\alpha_{f,g}: M \times N \rightarrow S^{n-1} \subset \mathbb{R}^n - \{0\}$$

by

$$\alpha_{f,g}(p, q) = r(g(q) - f(p)) = \frac{g(q) - f(p)}{|g(q) - f(p)|}.$$

We define the linking number of f and g to be

$$\ell(f, g) = \deg \alpha_{f,g},$$

where $M \times N$ is oriented as in Problem 18.

(a) $\ell(f, g) = (-1)^{kl+1} \ell(g, f)$.

(b) Let $H: M \times [0, 1] \rightarrow \mathbb{R}^n$ and $K: N \times [0, 1] \rightarrow \mathbb{R}^n$ be smooth homotopies with

$$\begin{aligned} H(p, 0) &= f(p) & K(q, 0) &= g(q) \\ H(p, 1) &= \tilde{f}(p) & K(q, 1) &= \tilde{g}(q) \end{aligned}$$

such that

$$\{H(p, t) : p \in M\} \cap \{K(q, t) : q \in N\} = \emptyset \quad \text{for every } t.$$

Show that

$$\ell(f, g) = \ell(\tilde{f}, \tilde{g}).$$

(c) For $f, g: S^1 \rightarrow \mathbb{R}^3$ show that

$$\ell(f, g) = \frac{-1}{4\pi} \int_0^1 \int_0^1 \frac{A(u, v)}{[r(u, v)]^3} du dv,$$

where

$$r(u, v) = |g(v) - f(u)|$$

$$A(u, v) = \det \begin{pmatrix} (f^1)'(u) & (f^2)'(u) & (f^3)'(u) \\ (g^1)'(v) & (g^2)'(v) & (g^3)'(v) \\ g^1(v) - f^1(u) & g^2(v) - f^2(u) & g^3(v) - f^3(u) \end{pmatrix}$$

(the factor $1/4\pi$ comes from the fact that $\int_{S^2} \sigma' = 4\pi$ [Problem 9-14]).

(d) Show that $\ell(f, g) = 0$ if f and g both lie in the same plane (first do it for (x, y) -plane). The next problem shows how to determine $\ell(f, g)$ without calculating.

29. (a) For $(a, b, c) \in \mathbb{R}^3$ define

$$d\Theta_{(a,b,c)} = \frac{(x-a)dy \wedge dz - (y-b)dx \wedge dz + (z-c)dx \wedge dy}{[(x-a)^2 + (y-b)^2 + (z-c)^2]^{3/2}}.$$

For a compact oriented 2-manifold-with-boundary $M \subset \mathbb{R}^3$ and $(a, b, c) \notin M$, let

$$\Omega(a, b, c) = \int_M d\Theta_{(a,b,c)}.$$

Let (a, b, c) and (a', b', c') be points close to $p \in M$, on opposite sides of M . Suppose (a, b, c) is on the same side as a vector $w_p \in \mathbb{R}^3_p - M_p$ for which the

triple $w_p, (v_1)_p, (v_2)_p$ is positively oriented in \mathbb{R}^3_p when $(v_1)_p, (v_2)_p$ is positively oriented in M_p . Show that

$$\lim_{\substack{(a,b,c) \rightarrow p \\ (a',b',c') \rightarrow p}} \Omega(a, b, c) - \Omega(a', b', c') = -4\pi.$$

Hint: First show that if $M = \partial N$, then $\Omega(a, b, c) = -4\pi$ for $(a, b, c) \in N - M$ and $\Omega(a, b, c) = 0$ for $(a, b, c) \notin N$.

(b) Let $f: S^1 \rightarrow \mathbb{R}^3$ be an imbedding such that $f(S^1) = \partial M$ for some compact oriented 2-manifold-with-boundary M . (An M with this property always exists. See Fort, *Topology of 3-Manifolds*, pg. 138.) Let $g: S^1 \rightarrow \mathbb{R}^3$ and suppose

The figure on the left shows a *non-orientable* surface whose boundary is the “trefoil” knot,

but the surface on the right—including the hemisphere behind the plane of the paper—is orientable.

that when $g(t) = p \in M$ we have $dg/dt \notin M_p$. Let n^+ be the number of intersections where dg/dt points in the same direction as the vector w_p of part (a), and n^- the number of other intersections. Show that

$$n = n^+ - n^- = \frac{-1}{4\pi} \int_{S^1} g^*(d\Omega).$$

(c) Show that

$$\begin{aligned} \frac{\partial \Omega}{\partial a}(a, b, c) &= \int_{S^1} f^* \left(\frac{(y-b) dz - (z-c) dy}{|(x, y, z)|^3} \right) \\ \frac{\partial \Omega}{\partial b}(a, b, c) &= \int_{S^1} f^* \left(\frac{(z-c) dx - (x-a) dz}{|(x, y, z)|^3} \right) \\ \frac{\partial \Omega}{\partial c}(a, b, c) &= \int_{S^1} f^* \left(\frac{(x-a) dy - (y-b) dx}{|(x, y, z)|^3} \right). \end{aligned}$$

(d) Show that $n = \ell(f, g)$. Compute $\ell(f, g)$ for the pairs shown below.

30. (a) Let $p, q \in \mathbb{R}^n$ be distinct. Choose open sets $A, B \subset \mathbb{R}^n - \{p, q\}$ so that A and B are diffeomorphic to $\mathbb{R}^n - \{0\}$, and $A \cap B$ is diffeomorphic to \mathbb{R}^n . Using an argument similar to that in the proof of Theorem 16, show that

$H^k(\mathbb{R}^n - \{p, q\}) = 0$ for $0 < k < n - 1$, and that $H^{n-1}(\mathbb{R}^n - \{p, q\})$ has dimension 2.

(b) Find the de Rham cohomology vector spaces of $\mathbb{R}^n - F$ where $F \subset \mathbb{R}^n$ is a finite set.

31. We define the cup product $\cup: H^k(M) \times H^l(M) \rightarrow H^{k+l}(M)$ by

$$[\omega] \cup [\eta] = [\omega \wedge \eta].$$

(a) Show that \cup is well-defined, i.e., $\omega \wedge \eta$ is exact if ω is exact and η is closed.

(b) Show that \cup is bilinear.

(c) If $\alpha \in H^k(M)$ and $\beta \in H^l(M)$, then $\alpha \cup \beta = (-1)^{kl} \beta \cup \alpha$.

(d) If $f: M \rightarrow N$, and $\alpha \in H^k(N)$, $\beta \in H^l(N)$, then

$$f^*(\alpha \cup \beta) = f^*\alpha \cup f^*\beta.$$

(e) The cross-product $\times: H^k(M) \times H^l(N) \rightarrow H^{k+l}(M \times N)$ is defined by

$$[\omega] \times [\eta] = [\pi_M^*\omega \wedge \pi_N^*\eta].$$

Show that \times is well-defined, and that

$$\alpha \times \beta = \pi_M^*\alpha \cup \pi_N^*\beta.$$

(f) If $\Delta: M \rightarrow M \times M$ is the “diagonal map”, given by $\Delta(p) = (p, p)$, show that

$$\alpha \cup \beta = \Delta^*(\alpha \times \beta).$$

32. On the n -dimensional torus

$$T^n = \underbrace{S^1 \times \cdots \times S^1}_{n \text{ times}}$$

let $d\theta^i$ denote $\pi_i^*d\theta$, where $\pi_i: T^n \rightarrow S^1$ is projection on the i^{th} factor.

(a) Show that all $d\theta^{i_1} \wedge \cdots \wedge d\theta^{i_k}$ represent different elements of $H^k(T^n)$, by finding submanifolds of T^n over which they have different integrals. Hence $\dim H^k(T^n) \geq \binom{n}{k}$. Equality is proved in the Problems for Chapter 11.

(b) Show that every map $f: S^n \rightarrow T^n$ has degree 0. *Hint:* Use Problem 25.

CHAPTER 9

RIEMANNIAN METRICS

In previous chapters we have exploited nearly every construction associated with vector spaces, and thus with bundles, but there has been one notable exception—we have never mentioned inner products. The time has now come to make use of this neglected tool.

An **inner product** on a vector space V over a field F is a bilinear function from $V \times V$ to F , denoted by $(v, w) \mapsto (v, w)$, which is **symmetric**,

$$(v, w) = (w, v),$$

and **non-degenerate**: if $v \neq 0$, then there is some $w \neq 0$ such that

$$(w, v) \neq 0.$$

For us, the field F will always be \mathbb{R} .

For each r with $0 \leq r \leq n$, we can define an inner product $(\ , \)_r$ on \mathbb{R}^n by

$$(a, b)_r = \sum_{i=1}^r a^i b^i - \sum_{i=r+1}^n a^i b^i;$$

this is non-degenerate because if $a \neq 0$, then

$$\langle (a^1, \dots, a^n), (a^1, \dots, a^r, -a^{r+1}, \dots, -a^n) \rangle_r = \sum_{i=1}^n (a^i)^2 > 0.$$

In particular, for $r = n$ we obtain the “usual inner product”, $\langle \ , \ \rangle$ on \mathbb{R}^n ,

$$\langle a, b \rangle = \sum_{i=1}^n a^i b^i.$$

For this inner product we have $\langle a, a \rangle > 0$ for any $a \neq 0$. In general, a symmetric bilinear function $(\ , \)$ is called **positive definite** if

$$(v, v) > 0 \quad \text{for all } v \neq 0.$$

A positive definite bilinear function $(\ , \)$ is clearly non-degenerate, and consequently an inner product.

Notice that an inner product $(\ , \)$ on V is an element of $\mathcal{T}^2(V)$, so if $f: W \rightarrow V$ is a linear transformation, then $f^*(\ , \)$ is a symmetric bilinear function on W . This symmetric bilinear function may be degenerate even if f is one-one, e.g., if $(\ , \)$ is defined on \mathbb{R}^2 by

$$(a, b) = a^1 b^1 - a^2 b^2,$$

and $f: \mathbb{R} \rightarrow \mathbb{R}^2$ is

$$f(a) = (a, a).$$

However, $f^*(\ , \)$ is clearly non-degenerate if f is an isomorphism *onto* V . Also, if $(\ , \)$ is positive definite, then $f^*(\ , \)$ is positive definite if and only if f is one-one.

For any basis v_1, \dots, v_n of V , with corresponding dual basis v^*_1, \dots, v^*_n , we can write

$$(\ , \) = \sum_{i,j=1}^n g_{ij} v^*_i \otimes v^*_j.$$

In this expression,

$$g_{ij} = (v_i, v_j),$$

so symmetry of $(\ , \)$ implies that the matrix $\langle g_{ij} \rangle$ is symmetric,

$$g_{ij} = g_{ji}.$$

The matrix $\langle g_{ij} \rangle$ has another important interpretation. Since an inner product $(\ , \)$ is linear in the second argument, we can define a linear functional $\phi_v \in V^*$, for each $v \in V$, by

$$\phi_v(w) = (v, w).$$

Since $(\ , \)$ is linear in the first argument, the map $v \mapsto \phi_v$ is a linear transformation from V to V^* . Non-degeneracy of $(\ , \)$ implies that $\phi_v \neq 0$ if $v \neq 0$. Thus, if V is finite dimensional, an inner product $(\ , \)$ gives us an isomorphism $\alpha: V \rightarrow V^*$, with

$$(v, w) = \alpha(v)(w).$$

Clearly, the matrix $\langle g_{ij} \rangle$ is just the matrix of $\alpha: V \rightarrow V^*$ with respect to the bases $\{v_i\}$ for V and $\{v^*_i\}$ for V^* . Thus, non-degeneracy of $(\ , \)$ is equivalent to the condition that

$$\langle g_{ij} \rangle \text{ is non-singular, } \det(g_{ij}) \neq 0.$$

Positive definiteness of $(\ , \)$ corresponds to the more complicated condition that the matrix $\langle g_{ij} \rangle$ be “positive definite”, meaning that

$$\sum_{i=1}^n g_{ij} a^i a^j > 0 \quad \text{for all } a_1, \dots, a_n \text{ with at least one } a^i \neq 0.$$

Given any *positive definite* inner product $\langle \cdot, \cdot \rangle$ on V we define the associated norm $\| \cdot \|$ by

$$\|v\| = \sqrt{\langle v, v \rangle} \quad (\text{the positive square root is to be taken}).$$

In \mathbb{R}^n we denote the norm corresponding to $\langle \cdot, \cdot \rangle$ simply by

$$|a| = \sqrt{\langle a, a \rangle} = \sqrt{\sum_{i=1}^n (a^i)^2}.$$

The principal properties of $\| \cdot \|$ are the following

1. THEOREM. For all $v, w \in V$ we have

- (1) $\|av\| = |a| \cdot \|v\|$.
- (2) $|\langle v, w \rangle| \leq \|v\| \cdot \|w\|$, with equality if and only if v and w are linearly dependent (Schwarz inequality).
- (3) $\|v + w\| \leq \|v\| + \|w\|$ (Triangle inequality).

PROOF. (1) is trivial.

(2) If v and w are linearly dependent, equality clearly holds. If not, then $0 \neq \lambda v - w$ for all $\lambda \in \mathbb{R}$, so

$$\begin{aligned} 0 < \|\lambda v - w\|^2 &= \langle \lambda v - w, \lambda v - w \rangle \\ &= \lambda^2 \|v\|^2 - 2\lambda \langle v, w \rangle + \|w\|^2. \end{aligned}$$

So the right side is a quadratic equation in λ with no real solution, and its discriminant must be negative. Thus

$$4\langle v, w \rangle^2 - 4\|v\|^2\|w\|^2 < 0.$$

$$\begin{aligned} (3) \quad \|v + w\|^2 &= \langle v + w, v + w \rangle \\ &= \|v\|^2 + \|w\|^2 + 2\langle v, w \rangle \\ &\leq \|v\|^2 + \|w\|^2 + 2\|v\| \cdot \|w\| \quad \text{by (2)} \\ &= (\|v\| + \|w\|)^2. \quad \spadesuit \end{aligned}$$

The function $\| \cdot \|$ has certain unpleasant properties—for example, the function $| \cdot |$ on \mathbb{R}^n is not differentiable at $0 \in \mathbb{R}^n$ —which do not arise for the function $\| \cdot \|^2$. This latter function is a “quadratic function” on V —in terms of a basis $\{v_i\}$ for V it can be written as a “homogeneous polynomial of degree 2” in the components,

$$\left\| \sum_{i=1}^n a^i v^i \right\|^2 = \sum_{i,j=1}^n g_{ij} a^i a^j.$$

More succinctly,

$$\| \|^2 = \sum_{i,j=1}^n g_{ij} v_i^* \cdot v_j^*.$$

An invariant definition of a quadratic function can be obtained (Problem 1) from the following observation.

2. THEOREM (POLARIZATION IDENTITY). If $\| \cdot \|$ is the norm associated to an inner product $\langle \cdot, \cdot \rangle$ on V , then

$$(1) \quad \langle v, w \rangle = \frac{1}{2} [\|v + w\|^2 - \|v\|^2 - \|w\|^2]$$

$$(2) \quad \langle v, w \rangle = \frac{1}{4} [\|v + w\|^2 - \|v - w\|^2].$$

PROOF. Compute. ♦

Theorem 2 shows that two inner products which induce the same norm are themselves equal. Similarly, if $f: V \rightarrow V$ is norm preserving, that is, $\|f(v)\| = \|v\|$ for all $v \in V$, then f is also inner product preserving, that is, $\langle f(v), f(w) \rangle = \langle v, w \rangle$ for all $v, w \in V$.

We will now see that, “up to isomorphism”, there is only one positive definite inner product.

3. THEOREM. If $\langle \cdot, \cdot \rangle$ is a positive definite inner product on an n -dimensional vector space V , then there is a basis v_1, \dots, v_n for V such that $\langle v_i, v_j \rangle = \delta_{ij}$. (Such a basis is called **orthonormal** with respect to $\langle \cdot, \cdot \rangle$.) Consequently, there is an isomorphism $f: \mathbb{R}^n \rightarrow V$ such that

$$\langle a, b \rangle = \langle f(a), f(b) \rangle, \quad a, b \in \mathbb{R}^n.$$

In other words,

$$f^* \langle \cdot, \cdot \rangle = \langle \cdot, \cdot \rangle.$$

PROOF. Let w_1, \dots, w_n be any basis for V . We obtain the desired basis by applying the “Gram-Schmidt orthonormalization process” to this basis:

Since $w_1 \neq 0$, we can define

$$v_1 = \frac{w_1}{\|w_1\|},$$

and clearly $\|v_1\| = 1$. Suppose that we have constructed v_1, \dots, v_k so that

$$\langle v_i, v_j \rangle = \delta_{ij} \quad 1 \leq i, j \leq k$$

and

$$\text{span } v_1, \dots, v_k = \text{span } w_1, \dots, w_k.$$

Then w_{k+1} is linearly independent of v_1, \dots, v_k . Let

$$w'_{k+1} = w_{k+1} - \langle v_1, w_{k+1} \rangle v_1 - \dots - \langle v_k, w_{k+1} \rangle v_k \neq 0.$$

It is easy to see that

$$\langle w'_{k+1}, v_i \rangle = 0 \quad i = 1, \dots, k.$$

So we can define

$$v_{k+1} = \frac{w'_{k+1}}{\|w'_{k+1}\|},$$

and continue inductively. ♦

A positive definite inner product $\langle \cdot, \cdot \rangle$ on V is sometimes called a *Euclidean metric* on V . This is because we obtain a metric ρ on V by defining

$$\rho(v, w) = \|v - w\|.$$

The “triangle inequality” (Theorem 1(3)) shows that this is indeed a metric. We also call $\|v\|$ the **length** of v .

We have only one more algebraic trick to play. Recall that an inner product $\langle \cdot, \cdot \rangle$ on V provides an isomorphism $\alpha: V \rightarrow V^*$ with

$$\alpha(v)(w) = \langle v, w \rangle.$$

Using the natural isomorphism $i: V \rightarrow V^{**}$, defined by

$$i(v)(\lambda) = \lambda(v),$$

we obtain an isomorphism

$$\beta: V^* \xrightarrow{\alpha^{-1}} V \xrightarrow{i} (V^*)^*.$$

We can now use β to define a bilinear function $\langle \cdot, \cdot \rangle^*$ on V^* by

$$\langle \lambda, \mu \rangle^* = \beta(\lambda)(\mu) = i\alpha^{-1}(\lambda)(\mu) = \mu(\alpha^{-1}(\lambda)).$$

Now, the symmetry of $\langle \cdot, \cdot \rangle$ can be expressed by the equation

$$\alpha(v)(w) = \alpha(w)(v).$$

Letting

$$\alpha(v) = \lambda, \quad \alpha(w) = \mu,$$

this can be written

$$\lambda(\alpha^{-1}(\mu)) = \mu(\alpha^{-1}(\lambda)),$$

which shows that $\langle \cdot, \cdot \rangle^*$ is also symmetric,

$$(\mu, \lambda)^* = (\lambda, \mu)^*.$$

Consequently $\langle \cdot, \cdot \rangle^*$ is an inner product on the dual space V^* (in fact, the one which produces β).

To see what this all means, choose a basis $\{v_i\}$ for V , let $\{v_i^*\}$ be the dual basis for V^* , and let

$$\langle \cdot, \cdot \rangle = \sum_{i,j=1}^n g_{ij} v_i^* \otimes v_j^*.$$

Then

(g_{ij}) is the matrix of $\alpha: V \rightarrow V^*$ with respect to $\{v_i\}$ and $\{v_i^*\}$

so

$(g_{ij})^{-1}$ is the matrix of $\alpha^{-1}: V^* \rightarrow V$ with respect to $\{v_i^*\}$ and $\{v_i\}$

so

$(g_{ij})^{-1}$ is the matrix of $\beta: V^* \rightarrow V^{**}$ with respect to $\{v_i^*\}$ and $\{v_i^{**}\}$.

Thus, if we let g^{ij} be the entries of the inverse matrix, $(g^{ij}) = (g_{ij})^{-1}$, so that

$$\sum_{k=1}^n g^{ik} g_{kj} = \delta_j^i,$$

then

$$\begin{aligned} \langle \cdot, \cdot \rangle^* &= \sum_{i,j=1}^n g^{ij} v_i^{**} \otimes v_j^{**} \\ &= \sum_{i,j=1}^n g^{ij} v_i \otimes v_j, \quad \text{if we consider } v_i \in V^{**}. \end{aligned}$$

One can check directly (Problem 9), without the invariant definition, that this equation defines $\langle \cdot, \cdot \rangle^*$ independently of the choice of basis.

Notice that if (\cdot, \cdot) is positive definite, so that

$$\alpha(v)(v) > 0 \quad \text{for } v \neq 0,$$

then, letting $\alpha(v) = \lambda$, we have

$$\lambda(\alpha^{-1}(\lambda)) = \beta(\lambda)(\lambda) > 0 \quad \text{for } \lambda \neq 0,$$

so $(\cdot, \cdot)^*$ is also positive definite. This can also be checked directly from the definition in terms of a basis. In the positive definite case, the simplest way to describe $(\cdot, \cdot)^*$ is as follows: The basis v_1^*, \dots, v_n^* of V^* is orthonormal with respect to $(\cdot, \cdot)^*$ if and only if v_1, \dots, v_n is orthonormal with respect to (\cdot, \cdot) .

Similar tricks can be used (Problem 4) to produce an inner product on all the vector spaces $\mathcal{T}^k(V)$, $\mathcal{T}_k(V) = \mathcal{T}^k(V^*)$, and $\Omega^k(V)$. However, we are interested in only one case, which we will not describe in a completely invariant way. The vector space $\Omega^n(V)$ is 1-dimensional, so to produce an inner product on it, we need only describe which two elements, ω and $-\omega$, will have length 1. Let v_1, \dots, v_n and w_1, \dots, w_n be two bases of V which are orthonormal with respect to (\cdot, \cdot) . If we write

$$w_i = \sum_{j=1}^n \alpha_{ji} v_j,$$

then

$$\begin{aligned} \delta_{ij} = \langle w_i, w_j \rangle &= \left\langle \sum_{k=1}^n \alpha_{ki} v_k, \sum_{l=1}^n \alpha_{lj} v_l \right\rangle = \sum_{k,l=1}^n \alpha_{ki} \alpha_{lj} \langle v_k, v_l \rangle \\ &= \sum_{k=1}^n \alpha_{ki} \alpha_{kj}. \end{aligned}$$

So the transpose matrix A^t of $A = (\alpha_{ij})$ satisfies $A \cdot A^t = I$, which implies that $\det A = \pm 1$. It follows from Theorem 7-5 that for any $\omega \in \Omega^n(V)$ we have

$$\omega(v_1, \dots, v_n) = \pm \omega(w_1, \dots, w_n).$$

It clearly follows that

$$v_1^* \wedge \dots \wedge v_n^* = \pm w_1^* \wedge \dots \wedge w_n^*.$$

We have thus distinguished two elements of $\Omega^n(V)$; they are both of the form $v_1^* \wedge \dots \wedge v_n^*$ for $\{v_i\}$ an orthonormal basis of V . We will call these two elements

the elements of norm 1 in $\Omega^n(V)$. If we also have an orientation μ , then we can further distinguish the one which is positive when applied to any (v_1, \dots, v_n) with $[v_1, \dots, v_n] = \mu$; we will call it the **positive element of norm 1** in $\Omega^n(V)$.

To express the elements of norm 1 in terms of an arbitrary basis w_1, \dots, w_n , we choose an orthonormal basis v_1, \dots, v_n and write

$$w_i = \sum_{j=1}^n \alpha_{ji} v_j.$$

Problem 7-9 implies that

$$\det(\alpha_{ij}) w^*_1 \wedge \cdots \wedge w^*_n = v^*_1 \wedge \cdots \wedge v^*_n.$$

If we write

$$\langle \cdot, \cdot \rangle = \sum_{i,j=1}^n g_{ij} w^*_i \otimes w^*_j,$$

then

$$\begin{aligned} g_{ij} = \langle w_i, w_j \rangle &= \left\langle \sum_{k=1}^n \alpha_{ki} v_k, \sum_{l=1}^n \alpha_{lj} v_l \right\rangle \\ &= \sum_{k=1}^n \alpha_{ki} \alpha_{kj}, \end{aligned}$$

so if $A = (\alpha_{ij})$, then

$$\det(g_{ij}) = \det(A^t \cdot A) = (\det A)^2.$$

In particular, $\det(g_{ij})$ is always positive. Consequently, the elements of norm 1 in $\Omega^n(V)$ are

$$\pm \sqrt{\det(g_{ij})} w^*_1 \wedge \cdots \wedge w^*_n \quad g_{ij} = (w_i, w_j).$$

We now apply our new tool to vector bundles. If $\xi = \pi: E \rightarrow B$ is a vector bundle, we define a **Riemannian metric** on ξ to be a function $\langle \cdot, \cdot \rangle$ which assigns to each $p \in B$ a positive definite inner product $\langle \cdot, \cdot \rangle_p$ on $\pi^{-1}(p)$, and which is continuous in the sense that for any two continuous sections $s_1, s_2: B \rightarrow E$, the function

$$\langle s_1, s_2 \rangle = p \mapsto \langle s_1(p), s_2(p) \rangle_p$$

is also continuous. If ξ is a C^∞ vector bundle over a C^∞ manifold we can also speak of C^∞ Riemannian metrics.

[Another approach to the definition can be given. Let $Euc(V)$ be the set of all positive definite inner products on V . If we replace each $\pi^{-1}(p)$ by $Euc(\pi^{-1}(p))$, and let

$$Euc(\xi) = \bigcup_{p \in B} Euc(\pi^{-1}(p)),$$

then a Riemannian metric on ξ can be defined to be a section of $Euc(\xi)$. The only problem is that $Euc(V)$ is not a vector space; the new object $Euc(\xi)$ that we obtain is not a vector bundle at all, but an instance of a more general structure, a fibre bundle.]

4. THEOREM. Let $\xi = \pi: E \rightarrow M$ be a $[C^\infty]$ k -plane bundle over a C^∞ manifold M . Then there is a $[C^\infty]$ Riemannian metric on ξ .

PROOF. There is an open locally finite cover \mathcal{O} of M by sets U for which there exists $[C^\infty]$ trivializations

$$t_U: \pi^{-1}(U) \rightarrow U \times \mathbb{R}^k.$$

On $U \times \mathbb{R}^k$, there is an obvious Riemannian metric,

$$\langle (p, a), (p, b) \rangle_p = \langle a, b \rangle.$$

For $v, w \in \pi^{-1}(p)$, define

$$\langle v, w \rangle_p^U = \langle t_U(v), t_U(w) \rangle_p.$$

Then $\langle \cdot, \cdot \rangle^U$ is a $[C^\infty]$ Riemannian metric for $\xi|U$. Let $\{\phi_U\}$ be a partition of unity subordinate to \mathcal{O} . We define $\langle \cdot, \cdot \rangle$ by

$$\langle v, w \rangle_p = \sum_{U \in \mathcal{O}} \phi_U(p) \langle v, w \rangle_p^U \quad v, w \in \pi^{-1}(p).$$

Then $\langle \cdot, \cdot \rangle$ is continuous $[C^\infty]$ and each $\langle \cdot, \cdot \rangle_p$ is a symmetric bilinear function on $\pi^{-1}(p)$. To show that it is positive definite, note that

$$\langle v, v \rangle_p = \sum_{U \in \mathcal{O}} \phi_U(p) \langle v, v \rangle_p^U;$$

each $\phi_U(p) \langle v, v \rangle_p^U \geq 0$, and for some U strict inequality holds. ♦

[The same argument shows that any vector bundle over a paracompact space has a Riemannian metric.]

Notice that the argument in the final step would not work if we had merely picked non-degenerate inner products $\langle \cdot, \cdot \rangle^U$. In fact (Problem 7), there is no $\langle \cdot, \cdot \rangle$ on TS^2 which gives a symmetric bilinear function on each S^2_p which is not positive definite or negative definite but is still non-degenerate.

As an application of Theorem 4, we settle some questions which have till now remained unanswered.

5. COROLLARY. If $\xi = \pi : E \rightarrow M$ is a k -plane bundle, then $\xi \simeq \xi^*$.

PROOF. Let $\langle \cdot, \cdot \rangle$ be a Riemannian metric for ξ . Then for each $p \in M$, we have an isomorphism

$$\alpha_p : \pi^{-1}(p) \rightarrow [\pi^{-1}(p)]^*$$

defined by

$$\alpha_p(v)(w) = \langle v, w \rangle_p \quad v, w \in \pi^{-1}(p).$$

Continuity of $\langle \cdot, \cdot \rangle$ implies that the union of all α_p is a homeomorphism from E to $E' = \bigcup_{p \in M} [\pi^{-1}(p)]^*$. ♦

6. COROLLARY. If $\xi = \pi : E \rightarrow M$ is a 1-plane bundle, then ξ is trivial if and only if ξ is orientable.

PROOF. The “only if” part is trivial. If ξ has an orientation μ and $\langle \cdot, \cdot \rangle$ is a Riemannian metric on M then there is a unique

$$s(p) \in \pi^{-1}(p)$$

with

$$\langle s(p), s(p) \rangle_p = 1, \quad [s(p)] = \mu_p.$$

Clearly s is a section; we then define an equivalence $f : E \rightarrow M \times \mathbb{R}$ by

$$f(\lambda s(p)) = (p, \lambda).$$

ALTERNATIVE PROOF. We know (see the discussion after Theorem 7-9) that if ξ is orientable, then there is a nowhere 0 section of

$$\Omega^1(\xi) = \xi^*,$$

so that ξ^* is trivial. But $\xi \simeq \xi^*$. ♦

All these considerations take on special significance when our bundle is the tangent bundle TM of a C^∞ manifold M . In this case, a C^∞ Riemannian metric $\langle \cdot, \cdot \rangle$ for TM , which gives a positive definite inner product $\langle \cdot, \cdot \rangle_p$ on

each M_p , is called a **Riemannian metric on M** . If (x, U) is a coordinate system on M , then on U we can write our Riemannian metric $\langle \cdot, \cdot \rangle$ as

$$\langle \cdot, \cdot \rangle = \sum_{i,j=1}^n g_{ij} dx^i \otimes dx^j,$$

where the C^∞ functions g_{ij} satisfy $g_{ij} = g_{ji}$, since $\langle \cdot, \cdot \rangle$ is symmetric, and $\det(g_{ij}) > 0$ since $\langle \cdot, \cdot \rangle$ is positive definite. A Riemannian metric $\langle \cdot, \cdot \rangle$ on M is, of course, a covariant tensor of order 2. So for every C^∞ map $f: N \rightarrow M$ there is a covariant tensor $f^*\langle \cdot, \cdot \rangle$ on N , which is clearly symmetric; it is a Riemannian metric on N if and only if f is an immersion (f_{*p} is one-one for all $p \in N$).

The Riemannian metric $\langle \cdot, \cdot \rangle^*$, which $\langle \cdot, \cdot \rangle$ induces on the dual bundle T^*M , is a contravariant tensor of order 2, and we can write it as

$$\langle \cdot, \cdot \rangle^* = \sum_{i,j=1}^n g^{ij} \frac{\partial}{\partial x^i} \otimes \frac{\partial}{\partial x^j}.$$

Our discussion of inner products induced on V^* shows that for each p , the matrix $(g^{ij}(p))$ is the inverse of the matrix $(g_{ij}(p))$; thus

$$\sum_{k=1}^n g_{ik} g^{kj} = \delta_i^j.$$

Similarly, for each $p \in M$ the Riemannian metric $\langle \cdot, \cdot \rangle$ on M determines two elements of $\Omega^n(M_p)$, the elements of norm 1. We have seen that they can be written

$$\pm \sqrt{\det(g_{ij}(p))} dx^1(p) \wedge \cdots \wedge dx^n(p).$$

If M has an orientation μ , then μ_p allows us to pick out the positive element of norm 1, and we obtain an n -form on M ; if $x: U \rightarrow \mathbb{R}^n$ is *orientation preserving*, then on U this form can be written

$$\sqrt{\det(g_{ij})} dx^1 \wedge \cdots \wedge dx^n.$$

Even if M is not orientable, we obtain a “volume element” on M , as defined in Chapter 8; in a coordinate system (x, U) it can be written as

$$\sqrt{\det(g_{ij})} |dx^1 \wedge \cdots \wedge dx^n|.$$

This volume element is denoted by dV , even though it is usually not d of anything (even when M is orientable and it can be considered to be an n -form),

and is called the volume element determined by (\cdot, \cdot) . We can then define the volume of M as

$$\int_M dV.$$

This certainly makes sense if M is compact, and in the non-compact case (see Problem 8-10) it either converges to a definite number, or becomes arbitrarily large over compact subsets of M , in which case we say that M has “infinite volume”.

If M is an n -dimensional manifold (-with-boundary) in \mathbb{R}^n , with the “usual Riemannian metric”

$$(\cdot, \cdot) = \sum_{i=1}^n dx^i \otimes dx^i,$$

then $g_{ij} = \delta_{ij}$, so

$$dV = |dx^1 \wedge \cdots \wedge dx^n|,$$

and “volume” becomes ordinary volume.

There is an even more important construction associated with a Riemannian metric on M , which will occupy us for the rest of the chapter. For every C^∞ curve $\gamma: [a, b] \rightarrow M$, we have tangent vectors

$$\gamma'(t) = \frac{d\gamma}{dt} \in M_{\gamma(t)},$$

and can therefore use (\cdot, \cdot) to define their length

$$\left\| \frac{d\gamma}{dt} \right\| = \sqrt{\left\langle \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle} \quad \left(= \sqrt{\left\langle \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle_{\gamma(t)}}, \text{ to be precise} \right).$$

We can then define the length of γ from a to b ,

$$L_a^b(\gamma) = \int_a^b \left\| \frac{d\gamma}{dt} \right\| dt \quad \left(= \int_a^b \|\gamma'(t)\| dt \right).$$

If γ is merely *piecewise smooth*, meaning that there is a partition $a = t_0 < \cdots < t_n = b$ of $[a, b]$ such that γ is smooth on each $[t_{i-1}, t_i]$ (with possibly different

left- and right-hand derivatives at t_1, \dots, t_{n-1}), we can define the **length** of γ by

$$L_a^b(\gamma) = \sum_{i=1}^n L_{t_{i-1}}^{t_i}(\gamma|_{[t_{i-1}, t_i]}).$$

Whenever there is no possibility of misunderstanding we will denote L_a^b simply by L . A little argument shows (Problem 15) that for piecewise smooth curves in \mathbb{R}^n , with the usual Riemannian metric

$$\sum_{i=1}^n dx^i \otimes dx^i,$$

this definition agrees with the definition of length as the least upper bound of the lengths of inscribed polygonal curves.

We can also define a function $s: [a, b] \rightarrow \mathbb{R}$, the “arclength function of γ ” by

$$s(t) = L_a^t(\gamma) = \int_a^t \left\| \frac{d\gamma}{dt} \right\| dt.$$

Naturally,

$$(*) \quad s'(t) = \left\| \frac{d\gamma}{dt} \right\|.$$

Consequently $d\gamma/dt$ has constant length 1 precisely when $s(t) = t + \text{constant}$, thus precisely when $s(t) = t - a$. Then

$$b - a = s(b) = L_a^b(\gamma).$$

We can reparameterize γ to be a curve on $[0, b - a]$ by defining

$$\tilde{\gamma}(t) = \gamma(t - a).$$

For the new curve $\tilde{\gamma}$ we have

$$\begin{aligned} \text{new } s(t) &= L_0^t(\tilde{\gamma}) = L_a^{t+a}(\gamma) = \text{old } s(t + a) - \text{old } s(a) \\ &= t. \end{aligned}$$

If γ satisfies $s(t) = t$ we say that γ is **parameterized by arclength** (and then often use s instead of t to denote the argument in the domain of γ).

Classically, the norm $\| \cdot \|$ on M was denoted by ds . (This makes some sort of sense even in modern notation; equation $(*)$ says that for each curve γ and corresponding $s: [a, b] \rightarrow \mathbb{R}$ we have

$$|ds| = \gamma^*(\| \cdot \|)$$

on $[a, b]$.) Consequently, in classical books one usually sees the equation

$$ds^2 = \sum_{i,j=1}^n g_{ij} dx^i dx^j.$$

Nowadays, this is sometimes interpreted as being the equivalent of the modern equation $(\cdot, \cdot) = \sum_{i,j=1}^n g_{ij} dx^i \otimes dx^j$, but what it always actually meant was

$$\| \cdot \|^2 = \sum_{i,j=1}^n g_{ij} dx^i dx^j.$$

The symbol $dx^i dx^j$ appearing here is *not* a classical substitute for $dx^i \otimes dx^j$ — the value $(dx^i dx^j)(p)$ of $dx^i dx^j$ at p should not be interpreted as a bilinear function at all, but as the quadratic function

$$v \mapsto dx^i(p)(v) \cdot dx^j(p)(v) \quad v \in M_p,$$

and we would use the same symbol today. The classical way of indicating $dx^i \otimes dx^j$ was very strange: one wrote

$$\sum_{i,j=1}^n g_{ij} dx^i \delta x^j \quad \text{where } dx \text{ and } \delta x \text{ are independent infinitesimals.}$$

(Classically, the Riemannian metric was not a function on tangent vectors, but the inner product of two “infinitely small displacements” dx and δx .)

Consider now a Riemannian metric (\cdot, \cdot) on a *connected* manifold M . If $p, q \in M$ are any two points, then there is at least one piecewise smooth curve $\gamma: [a, b] \rightarrow M$ from p to q (there is even a smooth curve from p to q). Define

$$d(p, q) = \inf \{ L(\gamma) : \gamma \text{ a piecewise smooth curve from } p \text{ to } q \}.$$

It is clear that $d(p, q) \geq 0$ and $d(p, p) = 0$. Moreover, if $r \in M$ is a third point, then for any $\varepsilon > 0$, we can choose piecewise smooth curves

$$\gamma_1: [a, b] \rightarrow M \text{ from } p \text{ to } q \text{ with } L(\gamma_1) - d(p, q) < \varepsilon$$

$$\gamma_2: [b, c] \rightarrow M \text{ from } q \text{ to } r \text{ with } L(\gamma_2) - d(q, r) < \varepsilon.$$

If we define $\gamma: [a, c] \rightarrow M$ to be γ_1 on $[a, b]$ and γ_2 on $[b, c]$, then γ is a piecewise smooth curve from p to r and

$$L(\gamma) = L(\gamma_1) + L(\gamma_2) < d(p, q) + d(q, r) + 2\varepsilon.$$

Since this is true for all $\varepsilon > 0$, it follows that

$$d(p, r) \leq d(p, q) + d(q, r).$$

[If we did not allow piecewise smooth curves, there would be difficulties in fitting together γ_1 and γ_2 , but d would still turn out to be the same (Problem 17).] The function $d: M \times M \rightarrow \mathbb{R}$ has all properties for a metric, except that it is not so clear that $d(p, q) > 0$ for $p \neq q$. This is made clear in the following.

7. THEOREM. The function $d: M \times M \rightarrow \mathbb{R}$ is a metric on M , and if $\rho: M \times M \rightarrow \mathbb{R}$ is the original metric on M (which makes M a manifold), then (M, d) is homeomorphic to (M, ρ) .

PROOF. Both parts of the theorem are obviously consequences of the following

7'. LEMMA. Let U be an open neighborhood of the closed ball $B = \{p \in \mathbb{R}^n : |p| \leq 1\}$, let $\langle \cdot, \cdot \rangle_e$ be the "Euclidean" or usual Riemannian metric on U ,

$$\langle \cdot, \cdot \rangle_e = \sum_{i=1}^n dx^i \otimes dx^i,$$

and let $\langle \cdot, \cdot \rangle$ be any other Riemannian metric. Let $|\cdot| = \|\cdot\|_e$ and $\|\cdot\|$ be the corresponding norms. Then there are numbers $m, M > 0$ such that

$$m \cdot |\cdot| \leq \|\cdot\| \leq M \cdot |\cdot| \quad \text{on } B,$$

and consequently for any curve $\gamma: [a, b] \rightarrow B$ we have

$$mL_e(\gamma) \leq L(\gamma) \leq ML_e(\gamma).$$

PROOF. Define $G: B \times S^{n-1} \rightarrow \mathbb{R}$ by

$$G(p, a) = \|a_p\|_p.$$

Then G is continuous and positive. Since $B \times S^{n-1}$ is compact there are numbers $m, M > 0$ such that

$$m < G < M \quad \text{on } B \times S^{n-1}.$$

Now if $p \in B$ and $0 \neq b_p \in \mathbb{R}^n_p$, let $a \in S^{n-1}$ be $a = b/|b|$. Then

$$m|b| < |b|G(p, a) < M|b|;$$

since

$$|b|G(p, a) = |b| \cdot \|a_p\|_p = \|(|b|a)_p\|_p = \|b\|_p,$$

this gives the desired inequality (which clearly also holds for $b = 0$). ♦

Notice that the distance $d(p, q)$ defined by our metric need not be $L(\gamma)$ for any piecewise smooth curve from p to q . For example, the manifold M might be $\mathbb{R}^2 - \{0\}$, and q might be $-p$. Of course, if $d(p, q) = L(\gamma)$ for some γ ,

then γ is clearly a shortest piecewise smooth curve from p to q (there might be more than one shortest curve, e.g., the two semi-circles between the points p and $-p$ on S^1).

In order to investigate the question of shortest curves more thoroughly, we have to employ techniques from the “calculus of variations”. As an introduction to such techniques, we consider first a simple problem of this sort. Suppose we are given a (suitably differentiable) function

$$F: \mathbb{R} \times \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R},$$

We seek, among all functions $f: [a, b] \rightarrow \mathbb{R}$ with $f(a) = a'$ and $f(b) = b'$ one

which will maximize (or minimize) the quantity

$$\int_a^b F(t, f(t), f'(t)) dt.$$

For example, if

$$F(t, x, y) = \sqrt{1 + y^2},$$

then we are looking for a function f on $[a, b]$ which makes the curve $t \mapsto (t, f(t))$ between (a, a') and (b, b') of shortest length

$$\int_a^b \sqrt{1 + [f'(t)]^2} dt.$$

As a second example, if

$$F(t, x, y) = 2\pi x \sqrt{1 + y^2},$$

then we are trying to minimize the area of the surface obtained by revolving the graph of f around the x -axis, which is given (Problem 12) by

$$2\pi \int_a^b f(t) \sqrt{1 + [f'(t)]^2} dt.$$

To approach this sort of problem we recall first the methods used for solving the much simpler problem of determining the maximum or minimum of a function $f: \mathbb{R} \rightarrow \mathbb{R}$. To solve this problem, we examine the critical points of f , i.e., those points x for which $f'(x) = 0$. A critical point is not necessarily a maximum or minimum, or even a local maximum or minimum, but critical points are the only candidates for maxima or minima if f is everywhere differentiable. Similarly, for a function $f: \mathbb{R}^2 \rightarrow \mathbb{R}$ we consider points $(x, y) \in \mathbb{R}^2$ for which

$$(*) \quad D_1 f(x, y) = D_2 f(x, y) = 0.$$

This is the same as saying that the curves

$$t \mapsto f(x + t, y)$$

$$t \mapsto f(x, y + t)$$

have derivative 0 at 0. We might try to get more information by considering the condition

$$0 = (f \circ c)'(0)$$

for every curve $c: (-\varepsilon, \varepsilon) \rightarrow \mathbb{R}^2$ with $c(0) = (x, y)$, but it turns out that these conditions follow from (*), because of the chain rule.

To find maxima and minima for

$$J(f) = \int_a^b F(t, f(t), f'(t)) dt$$

we wish to proceed in an analogous way, by considering curves *in the set of all functions* $f: [a, b] \rightarrow \mathbb{R}$. This can be done by considering a “variation” of f , that is, a function

$$\alpha: (-\varepsilon, \varepsilon) \times [a, b] \rightarrow \mathbb{R}$$

such that

$$\alpha(0, t) = f(t).$$

The functions $t \mapsto \alpha(u, t)$ are then a family of functions on $(-\varepsilon, \varepsilon)$ which pass through f for $u = 0$. We will denote this function by $\tilde{\alpha}(u)$. Thus $\tilde{\alpha}$ is a function from $(-\varepsilon, \varepsilon)$ to the set of functions $f: [a, b] \rightarrow \mathbb{R}$. If each $\tilde{\alpha}(u)$ satisfies $\tilde{\alpha}(u)(a) = a'$, $\tilde{\alpha}(u)(b) = b'$, in other words if

$$\begin{aligned}\alpha(u, a) &= a' \\ \alpha(u, b) &= b'\end{aligned}$$

for all $u \in (-\varepsilon, \varepsilon)$, then we call α a variation of f keeping endpoints fixed.

For a variation α we now compute

$$\left. \frac{dJ(\tilde{\alpha}(u))}{du} \right|_{u=0} = \left. \frac{d}{du} \right|_{u=0} \int_a^b F\left(t, \alpha(u, t), \frac{\partial \alpha}{\partial t}(u, t)\right) dt$$

$$\begin{aligned}
&= \int_a^b \left[\frac{d}{du} \Big|_{u=0} F\left(t, \alpha(u, t), \frac{\partial \alpha}{\partial t}(u, t)\right) \right] dt \\
&= \int_a^b \left[\frac{\partial \alpha}{\partial u}(0, t) \frac{\partial F}{\partial x}(t, f(t), f'(t)) \right. \\
&\quad \left. + \frac{\partial^2 \alpha}{\partial u \partial t}(0, t) \frac{\partial F}{\partial y}(t, f(t), f'(t)) \right] dt.
\end{aligned}$$

Since $\partial^2 \alpha / \partial u \partial t = \partial^2 \alpha / \partial t \partial u$, we can apply integration by parts to the second term in the integrand, thus obtaining

$$\begin{aligned}
(*) \quad \frac{dJ(\tilde{\alpha}(u))}{du} \Big|_{u=0} &= \int_a^b \frac{\partial \alpha}{\partial u}(0, t) \left[\frac{\partial F}{\partial x}(t, f(t), f'(t)) \right. \\
&\quad \left. - \frac{d}{dt} \left(\frac{\partial F}{\partial y}(t, f(t), f'(t)) \right) \right] dt \\
&\quad + \frac{\partial \alpha}{\partial u}(0, t) \frac{\partial F}{\partial y}(t, f(t), f'(t)) \Big|_a^b.
\end{aligned}$$

For variations α keeping endpoints fixed, the second term is 0, and we obtain

$$\begin{aligned}
(**) \quad \frac{dJ(\tilde{\alpha}(u))}{du} \Big|_{u=0} &= \int_a^b \frac{\partial \alpha}{\partial u}(0, t) \left[\frac{\partial F}{\partial x}(t, f(t), f'(t)) \right. \\
&\quad \left. - \frac{d}{dt} \left(\frac{\partial F}{\partial y}(t, f(t), f'(t)) \right) \right] dt.
\end{aligned}$$

In classical treatments of the calculus of variations, the variations α were taken to be of the special form

$$\alpha(u, t) = f(t) + u\eta(t),$$

for some $\eta: [a, b] \rightarrow \mathbb{R}$ with $\eta(a) = \eta(b) = 0$. Then we obtain

$$\frac{dJ(\tilde{\alpha}(u))}{du} \Big|_{u=0} = \int_a^b \eta(t) \left[\frac{\partial F}{\partial x}(t, f(t), f'(t)) - \frac{d}{dt} \left(\frac{\partial F}{\partial y}(t, f(t), f'(t)) \right) \right] dt.$$

The final result is, of course, essentially the same. The derivative $\frac{d}{du} \Big|_{u=0} J(\tilde{\alpha}(u))$ is called the “first variation” of J and is denoted classically by

$$\delta J = \int_a^b \eta \left[\frac{\partial F}{\partial x} - \frac{d}{dt} \frac{\partial F}{\partial y} \right] dt.$$

As is usual in classical notation, the arguments of functions are either put in indiscriminately or left out indiscriminately—in this case, not only are the arguments t and $(t, f(t), f'(t))$ omitted (resulting in the disappearance of the function f for which we are solving), but the dependence of δJ on α is not indicated (which can make things pretty confusing).

If f is to maximize or minimize J , then $\delta J(\alpha)$ must be 0 for every variation α of f keeping endpoints fixed. As in the case of 1-dimensional calculus, there is no reason to expect that the condition $\delta J(\alpha) = 0$ for all α will imply that f is even a local maximum or minimum for J , and we emphasize this by introducing a definition. We call f a **critical point** of J (or an **extremal** for J) if $\delta J(\alpha) = 0$ for all variations α of f keeping endpoints fixed. The particular form (**) into which we have put δJ now allows us to deduce an important condition.

8. THEOREM (EULER'S EQUATION). The C^2 function f is a critical point of J if and only if f satisfies

$$\frac{\partial F}{\partial x}(t, f(t), f'(t)) - \frac{d}{dt} \left(\frac{\partial F}{\partial y}(t, f(t), f'(t)) \right) = 0.$$

PROOF. Clearly f must make the integral in (**) vanish for *every*

$$\eta(t) = \frac{\partial \alpha}{\partial u}(0, t)$$

which vanishes at a and b . So the theorem is a consequence of the following simple

8'. LEMMA. If a continuous function $g : [a, b] \rightarrow \mathbb{R}$ satisfies

$$\int_a^b \eta(t)g(t) dt = 0$$

for every C^∞ function η on $[a, b]$ with $\eta(a) = \eta(b) = 0$, then $g = 0$.

PROOF. Choose η to be ϕg where ϕ is positive on (a, b) and $\phi(a) = \phi(b) = 0$. ♦

As an example, consider the case where $F(t, x, y) = \sqrt{1 + y^2}$. The Euler equation is

$$0 = \frac{d}{dt} \left(\frac{f'(t)}{\sqrt{1 + [f'(t)]^2}} \right).$$

so

$$0 = \frac{\sqrt{1 + f'^2} \cdot f'' - f' \cdot \frac{f''}{\sqrt{1 + f'^2}}}{(-)},$$

hence

$$0 = (1 + f'^2) f'' - f' f'' = (1 - f' + f'^2) f'',$$

which implies that $f'' = 0$, so f is linear.

Notice that we would have obtained the same result if we had considered the case $F(t, x, y) = 1 + y^2$, for then the Euler equation is simply

$$0 = \frac{d}{dt}(2f'(t)).$$

This is analogous to the situation in 1-dimensional calculus, where the critical points of \sqrt{f} are the same as those of f , since

$$(\sqrt{f})' = \frac{f'}{2\sqrt{f}}.$$

For the case of the surface of revolution, where $F(t, x, y) = x\sqrt{1 + y^2}$, the Euler equation is

$$0 = \sqrt{1 + [f'(t)]^2} - \frac{d}{dt} \left(\frac{f(t)f'(t)}{\sqrt{1 + [f'(t)]^2}} \right);$$

this leads to the equation

$$1 + f'^2 - ff'' = 0,$$

which we will also write in the classical form

$$1 + \left(\frac{dy}{dx} \right)^2 - y \frac{d^2y}{dx^2} = 0.$$

To solve this, we use one of the \aleph_0 standard tricks (leaving justification of the details to the reader). We let

$$p = y' = \frac{dy}{dx}.$$

Then

$$\frac{d^2y}{dx^2} = \frac{dp}{dx} = \frac{dp}{dy} \cdot \frac{dy}{dx} = p \frac{dp}{dy},$$

so our equation becomes

$$\begin{aligned}
 1 + p^2 - yp \frac{dp}{dy} &= 0, \\
 \frac{p}{1 + p^2} dp &= \frac{1}{y} dy, \\
 \frac{1}{2} \log(1 + p^2) &= \log y + \text{constant} \\
 y &= \text{constant} \cdot \sqrt{1 + p^2} \\
 p = \frac{dy}{dx} &= \sqrt{cy^2 - 1} \\
 \frac{dy}{\sqrt{cy^2 - 1}} &= dx
 \end{aligned}$$

and thus (see Problem 20 for the definition and properties of the “hyperbolic cosine” function \cosh and its inverse)

$$\frac{\cosh^{-1} cy}{c} = x + k.$$

Replacing c by $1/c$, we write this as

$$(*) \quad y = c \cosh \left(\frac{x + k}{c} \right).$$

The graph of

$$\cosh x = \frac{e^x + e^{-x}}{2}$$

is shown below; it is symmetric about the y -axis, decreasing for $x \leq 0$, and increasing for $x \geq 0$.

So our surface must look like the one drawn below. It is, by the way, not trivial to decide whether there *are* constants k and c which will make the graph of $(*)$ pass through (a, a') and (b, b') . Problem 21 investigates the special case where $a' = b'$.

It is easy to generalize these considerations to the case where $f: [a, b] \rightarrow \mathbb{R}^n$ and

$$J(f) = \int_a^b F(t, f(t), f'(t)) dt \quad \text{for } F: \mathbb{R} \times \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}.$$

In this case we consider $\alpha: (-\varepsilon, \varepsilon) \times [a, b] \rightarrow \mathbb{R}^n$ with $\bar{\alpha}(0) = f$, and compute that

$$\begin{aligned} (***) \quad \left. \frac{dJ(\bar{\alpha}(u))}{du} \right|_{u=0} &= \int_a^b \sum_{i=1}^n \frac{\partial \alpha^i}{\partial u}(0, t) \left[\frac{\partial F}{\partial x^i}(t, f(t), f'(t)) \right. \\ &\quad \left. - \frac{d}{dt} \left(\frac{\partial F}{\partial y^i}(t, f(t), f'(t)) \right) \right] dt \\ &\quad + \sum_{i=1}^n \frac{\partial \alpha^i}{\partial u}(0, t) \frac{\partial F}{\partial y^i}(t, f(t), f'(t)) \Big|_a^b. \end{aligned}$$

Thus, any critical point f of J must satisfy the n equations

$$\frac{\partial F}{\partial x^i}(t, f(t), f'(t)) - \frac{d}{dt} \left(\frac{\partial F}{\partial y^i}(t, f(t), f'(t)) \right) = 0.$$

We are now going to apply these results to the problem of finding shortest paths in a manifold M . If $\gamma: [a, b] \rightarrow M$ is a piecewise smooth curve, with $\gamma(a) = p$ and $\gamma(b) = q$, we define a variation of γ to be a function

$$\alpha: (-\varepsilon, \varepsilon) \times [a, b] \rightarrow M$$

for some $\varepsilon > 0$, such that

- (1) $\alpha(0, t) = \gamma(t)$,
- (2) there is a partition $a = t_0 < t_1 < \cdots < t_N = b$ of $[a, b]$ so that α is C^∞ on each strip $(-\varepsilon, \varepsilon) \times [t_{i-1}, t_i]$.

We call α a variation of γ **keeping endpoints fixed** if

$$(3) \quad \begin{aligned} \alpha(u, a) &= p \\ \alpha(u, b) &= q \end{aligned} \quad \text{for all } u \in (-\varepsilon, \varepsilon).$$

As before, we let $\tilde{\alpha}(u)$ be the path $t \mapsto \alpha(u, t)$. We would like to find which paths γ satisfy

$$\left. \frac{dL(\tilde{\alpha}(u))}{du} \right|_{u=0} = 0$$

for all variations α keeping endpoints fixed. However, we will take a hint from our first example and first find the critical points for the “energy”

$$E(\gamma) = \frac{1}{2} \int_a^b \left\| \frac{d\gamma}{dt} \right\|^2 dt = \frac{1}{2} \int_a^b \left\langle \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle dt,$$

which has a much nicer integrand; afterwards we will consider the relation between the two integrals.

We can assume that each $\gamma|_{[t_{i-1}, t_i]}$ lies in some coordinate system (x, U) (otherwise we just refine the partition). If (u, t) is the standard coordinate system in $(-\varepsilon, \varepsilon) \times [a, b]$ we write

$$\begin{aligned} \frac{\partial \alpha}{\partial u}(u, t) &= \alpha_* \left(\frac{\partial}{\partial u} \Big|_{(u, t)} \right) \\ \frac{\partial \alpha}{\partial t}(u, t) &= \alpha_* \left(\frac{\partial}{\partial t} \Big|_{(u, t)} \right). \end{aligned}$$

Then $\partial\alpha/\partial t(u, t)$ is the tangent vector at time t to the curve $\tilde{\alpha}(u)$. If we adopt the abbreviations

$$\alpha^i(u, t) = x^i(\alpha(u, t)), \quad \gamma^i(t) = x^i(\gamma(t)) = \alpha^i(0, t),$$

then

$$\frac{\partial\alpha}{\partial t}(u, t) = \sum_{i=1}^n \frac{\partial\alpha^i}{\partial t}(u, t) \cdot \frac{\partial}{\partial x^i} \Big|_{\alpha(u, t)}, \quad \frac{d\gamma}{dt} = \sum_{i=1}^n \frac{d\gamma^i}{dt} \cdot \frac{\partial}{\partial x^i} \Big|_{\gamma(t)}.$$

So

$$\begin{aligned} E(\gamma | [t_{i-1}, t_i]) &= \frac{1}{2} \int_{t_{i-1}}^{t_i} \left\langle \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle dt \\ &= \frac{1}{2} \int_{t_{i-1}}^{t_i} \sum_{i,j=1}^n g_{ij}(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} dt. \end{aligned}$$

If we use the coordinate system x to identify U with \mathbb{R}^n , and consider the g_{ij} as functions on \mathbb{R}^n , then we are considering

$$\int_{t_{i-1}}^{t_i} F(\gamma(t), \gamma'(t)) dt$$

where

$$F(x, y) = \frac{1}{2} \sum_{i,j=1}^n g_{ij}(x) \cdot y^i y^j.$$

Then

$$\frac{\partial F}{\partial x^i} \left(\gamma(t), \frac{d\gamma}{dt} \right) = \frac{1}{2} \sum_{i,j=1}^n \frac{\partial g_{ij}}{\partial x^i}(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt},$$

and

$$\frac{\partial F}{\partial y^r} \left(\gamma(t), \frac{d\gamma}{dt} \right) = \sum_{r=1}^n g_{tr}(\gamma(t)) \frac{d\gamma^r}{dt},$$

so

$$\frac{d}{dt} \left(\frac{\partial F}{\partial y^r} \left(\gamma(t), \frac{d\gamma}{dt} \right) \right) = \sum_{r=1}^n g_{tr}(\gamma(t)) \frac{d^2\gamma^r}{dt^2} + \sum_{r,j=1}^n \frac{\partial g_{tr}}{\partial x^j}(\gamma(t)) \frac{d\gamma^j}{dt} \frac{d\gamma^r}{dt}.$$

In order to obtain a symmetrical looking result, we note that a little index juggling gives

$$\sum_{r,j=1}^n \frac{\partial g_{tr}}{\partial x^j} \frac{d\gamma^j}{dt} \frac{d\gamma^r}{dt} = \sum_{i,j=1}^n \frac{\partial g_{it}}{\partial x^j} \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = \sum_{i,j=1}^n \frac{\partial g_{ji}}{\partial x^i} \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt}$$

so

$$\sum_{r,j=1}^n \frac{\partial g_{tr}}{\partial x^j} \frac{d\gamma^j}{dt} \frac{d\gamma^r}{dt} = \frac{1}{2} \sum_{i,j=1}^n \frac{\partial g_{it}}{\partial x^j} \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} + \frac{1}{2} \sum_{i,j=1}^n \frac{\partial g_{jt}}{\partial x^i} \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt}.$$

From (***) we now obtain

$$\begin{aligned} & \left. \frac{dE(\tilde{\alpha}(u) | [t_{i-1}, t_i])}{du} \right|_{u=0} \\ &= - \int_{t_{i-1}}^{t_i} \sum_{r=1}^n \frac{\partial \alpha^r}{\partial u}(0, t) \left[\sum_{r=1}^n g_{tr}(\gamma(t)) \frac{d^2 \gamma^r}{dt^2} \right. \\ & \quad \left. + \sum_{i,j=1}^n \frac{1}{2} \left(\frac{\partial g_{it}}{\partial x^j}(\gamma(t)) + \frac{\partial g_{jt}}{\partial x^i}(\gamma(t)) - \frac{\partial g_{ij}}{\partial x^t}(\gamma(t)) \right) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} \right] dt \\ & \quad + \sum_{r=1}^n \frac{\partial \alpha^r}{\partial u}(0, t) \sum_{r=1}^n g_{tr}(\gamma(t)) \frac{d\gamma^r}{dt} \Big|_{t_{i-1}}^{t_i}. \end{aligned}$$

Remember that γ is only piecewise C^∞ . Let

$\frac{d\gamma}{dt}(t_i^+) =$ right hand tangent vector of γ at t_i

$\frac{d\gamma}{dt}(t_i^-) =$ left hand tangent vector of γ at t_i .

Notice that the final sum in the above formula is simply

$$\left\langle \frac{\partial \alpha}{\partial u}(0, t_i), \frac{d\gamma}{dt}(t_i^-) \right\rangle - \left\langle \frac{\partial \alpha}{\partial u}(0, t_{i-1}), \frac{d\gamma}{dt}(t_{i-1}^+) \right\rangle.$$

To abbreviate the integral somewhat we introduce the symbols

$$[ij, t] = \frac{1}{2} \left(\frac{\partial g_{it}}{\partial x^j} + \frac{\partial g_{jt}}{\partial x^i} - \frac{\partial g_{ij}}{\partial x^t} \right).$$

These depend on the coordinate system, but the integral

$$- \int_{t_{i-1}}^{t_i} \sum_{l=1}^n \frac{\partial \alpha^l}{\partial u}(0, t) \left[\sum_{r=1}^n g_{lr}(\gamma(t)) \frac{d^2 \gamma^r}{dt^2} + \sum_{i,j=1}^n [ij, l](\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} \right] dt,$$

which appears in our result, clearly cannot. Consequently, we will use the exact same expression for each $[t_{i-1}, t_i]$, even though different coordinate systems may actually be involved (and hence different g_{ij} and γ^i).

Now we just have to add up these results. Let

$$\begin{aligned} \Delta_{t_i} \frac{d\gamma}{dt} &= \frac{d\gamma}{dt}(t_i^+) - \frac{d\gamma}{dt}(t_i^-) \quad i = 1, \dots, N-1 \\ \Delta_{t_0} \frac{d\gamma}{dt} &= \frac{d\gamma}{dt}(t_0^+) \\ \Delta_{t_N} \frac{d\gamma}{dt} &= -\frac{d\gamma}{dt}(t_N^-). \end{aligned}$$

Then we obtain the following formula (where there is a convention being used in the integral).

9. THEOREM (FIRST VARIATION FORMULA). For any variation α , we have

$$\begin{aligned} & \frac{dE(\tilde{\alpha}(u))}{du} \Big|_{u=0} \\ &= - \int_a^b \sum_{l=1}^n \frac{\partial \alpha^l}{\partial u}(0, t) \left[\sum_{r=1}^n g_{lr}(\gamma(t)) \frac{d^2 \gamma^r}{dt^2} + \sum_{i,j=1}^n [ij, l](\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} \right] dt \\ & \quad - \sum_{i=0}^N \left\langle \frac{\partial \alpha}{\partial u}(0, t_i), \Delta_{t_i} \frac{d\gamma}{dt} \right\rangle. \end{aligned}$$

(In the case of a variation α leaving endpoints fixed, the sum can be written from 1 to $N-1$.)

This result is not very pretty, but there it is. It should be noted that $[ij, l]$ are *not* the components of a tensor. Nevertheless, later on we will have an invariant interpretation of the first variation formula. For the time being we present, with apologies, this coordinate dependent approach. From the first variation formula it is, of course, simple to obtain conditions for critical points of E .

10. COROLLARY. If $\gamma: [a, b] \rightarrow M$ is a C^∞ path, then γ is a critical point of E_a^b if and only if for every coordinate system (x, U) we have

$$\sum_{r=1}^n g_{lr}(\gamma(t)) \frac{d^2 \gamma^r}{dt^2} + \sum_{i,j=1}^n [ij, l](\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0 \quad \text{for } \gamma(t) \in U.$$

PROOF. Suppose γ is a critical point. Given t with $\gamma(t) \in U$, choose a partition of $[a, b]$ with $t \in (t_{i-1}, t_i)$ for some i , and such that $\gamma|_{[t_{i-1}, t_i]}$ is in U . If α is a variation of γ keeping endpoints fixed, then in the first variation formula we can assume that the part of the integral from t_{i-1} to t_i is written in terms of (x, U) . The final term in the formula vanishes since γ is C^∞ . Now apply the method of proof in Lemma 8', choosing all $\partial \alpha^l / \partial u(0, t)$ to be 0, except one, which is 0 outside of (t_{i-1}, t_i) , but a positive function times the term in brackets on (t_{i-1}, t_i) . ♦

In order to put the equations of Corollary 10 in a standard form we introduce another set of symbols

$$\Gamma_{ij}^k = \sum_{l=1}^n g^{kl} [ij, l] = \sum_{l=1}^n g^{kl} \frac{1}{2} \left(\frac{\partial g_{il}}{\partial x^j} + \frac{\partial g_{jl}}{\partial x^i} - \frac{\partial g_{ij}}{\partial x^l} \right).$$

Our equations can now be written

$$\frac{d^2 \gamma^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0.$$

We know from the standard theorem about systems of second order differential equations (Problem 5-4), that for each $p \in M$ and each $v \in M_p$, there is a unique $\gamma: (-\varepsilon, \varepsilon) \rightarrow M$, for some $\varepsilon > 0$, such that γ satisfies

$$\gamma(0) = p$$

$$\frac{d\gamma}{dt}(0) = v$$

$$\frac{d^2 \gamma^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0.$$

Moreover, this γ is C^∞ on $(-\varepsilon, \varepsilon)$. This last fact shows that if $\gamma_1: [0, \varepsilon) \rightarrow M$ and $\gamma_2: (-\varepsilon, 0] \rightarrow M$ are C^∞ functions satisfying this equation, and if moreover

$$\gamma_1(0) = \gamma_2(0)$$

$$\frac{d\gamma_1}{dt}(0^+) = \frac{d\gamma_2}{dt}(0^-),$$

then γ_1 and γ_2 together give a C^∞ function on $(-\varepsilon, \varepsilon)$. Naturally, we could replace 0 by any other t . We now have the more precise result,

11. COROLLARY. A piecewise C^∞ path $\gamma: [a, b] \rightarrow M$ is a critical point for E_a^b if and only if γ is actually C^∞ on $[a, b]$ and for every coordinate system (x, U) satisfies

$$\boxed{\frac{d^2\gamma^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0} \quad \text{for } \gamma(t) \in U.$$

PROOF. Let γ be a critical point. Choosing the same α^l as before (all α^l are 0 outside of (t_{i-1}, t_i)), we see that $\gamma|_{[t_{i-1}, t_i]}$ satisfies the equation, because the final term in the first variation formula still vanishes. Now choose α so that

$$\frac{\partial \alpha}{\partial u}(0, t_i) = \Delta_{t_i} \frac{d\gamma}{dt}, \quad i = 1, \dots, N-1.$$

We already know that the integral in the first variation formula vanishes. So we obtain

$$0 = - \sum_{i=1}^{N-1} \left\langle \Delta_{t_i} \frac{d\gamma}{dt}, \Delta_{t_i} \frac{d\gamma}{dt} \right\rangle,$$

which implies that all $\Delta_{t_i} \frac{d\gamma}{dt}$ are 0. By our previous remarks, this means that γ is actually C^∞ on all of $[a, b]$. ♦

As the simplest possible case, consider the Euclidean metric on \mathbb{R}^n ,

$$(\ , \) = \sum_{i=1}^n dx^i \otimes dx^i.$$

Here $g_{ij} = \delta_{ij}$, so all $\partial g_{ij} / \partial x^k = 0$, and $\Gamma_{ij}^k = 0$. The critical points γ for the energy function satisfy

$$\frac{d^2\gamma^k}{dt^2} = 0.$$

Thus γ lies along a straight line, so γ is a critical point for the length function as well. The situation is now quite different from the first variational problem we considered, when we considered only curves of the form $t \mapsto (t, f(t))$. Any reparameterization of γ is also a critical point for length, since length is independent of parameterization (Problem 16). This shows that there are critical points for length which definitely aren't critical points for energy, since we have just seen that for γ to be a critical point for energy, the component functions of γ must be linear, and hence γ must be parameterized proportionally to arclength. This situation always prevails.

12. THEOREM. If $\gamma: [a, b] \rightarrow M$ is a critical point for E , then γ is parameterized proportionally to arclength.

PROOF. Observe first, from the definitions, that

$$\frac{\partial g_{ij}}{\partial x^l} = [il, j] + [jl, i].$$

Now we have

$$\begin{aligned} \frac{d}{dt} \left\| \frac{d\gamma}{dt} \right\|^2 &= \frac{d}{dt} \left(\sum_{i,j=1}^n g_{ij}(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} \right) \\ &= \sum_{i,j=1}^n \sum_{l=1}^n \frac{\partial g_{ij}}{\partial x^l}(\gamma(t)) \frac{d\gamma^l}{dt} \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} + \sum_{r,j=1}^n g_{rj}(\gamma(t)) \frac{d^2\gamma^r}{dt^2} \frac{d\gamma^j}{dt} \\ &\quad + \sum_{i,r=1}^n g_{ir}(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d^2\gamma^r}{dt^2}. \end{aligned}$$

Replacing $\partial g_{ij}/\partial x^l$ by the value given above, this can be written as

$$\begin{aligned} \frac{d}{dt} \left\| \frac{d\gamma}{dt} \right\|^2 &= \sum_{j=1}^n \frac{d\gamma^j}{dt} \left(\sum_{r=1}^n g_{rj}(\gamma(t)) \frac{d^2\gamma^r}{dt^2} + \sum_{i,l=1}^n [il, j](\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^l}{dt} \right) \\ &\quad + \sum_{i=1}^n \frac{d\gamma^i}{dt} \left(\sum_{r=1}^n g_{ir}(\gamma(t)) \frac{d^2\gamma^r}{dt^2} + \sum_{j,l=1}^n [jl, i](\gamma(t)) \frac{d\gamma^j}{dt} \frac{d\gamma^l}{dt} \right). \end{aligned}$$

Since γ is a critical point for E , both terms in parentheses are 0 (Corollary 10). Thus the length $\|d\gamma/dt\|$ is constant. ♦

The formula

$$(*) \quad \frac{\partial g_{ij}}{\partial x^k} = [ik, j] + [jk, i]$$

occurring in this proof will be used on several occasions later on. It will also be useful to know a formula for $\partial g^{ij}/\partial x^k$. To derive one, we first differentiate

$$\sum_{m=1}^n g_{lm} g^{mj} = \delta_l^j$$

to obtain

$$\sum_{m=1}^n g_{lm} \frac{\partial g^{mj}}{\partial y^k} = - \sum_{m=1}^n \frac{\partial g_{lm}}{\partial y^k} g^{mj}.$$

Thus we have

$$\begin{aligned} \frac{\partial g^{ij}}{\partial y^k} &= \sum_{l,m} g^{il} g_{lm} \frac{\partial g^{mj}}{\partial y^k} = - \sum_{l,m} g^{il} g^{mj} \frac{\partial g_{lm}}{\partial y^k} \\ &= - \sum_{l,m} g^{il} g^{mj} ([lk, m] + [mk, l]) \quad \text{by } (*) \\ &= - \sum_l g^{il} \Gamma_{lk}^j - \sum_m g^{mj} \Gamma_{mk}^i, \end{aligned}$$

or

$$(**) \quad \frac{\partial g^{ij}}{\partial y^k} = - \sum_{l=1}^n (g^{il} \Gamma_{lk}^j + g^{lj} \Gamma_{lk}^i).$$

We can find the equations for critical points of the length function L in exactly the same way as we treated the energy function. For the moment we consider only paths $\gamma: [a, b] \rightarrow M$ with $d\gamma/dt \neq 0$ everywhere. For the portion $\gamma|_{[t_{i-1}, t_i]}$ of γ contained in a coordinate system (x, U) , we have

$$L(\gamma|_{[t_{i-1}, t_i]}) = \int_{t_{i-1}}^{t_i} \sqrt{\sum_{i,j=1}^n g_{ij}(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt}} dt.$$

Considering our coordinate system as \mathbb{R}^n , we are now dealing with the case

$$F(x, y) = \sqrt{\sum_{i,j=1}^n g_{ij}(x) y^i y^j}.$$

We introduce the arclength function

$$s(t) = L_a^t(\gamma).$$

Then

$$\frac{ds}{dt} = \left\| \frac{d\gamma}{dt} \right\| = F\left(\gamma(t), \frac{d\gamma}{dt}\right).$$

So we have

$$\begin{aligned} \frac{\partial F}{\partial x^I}\left(\gamma(t), \frac{d\gamma}{dt}\right) &= \frac{1}{2} \frac{\sum_{i,j=1}^n \frac{\partial g_{ij}}{\partial x^I}(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt}}{\frac{ds}{dt}} \\ \frac{\partial F}{\partial y^I}\left(\gamma(t), \frac{d\gamma}{dt}\right) &= \frac{\sum_{r=1}^n g_{Ir}(\gamma(t)) \frac{d\gamma^r}{dt}}{\frac{ds}{dt}}. \end{aligned}$$

After a little more calculation we finally obtain the equations for a critical point of L :

$$\frac{d^2\gamma^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} - \frac{d\gamma^k}{dt} \frac{\frac{d^2s}{dt^2}}{\frac{ds}{dt}} = 0.$$

It is clear from this that critical points of E are also critical points of L (since they satisfy $d^2s/dt^2 = 0$). Conversely, given a critical point γ for L with $d\gamma/dt \neq 0$ everywhere, the function

$$s: [a, b] \rightarrow [0, L_a^b(\gamma)]$$

is a diffeomorphism, and we can consider the reparameterized curve

$$\gamma \circ s^{-1}: [0, L_a^b(\gamma)] \rightarrow M.$$

This reparameterized curve is automatically also a critical point for L , so it must satisfy the same differential equation. Since it is now parameterized by arclength, the third term vanishes, so $\gamma \circ s^{-1}$ is a critical point for E .

There is only one detail which remains unsettled. Conceivably a critical point for L might have a kink, but be C^∞ because it has a zero tangent vector

there, as in the figure below. In this case it would not be possible to reparam-

terize γ by arclength. Problem 37 shows that this situation cannot arise.

Henceforth we will call a critical point of E a **geodesic** on M (for the Riemannian metric (\cdot, \cdot)). This name comes from the science of geodesy, which is concerned with the measurement of the earth's surface, including surveying and the measurement of degrees of latitude and longitude. A geodesic on the earth's surface is a segment of a great circle, which is the shortest path between two points. Before we can say whether this is true for geodesics in general, which are so far merely known to be critical points for length, we must initiate a local study of geodesics.

The most elementary properties of geodesics depend only on facts about differential equations. Observe that the equations for a geodesic,

$$\frac{d^2\gamma^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0,$$

have an important homogeneity property: if γ is a geodesic, then $t \mapsto \gamma(ct)$ is also clearly a geodesic. This feature of the equation allows us to improve the result given by the basic existence and uniqueness theorems.

13. THEOREM. Let $p \in M$. Then there is a neighborhood U of p and a number $\varepsilon > 0$ such that for every $q \in U$ and every tangent vector $v \in M_q$ with $\|v\| < \varepsilon$ there is a unique geodesic

$$\gamma_v: (-2, 2) \rightarrow M$$

satisfying

$$\gamma_v(0) = q, \quad \frac{d\gamma_v}{dt}(0) = v.$$

PROOF. The fundamental existence and uniqueness theorem says that there is a neighborhood U of p and $\varepsilon_1, \varepsilon_2 > 0$ so that for $q \in U$ and $v \in M_q$ with $\|v\| < \varepsilon_1$ there is a unique geodesic

$$\gamma_v: (-2\varepsilon_2, 2\varepsilon_2) \rightarrow M$$

with the required initial conditions.

Choose $\varepsilon < \varepsilon_1 \varepsilon_2$: Then if $|v| < \varepsilon$ and $|t| < 2$ we have

$$\|v/\varepsilon_2\| < \varepsilon_1 \quad \text{and} \quad |\varepsilon_2 t| < 2\varepsilon_2.$$

So we can define $\gamma_v(t)$ to be $\gamma_{v/\varepsilon_2}(\varepsilon_2 t)$. ♦

If $v \in M_q$ is a vector for which there is a geodesic

$$\gamma: [0, 1] \rightarrow M$$

satisfying

$$\gamma(0) = q, \quad \frac{d\gamma}{dt}(0) = v,$$

then we define the **exponential** of v to be

$$\exp(v) = \exp_q(v) = \gamma(1).$$

(The reason for this terminology will be explained in the next chapter.) The geodesic γ can thus be described as

$$\gamma(t) = \exp_q(tv).$$

Since M_q is an n -dimensional vector space, there is a natural way to give it a C^∞ structure. If $\mathcal{O} \subset M_q$ is the set of all vectors $v \in M_q$ for which $\exp_q(v)$ is defined, then the map

$$\exp_q: \mathcal{O} \rightarrow M$$

is C^∞ , since the solutions of the differential equations for geodesics have a C^∞ flow. Identifying the tangent space $(M_q)_v$ at $v \in M_q$ with M_q itself, we have an induced map

$$(\exp_q)_{v*}: M_q \rightarrow M_{\exp_q(v)}.$$

In particular, we claim that the map

$$(\exp_q)_{0*}: M_q \rightarrow M_q \quad \text{is the identity.}$$

In fact, to obtain a curve c in the manifold M_q with $dc/dt(0) = v \in M_q = (M_q)_0$, we can let $c(t) = tv$. Then $\exp_q \circ c(t) = \exp_q(tv)$, the geodesic with tangent vector v at time 0, so

$$(\exp_q)_{0*}(v) = \left. \frac{d}{dt} \right|_{t=0} \exp_q(c(t)) = v.$$

Before proving the next result, we recall some facts about the manifold TM . If (x, U) is a coordinate system on M , then for $q \in U$ we can express every vector $v \in M_q$ uniquely as

$$v = \sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_q.$$

We will denote a^i by $\dot{x}^i(v)$, so that

$$v = \sum_{i=1}^n \dot{x}^i(v) \frac{\partial}{\partial x^i} \Big|_{\pi(v)},$$

where $\pi: TM \rightarrow M$ is the projection. Then

$$(x^1 \circ \pi, \dots, x^n \circ \pi, \dot{x}^1, \dots, \dot{x}^n) = (\bar{x}^1, \dots, \bar{x}^n, \dot{x}^1, \dots, \dot{x}^n)$$

is a coordinate system on $\pi^{-1}(U)$. For $v \in M_q$, $q \in U$ we therefore have tangent vectors

the vectors $\partial/\partial \dot{x}^i|_v$ are all in the tangent space of the submanifold $M_q \subset TM$, while the vectors $\partial/\partial \bar{x}^i|_v$ span a complimentary subspace.

14. THEOREM. For every $p \in M$ there is a neighborhood W and a number $\varepsilon > 0$ such that

- (1) Any two points of W are joined by a unique geodesic in M of length $< \varepsilon$.
- (2) Let $v(q, q')$ denote the unique vector $v \in M_q$ of length $< \varepsilon$ such that $\exp_q(v) = q'$. Then $(q, q') \mapsto v(q, q')$ is a C^∞ function from $W \times W \rightarrow TM$.
- (3) For each $q \in W$, the map \exp_q maps the open ε -ball in M_q diffeomorphically onto an open set $U_q \supset W$.

PROOF. Theorem 13 says that the vector $0 \in M_p$ has a neighborhood V in the manifold TM such that \exp is defined on V . Define the C^∞ function $F: V \rightarrow M \times M$ by

$$F(v) = (\pi(v), \exp(v)).$$

Let (x, U) be a coordinate system around p . We will use the coordinate system

$$(\bar{x}^1, \dots, \bar{x}^n, \dot{x}^1, \dots, \dot{x}^n),$$

described above, for $\pi^{-1}(U)$. If $\pi_i: M \times M \rightarrow M$ is projection on the i^{th} factor, then

$$(x^1 \circ \pi_1, \dots, x^n \circ \pi_1, x^1 \circ \pi_2, \dots, x^n \circ \pi_2) = (x_1^1, \dots, x_1^n, x_2^1, \dots, x_2^n)$$

is a coordinate system on $U \times U$. Now, using the fact that

$$(\exp_p)_{0*}: M_p \rightarrow M_p$$

is the identity, it is not hard to see that at $0 \in M_p$ we have

$$F_* \left(\frac{\partial}{\partial \bar{x}^i} \Big|_0 \right) = \frac{\partial}{\partial x_1^i} \Big|_{(p,p)} + \frac{\partial}{\partial x_2^i} \Big|_{(p,p)}$$

$$F_* \left(\frac{\partial}{\partial \dot{x}^i} \Big|_0 \right) = \frac{\partial}{\partial x_2^i} \Big|_{(p,p)}.$$

Consequently, F_* is one-one at $0 \in M_p$, so F maps some neighborhood V' of 0 diffeomorphically onto some neighborhood of $(p, p) \in M \times M$. We may assume that V' consists of all vectors $v \in M_q$ with q in some neighborhood U' of p and $\|v\| < \varepsilon$. Choose W to be a smaller neighborhood of p for which $F(V') \supset W \times W$. ♦

Given a W as in the theorem, and $q \in W$, consider the geodesics through q of the form $t \mapsto \exp_q(tv)$ for $\|v\| < \varepsilon$. These fill out U_q . The close analysis of geodesics depends on the following.

15. LEMMA (GAUSS' LEMMA). In U_q , the geodesics through q are perpendicular to the hypersurfaces

$$\{\exp_q(v) : \|v\| = \text{constant} < \varepsilon\}.$$

FIRST PROOF. Let $v: \mathbb{R} \rightarrow M_q$ be a smooth curve with $\|v(t)\| = k$ a constant $k < \varepsilon$ for all t , and define

$$\alpha(u, t) = \exp_q(u \cdot v(t)) \quad -1 < u < 1.$$

We are claiming that for every such α we have

$$\left\langle \frac{\partial \alpha}{\partial u}(u, t), \frac{\partial \alpha}{\partial t}(u, t) \right\rangle = 0 \quad \text{for all } (u, t).$$

A calculation precisely like that in the proof of Theorem 12 proves the following equation, in which the arguments (u, t) and $\alpha(u, t)$ are omitted, for convenience:

$$(1) \quad \frac{\partial}{\partial u} \left\langle \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial t} \right\rangle = \sum_{j=1}^n \frac{\partial \alpha^j}{\partial t} \left(\sum_{r=1}^n g_{rj} \frac{\partial^2 \alpha^r}{\partial u^2} + \sum_{i,l=1}^n [il, j] \frac{\partial \alpha^i}{\partial u} \frac{\partial \alpha^l}{\partial u} \right) \\ + \sum_{i=1}^n \frac{\partial \alpha^i}{\partial u} \left(\sum_{r=1}^n g_{ir} \frac{\partial^2 \alpha^r}{\partial u \partial t} + \sum_{j,l=1}^n [jl, i] \frac{\partial \alpha^j}{\partial u} \frac{\partial \alpha^l}{\partial t} \right).$$

The first term on the right is 0 since each curve $u \mapsto \alpha(u, t)$ is a geodesic. Similarly, we obtain

$$(2) \quad \frac{\partial}{\partial t} \left\langle \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial u} \right\rangle = 2 \sum_{i=1}^n \frac{\partial \alpha^i}{\partial u} \left(\sum_{r=1}^n g_{ir} \frac{\partial^2 \alpha^r}{\partial u \partial t} + \sum_{j,l=1}^n [jl, i] \frac{\partial \alpha^j}{\partial u} \frac{\partial \alpha^l}{\partial t} \right),$$

which is just twice the second term on the right of (1). But $\partial \alpha / \partial u(u, t)$ is just the tangent vector at time u to the geodesic $u \mapsto \exp_q(u \cdot v(t))$, where $\|v(t)\| = k$; so $\|\partial \alpha / \partial u\| = k$. Thus the second term on the right of (2) is also 0. So

$$\left\langle \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial t} \right\rangle \quad \text{is independent of } u.$$

But $\alpha(0, t) = \exp_q(0) = q$, so $\partial \alpha / \partial t(0, t) = 0$. It follows that

$$\left\langle \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial t} \right\rangle = 0 \quad \text{for all } (u, t).$$

SECOND PROOF. Let $v: \mathbb{R} \rightarrow M_q$ be any smooth curve with $\|v(t)\| =$ a constant $k < \varepsilon$ for all t , and define

$$\beta(u, t) = \exp_q(t \cdot v(u)) \quad (\text{note carefully the roles played by } t \text{ and } u).$$

Then β is a variation of the geodesic $\gamma(t) = \exp_q(t \cdot v(0))$, defined on $[0, 1]$. By

the first variation formula, we have

$$\begin{aligned} \left. \frac{dE(\tilde{\beta}(u))}{du} \right|_{u=0} &= - \left\langle \frac{\partial \beta}{\partial u}(0, 1), \frac{d\gamma}{dt}(1) \right\rangle - \left\langle \frac{\partial \beta}{\partial u}(0, 0), \frac{d\gamma}{dt}(0) \right\rangle \\ &= - \left\langle \frac{\partial \beta}{\partial u}(0, 1), \frac{d\gamma}{dt}(1) \right\rangle, \end{aligned}$$

the integral vanishing since γ is a geodesic. But each curve $\tilde{\beta}(u)$ has energy

$$E(\tilde{\beta}(u)) = \int_0^1 \left\| \frac{d\tilde{\beta}(u)(t)}{dt} \right\|^2 dt = \int_0^1 k^2 dt = k^2,$$

so

$$0 = \left. \frac{dE(\tilde{\beta}(u))}{du} \right|_{u=0} = - \left\langle \frac{\partial \beta}{\partial u}(0, 1), \frac{d\gamma}{dt}(1) \right\rangle. \quad \spadesuit$$

16. COROLLARY. Let $c: [a, b] \rightarrow U_q - \{q\}$ be a piecewise smooth curve,

$$c(t) = \exp_q(u(t) \cdot v(t)),$$

for $0 < u(t) < \varepsilon$ and $\|v(t)\| = 1$. Then

$$L_a^b c \geq |u(b) - u(a)|,$$

with equality if and only if u is monotonic and v is constant, so that c is a radial geodesic joining two concentric spherical shells around q .

PROOF. If $\alpha(u, t) = \exp_q(u \cdot v(t))$, then $c(t) = \alpha(u(t), t)$ and

$$\frac{dc}{dt} = \frac{\partial \alpha}{\partial u} u'(t) + \frac{\partial \alpha}{\partial t}.$$

Since

$$\left\langle \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial t} \right\rangle = 0, \quad \left\| \frac{\partial \alpha}{\partial u} \right\| = 1,$$

we have

$$\left\| \frac{dc}{dt} \right\|^2 = |u'(t)|^2 + \left\| \frac{\partial \alpha}{\partial t} \right\|^2 \geq |u'(t)|^2,$$

with equality if and only if $\partial \alpha / \partial t = 0$, and hence $v'(t) = 0$. Thus

$$\int_0^b \left\| \frac{dc}{dt} \right\| dt \geq \int_0^b |u'(t)| dt \geq |u(b) - u(a)|,$$

with equality if and only if u is monotonic and v is constant. ♦

17. COROLLARY. Let W and ε be as in Theorem 15, let $\gamma: [0, 1] \rightarrow M$ be the geodesic of length $< \varepsilon$ joining $q, q' \in W$, and let $c: [0, 1] \rightarrow M$ be any piecewise C^∞ path from q to q' . Then

$$L(\gamma) \leq L(c),$$

with equality holding if and only if c is a reparameterization of γ .

PROOF. We can assume that $q' = \exp_q(rv) \in U_q - \{q\}$ (otherwise break c up into smaller pieces). For $\delta > 0$, the path c must contain a segment which joins the spherical shell of radius δ to the spherical shell of radius r , and lies between them. By Corollary 16, the length of this segment has length $\geq r - \delta$. So the length of c is $\geq r$, and clearly c must be a reparameterization of γ for equality to hold. ♦

We thus see that *sufficiently small pieces* of geodesics are minimal paths for arc-length. We can use Corollary 17 to determine the geodesics on a few simple surfaces, without any computations, if we first introduce a notion which will play a crucial role later. If $(M, (\cdot, \cdot))$ and $(M', (\cdot, \cdot)')$ are C^∞ manifolds with Riemannian metrics, then a one-one C^∞ function $f: M \rightarrow M'$ is called an **isometry** of M into M' if $f^*(\cdot, \cdot)' = (\cdot, \cdot)$. For example, reflection through a plane $E^2 \subset \mathbb{R}^{n+1}$ is an isometry $I: S^n \rightarrow S^n$. It is clear that if $c: [0, 1] \rightarrow M$ is a C^∞ curve, then the length of c with respect to (\cdot, \cdot) is the length of $f \circ c$ with respect to $(\cdot, \cdot)'$; and if c is a geodesic, then $f \circ c$ is likewise a geodesic.

For the isometry $I: S^n \rightarrow S^n$ mentioned above, the fixed point set is the great circle $C = S^n \cap E^2$. Let $p, q \in C$ be two points with a unique geodesic C' of minimal length between them. Then $I(C')$ is a geodesic of the same length as C' between $I(p) = p$ and $I(q) = q$. So $C' = I(C')$, which implies that $C' \subset C$, so that C is a geodesic. Since there is a great circle through any point of S^n in any given direction, these are all the geodesics.

Notice that a portion of a great circle which is larger than a semi-circle is definitely not of minimal length, *even among nearby paths*. Antipodal points on

the sphere have a continuum of geodesics of minimal length between them. All other pairs of points have a unique geodesic of minimal length between them but an infinite family of non-minimal geodesics, depending on how many times the geodesic goes around the sphere and in which direction it starts.

The geodesics on a right circular cylinder Z are the generating lines, the

circles cut by planes perpendicular to the generating lines, and the helices on Z . In fact, if L is a generating line of Z , then we can set up an isometry $I: Z - L \rightarrow \mathbb{R}^2$ by rolling Z onto \mathbb{R}^2 . The geodesics on Z are just the images

under I^{-1} of the straight lines in \mathbb{R}^2 . Two points on Z have infinitely many geodesics between them.

We are now in a position to wind up our discussion of Riemannian metrics on M by establishing an important connection between the Riemannian metric (\cdot, \cdot) and the metric $d: M \times M \rightarrow \mathbb{R}$ it determines,

$$d(p, q) = \inf \{L(\gamma) : \gamma \text{ a piecewise smooth curve from } p \text{ to } q\}.$$

Notice that on both the sphere and the infinite cylinder every geodesic γ defined on an interval $[a, b]$ can be extended to a geodesic defined on all of \mathbb{R} . This is false on a cylinder of bounded height, a bounded portion of \mathbb{R}^n , or $\mathbb{R}^n - \{0\}$. In general, a manifold M with a Riemannian metric (\cdot, \cdot) is called **geodesically complete** if every geodesic $\gamma: [a, b] \rightarrow M$ can be extended to a geodesic from \mathbb{R} to M .

18. THEOREM (HOPF-RINOW-DE RHAM). If (\cdot, \cdot) is a Riemannian metric on M , then M is geodesically complete if and only if M is complete in the metric d determined by (\cdot, \cdot) . Moreover, any two points in a geodesically complete manifold can be joined by a geodesic of minimal length.

PROOF. Suppose M is geodesically complete. Given $p, q \in M$ with $d(p, q) = r > 0$, choose U_p as in Theorem 14. Let $S \subset U_p$ be the spherical shell of radius $\delta < \varepsilon$. There is a point

$$p_0 = \exp_p \delta v, \quad \|v\| = 1$$

on S such that $d(p_0, q) \leq d(s, q)$ for all $s \in S$. We claim that

$$(*) \quad \exp_p(rv) = q;$$

this will show that the geodesic $\gamma(t) = \exp_p(tv)$ is a geodesic of minimal length between p and q . To prove this result, we will prove that

$$(**) \quad d(\gamma(t), q) = r - t \quad t \in [\delta, r].$$

First of all, since every curve from p to q must intersect S , we clearly have

$$d(p, q) = \min_{s \in S} (d(p, s) + d(s, q)) = \delta + d(p_0, q).$$

So $d(p_0, q) = r - \delta$. This proves that $(**)$ holds for $t = \delta$.

Now let $t_0 \in [\delta, r]$ be the least upper bound of all t for which $(**)$ holds. Then $(**)$ holds for t_0 also, by continuity. Suppose $t_0 < r$. Let S' be a spherical shell

of radius δ' around $\gamma(t_0)$ and let $p_0' \in S'$ be a point closest to q . Then

$$d(\gamma(t_0), q) = \min_{s \in S'} (d(\gamma(t_0), s) + d(s, q)) = \delta' + d(p_0', q),$$

so

$$(***) \quad d(p_0', q) = (r - t_0) - \delta'.$$

Hence

$$d(p, p_0') \geq d(p, q) - d(p_0', q) = t_0 + \delta'.$$

But the path c obtained by following γ from p to $\gamma(t_0)$ and then the minimal geodesic from $\gamma(t_0)$ to p_0' has length precisely $t_0 + \delta'$. So c is a path of minimal length, and must therefore be a geodesic, which means that it coincides with γ . Hence

$$\gamma(t_0 + \delta') = p_0'.$$

Hence (***) gives

$$d(\gamma(t_0 + \delta'), q) = r - (t_0 + \delta'),$$

showing that (**) holds for $t_0 + \delta'$. This contradicts the choice of t_0 , so it must be that $t_0 = r$. In other words, (**) holds for $t = r$, which proves (*).

From this result, it follows easily that M is complete with the metric d . In fact, if $A \subset M$ has diameter D , and $p \in A$, then the map $\exp_p: M_p \rightarrow M$ maps the closed disc of radius D in M_p onto a compact set containing A . In other words, bounded subsets of M have compact closure. From this it is clear that Cauchy sequences converge.

Conversely, suppose M is complete as a metric space. Given any geodesic $\gamma: (a, b) \rightarrow M$, choose $t_n \rightarrow b$. Clearly $\gamma(t_n)$ is a Cauchy sequence in M , so it converges to some point $p \in M$. Using Theorem 14, it is not difficult to show that γ can be extended past b . Consequently, by a least upper bound argument, any geodesic can be extended to \mathbb{R} . ♦

As a particular consequence of Theorem 18, note that there is always a minimal geodesic joining any two points of a compact manifold.

ADDENDUM

TUBULAR NEIGHBORHOODS

Let $M^n \subset N^{n+k}$ be a submanifold of N , with $i: M \rightarrow N$ the inclusion map, so that for every $p \in M$ we have $i_*(M_p) \subset N_p$. If (\cdot, \cdot) is a Riemannian metric for N , then we can define $M_p^\perp \subset N_p$ as

$$M_p^\perp = \{v \in N_p : (v, i_*w) = 0 \text{ for all } w \in M_p\}.$$

Let

$$E = \bigcup_{p \in M} M_p^\perp \quad \text{and} \quad \varpi: E \rightarrow M \quad \text{take } M_p^\perp \text{ to } p.$$

It is not hard to see that $\nu = \varpi: E \rightarrow M$ is a k -plane bundle over M , the **normal bundle** of M in N .

For example, the normal bundle ν of $S^{n-1} \subset \mathbb{R}^n$ is the trivial 1-plane bundle, for ν has a section consisting of unit outward normal vectors. On the other hand

if M is the Möbius strip and $S^1 \subset M$ is a circle around the center, then it is not hard to see that the normal bundle ν will be isomorphic to the (non-trivial) bundle $M \rightarrow S^1$. If we consider $S^1 \subset M \subset \mathbb{P}^2$, then the normal bundle

of S^1 in \mathbb{P}^2 is exactly the same as the normal bundle of S^1 in M , so it too is non-trivial.

Our aim is to prove that for compact M the normal bundle of M in N is always equivalent to a bundle $\pi : U \rightarrow M$ for which U is an open neighborhood of M in N , and for which the 0-section $s : M \rightarrow U$ is just the inclusion of M into U . In the case where N is the total space of a bundle over M , this open neighborhood can be taken to be the whole total space. But in general the neighborhood cannot be all of N . For example, as an appropriate neighborhood of $S^1 \subset \mathbb{R}^2$ we can choose $\mathbb{R}^2 - \{0\}$.

A bundle $\pi : U \rightarrow M$ with U an open neighborhood of M in N , for which the 0-section $s : M \rightarrow U$ is the inclusion of M in U , is called a **tubular neighborhood** of M in N . Before proving the existence of tubular neighborhoods, we add some remarks and a Lemma.

If $\pi : U \rightarrow M$ is a tubular neighborhood, then clearly

$$\begin{aligned} \pi \circ s &= \text{identity of } M, \\ s \circ \pi &\text{ is smoothly homotopic to the identity of } U, \end{aligned}$$

so π is a deformation retraction, and $H^k(U) \approx H^k(M)$; thus M has the same de Rham cohomology as an open neighborhood. Moreover, if we choose a Riemannian metric (\cdot, \cdot) for $\pi : U \rightarrow M$ and define $D = \{e \in U : (e, e) \leq 1\}$, then D is a submanifold-with-boundary of U , and the map $\pi|_D : D \rightarrow M$ is also a deformation retraction. So M also has the same de Rham cohomology as a closed neighborhood.

19. LEMMA. Let X be a compact metric space and $X_0 \subset X$ a closed subset. Let $f : X \rightarrow Y$ be a local homeomorphism such that $f|_{X_0}$ is one-one. Then there is a neighborhood U of X_0 such that $f|_U$ is one-one.

PROOF. Let $C \subset X \times X$ be

$$\{(x, y) \in X \times X : x \neq y \text{ and } f(x) = f(y)\}.$$

Then C is closed, for if (x_n, y_n) is a sequence in C with $x_n \rightarrow x$ and $y_n \rightarrow y$, then $f(x) = \lim f(x_n) = \lim f(y_n) = f(y)$, and also $x \neq y$ since f is locally one-one.

If $g: C \rightarrow \mathbb{R}$ is $g(x, y) = d(x, X_0) + d(y, X_0)$, then $g > 0$ on C . Since C is compact, there is $\varepsilon > 0$ such that $g \geq 2\varepsilon$ on C . Then f is one-one on the ε -neighborhood of X_0 . ♦

20. THEOREM. Let $M \subset N$ be a compact submanifold of N . Then M has a tubular neighborhood $\pi: U \rightarrow M$ in N , which is equivalent to the normal bundle of M in N .

PROOF. Choose a Riemannian metric (\cdot, \cdot) for N , with the corresponding norm $\|\cdot\|$, and metric $d: N \times N \rightarrow \mathbb{R}$. Let

$$\begin{aligned} E &= \{v : v \in N_p \text{ and } v \in M_p^\perp, \text{ for some } p \in M\} \\ E_\varepsilon &= \{v \in E : \|v\| < \varepsilon\} \\ U_\varepsilon &= \{q \in N : d(q, M) < \varepsilon\}. \end{aligned}$$

It follows easily from Theorem 13, and compactness of M , that \exp is defined on E_ε for sufficiently small $\varepsilon > 0$. We claim that for sufficiently small ε , the map \exp is a diffeomorphism from E_ε onto U_ε . This will clearly prove the theorem.

Let $V \subset E$ be the set of a non-critical points for \exp . Then $V \supset M$ (considered as a subset of E via the 0-section), and $V_1 = \overline{V \cap E_1}$ is compact; since \exp is one-one on $M \subset V_1$, it follows from Lemma 19 that for sufficiently small ε the map \exp is a diffeomorphism on E_ε .

It is clear also that $\exp(E_\varepsilon) \subset U_\varepsilon$. To prove that \exp is onto U_ε , choose any $q \in U_\varepsilon$, and a point $p \in M$ closest to q . If $\gamma: [0, 1] \rightarrow N$ is the geodesic of length $< \varepsilon$ with $\gamma(0) = p$ and $\gamma(1) = q$, it is easy to see that γ is perpendicular to M at p (compare the second proof of Gauss' Lemma). This means that $q = \exp_p d\gamma/dt(0)$ where $d\gamma/dt(0) \in E_\varepsilon$. ♦

One of the interesting features of Theorem 20 is that all the paraphernalia of Riemannian metrics and geodesics are used in its proof, while they do not even appear in the statement. Theorem 20 will be needed only in Chapter 11, where we will also need the following modification.

21. THEOREM. Let N be a manifold-with-boundary, with compact boundary ∂N . Then ∂N has (arbitrarily small) open [and closed] neighborhoods for which there are deformation retractions onto ∂N .

PROOF. Exactly the same as the proof of Theorem 20, using only inward pointing normal vectors. ♦

PROBLEMS

1. Let V be a vector space over a field F of characteristic $\neq 2$, and let $h: V \times V \rightarrow F$ be symmetric and bilinear.

(a) Define $q: V \rightarrow F$ by $q(v) = h(v, v)$. Show that if ϕ_1, \dots, ϕ_n is a basis for V^* , then

$$q = \sum_{i,j=1}^n a_{ij} v_i^* \cdot v_j^*$$

for some a_{ij} .

(b) Show that

$$q(-v) = q(v)$$

$$h(u, v) = \frac{1}{2}[q(u+v) - q(u) - q(v)].$$

(c) Suppose $q: V \rightarrow F$ satisfies $q(-v) = q(v)$, and that $h(u, v) = q(u+v) - q(u) - q(v)$ is bilinear. Show that

$$q(u+v+w) - q(u) - q(v+w) = q(u+v) - q(u) - q(v) - q(u+w) + q(u) + q(w).$$

Conclude that $q(0) = 0$, and $q(2u) = 4q(u)$. Then show that $q(v) = h(v, v)$.

2. Let (\cdot, \cdot) be a Euclidean metric for V^* . Suppose $\phi_i, \psi_i \in V^*$ satisfy $\phi_1 \wedge \dots \wedge \phi_k = \psi_1 \wedge \dots \wedge \psi_k \neq 0$, and let W_ϕ and W_ψ be the subspaces of V^* spanned by the ϕ_i and ψ_i .

(a) Show that $\omega \in W_\phi$ if and only if $\omega \wedge \phi_1 \wedge \dots \wedge \phi_k = 0$. Conclude that $W_\phi = W_\psi$.

(b) Let $\sigma_1, \dots, \sigma_k$ be an orthonormal basis of $W_\phi = W_\psi$. If $\phi_i = \sum_j a_{ji} \sigma_j$, show that the signed k -dimensional volume of the parallelepiped spanned by ϕ_1, \dots, ϕ_k is $\det(a_{ij})$. (The sign is $+$ if ϕ_1, \dots, ϕ_k has the same orientation as $\sigma_1, \dots, \sigma_k$, and $-$ otherwise.)

(c) Using Problem 7-9, show that this volume is the same for ψ_1, \dots, ψ_k .

(d) Conversely, if $W_\phi = W_\psi$, and the signed volumes of the parallelepipeds are the same, show that $\phi_1 \wedge \dots \wedge \phi_k = \psi_1 \wedge \dots \wedge \psi_k$.

If we identify V with V^{**} , so that we have a wedge product $v_1 \wedge \dots \wedge v_k$ of vectors $v_i \in V$, then we have a geometric condition for equality with $w_1 \wedge \dots \wedge w_k$. In *Leçons sur la Géométrie des Espaces de Riemann*, É. Cartan uses this condition to define $\Omega^k(V^*)$ as formal sums of equivalence classes of k vectors; he deduces geometrically the corresponding conditions on the coordinates of v_i, w_i .

3. Let V be an n -dimensional vector space, and (\cdot, \cdot) an inner product on V which is not necessarily positive definite. A basis v_1, \dots, v_n for V is called **orthonormal** if $(v_i, v_j) = \pm \delta_{ij}$.

- (a) If $V \neq \{0\}$, then there is a vector $v \in V$ with $(v, v) \neq 0$.
- (b) For $W \subset V$, let $W^\perp = \{v \in V : (v, w) = 0 \text{ for all } w \in W\}$. Prove that $\dim W^\perp \geq n - \dim W$. *Hint:* If $\{w_i\}$ is a basis for W , consider the linear functionals $\lambda_i: V \rightarrow \mathbb{R}$ defined by $\lambda_i(v) = (v, w_i)$.
- (c) If $(\ , \)$ is non-degenerate on W , then $V = W \oplus W^\perp$, and $(\ , \)$ is also non-degenerate on W^\perp .
- (d) V has an orthonormal basis. Thus, there is an isomorphism $f: \mathbb{R}^n \rightarrow V$ with $f^*(\ , \) = (\ , \)_r$ for some r (the inner product $(\ , \)_r$ is defined on page 301).
- (e) The **index** of $(\ , \)$ is the largest dimension of a subspace $W \subset V$ such that $(\ , \)|_W$ is negative definite. Show that the index is $n - r$, thus showing that r is unique ("Sylvester's Law of Inertia").
4. Let $(\ , \)$ be a (possibly non-positive definite) inner product on V , and let v_1, \dots, v_n be an orthonormal basis (see Problem 3). Define an inner product $(\ , \)^k$ on $\Omega^k(V)$ by requiring that

$$v_{i_1}^* \wedge \cdots \wedge v_{i_k}^* \quad 1 \leq i_1 < \cdots < i_k \leq n$$

be an orthonormal basis, with

$$\langle v_{i_1}^* \wedge \cdots \wedge v_{i_k}^*, v_{j_1}^* \wedge \cdots \wedge v_{j_k}^* \rangle^k = \det((v_{i_\alpha}, v_{j_\beta})).$$

- (a) Show that $(\ , \)^k$ is independent of the basis v_1, \dots, v_n . (Use Problem 7-16.)
- (b) Show that

$$(\phi_1 \wedge \cdots \wedge \phi_k, \psi_1 \wedge \cdots \wedge \psi_k)^k = \det((\phi_i, \psi_j)^*) = \det((\phi_i, \psi_j)^1).$$

- (c) If $(\ , \)$ has index i , then

$$(v_1^* \wedge \cdots \wedge v_n^*, v_1^* \wedge \cdots \wedge v_n^*)^n = (-1)^i.$$

- (d) For those who know about \otimes and Λ^k . Using the isomorphisms $\otimes^k V^* \approx (\otimes^k V)^*$ and $\Lambda^k(V^*) \approx (\Lambda^k V)^*$, define inner products on $\otimes^k V$ and $\Lambda^k V$ by using the isomorphism $V \rightarrow V^*$ given by the inner product on V . Show that these inner products agree with the ones defined above.

5. Recall the definition of $v_1 \times \cdots \times v_{n-1}$ in Problem 7-26.

- (a) Show that $\langle v_1 \times \cdots \times v_{n-1}, v_i \rangle = 0$.
- (b) Show that $|v_1 \times \cdots \times v_{n-1}| = \sqrt{\det(g_{ij})}$, where $g_{ij} = \langle v_i, v_j \rangle$. *Hint:* Apply the result on page 308 to a certain $(n-1)$ -dimensional subspace of \mathbb{R}^n .

6. Let $\xi = \pi: E \rightarrow B$ be a vector bundle. An **indefinite metric** on ξ is a continuous choice of a non-positive definite inner product $(\ , \)_p$ on each $\pi^{-1}(p)$. Show that the index of $(\ , \)_p$ is constant on each component of B .

7. This problem requires a little knowledge of simple-connectedness and covering spaces.

(a) There is no way of continuously choosing a 1-dimensional subspace of S^2_p , for each $p \in S^2$. (Consider the space consisting of the two unit vectors in each subspace.)

(b) There is no Riemannian metric of index 1 on S^2 .

8. Let $(\ , \)$ and $(\ , \)'$ be two Riemannian metrics on a vector bundle $\xi = \pi: E \rightarrow B$. Let S be the set of $e \in E$ with $(e, e) = 1$, and define S' similarly. Show that S is homeomorphic to S' . If ξ is a smooth bundle over a manifold M , show that S is diffeomorphic to S' .

9. Show by a computation that if the functions g_{ij} and g'_{ij} are related by

$$g'_{\alpha\beta} = \sum_{i,j} g_{ij} \frac{\partial x^i}{\partial x'^\alpha} \frac{\partial x^j}{\partial x'^\beta},$$

with $\det(g_{ij}) \neq 0$, and the functions g^{ij} , g'^{ij} are defined by

$$\sum_{k=1}^n g^{ik} g_{kj} = \delta_j^i, \quad \sum_{k=1}^n g'^{ik} g'_{kj} = \delta_j^i,$$

then

$$g'^{\alpha\beta} = \sum_{i,j} g^{ij} \frac{\partial x'^\alpha}{\partial x^i} \frac{\partial x'^\beta}{\partial x^j}.$$

This, of course, is the classical way of defining the tensor [having the components] g^{ij} .

10. (a) Let $(\ , \)$ be a Riemannian metric on M , and A a tensor of type $\binom{1}{1}$, so that $A(p): M_p \rightarrow M_p$. Define a tensor B of type $\binom{2}{0}$ by

$$B(p)(v_1, v_2) = (A(p)(v_1), v_2).$$

If the expression for A in a coordinate system is

$$A = \sum_{i,j=1}^n A_i^j dx^i \otimes \frac{\partial}{\partial x^j},$$

show that $B = \sum_{i,k} B_{ik} dx^i \otimes dx^k$, where

$$B_{ik} = \sum_{j=1}^n A_i^j g_{jk}.$$

(b) Similarly, define a tensor C of type $\binom{0}{2}$ by

$$C(p)(\lambda_1, \lambda_2) = (A(p))^*(\lambda_1), \lambda_2).$$

Show that if C has components C^{kj} , then

$$C^{kj} = \sum_{i=1}^n g^{ki} A_i^j.$$

The tensors B and C are said to be obtained from A by “raising and lowering indices”.

11. (a) Let X_1, \dots, X_n be linearly independent vector fields on a manifold M with a Riemannian metric (\cdot, \cdot) . Show that the Gram-Schmidt process can be applied to the vector fields all at once, so that we obtain n everywhere orthonormal vector fields Y_1, \dots, Y_n .

(b) For the case of a non-positive definite metric, find Y_1, \dots, Y_n with $(Y_i, Y_j) = \pm \delta_{ij}$ in a neighborhood of any point.

12. (a) If $f: [a, b] \rightarrow \mathbb{R}$ is positive, show that the area of the surface obtained by revolving the graph of f around the x -axis is

$$\int_a^b 2\pi f \sqrt{1 + (f')^2}.$$

(b) Compute the area of S^2 .

13. Let $M \subset \mathbb{R}^n$ be an $(n-1)$ -dimensional submanifold with orientation μ . The **outward unit normal** $\nu(p)$ at $p \in M$ is defined to be that vector in \mathbb{R}^n_p of length 1 such that $\nu(p), (v_1)_p, \dots, (v_{n-1})_p$ is positively oriented in \mathbb{R}^n_p when $(v_1)_p, \dots, (v_{n-1})_p$ is positively oriented in M_p .

(a) If $M = \partial N$ for an n -dimensional manifold-with-boundary $N \subset \mathbb{R}^n$, then $\nu(p)$ is outward pointing in the sense of Chapter 8.

(b) Let dV_{n-1} be the volume element of M determined by the Riemannian metric it acquires as a submanifold of \mathbb{R}^n . Show that if we consider $\nu(p)$ as an element of \mathbb{R}^n , then

$$dV_{n-1}(p)((v_1)_p, \dots, (v_{n-1})_p) = \det \begin{pmatrix} \nu(p) \\ v_1 \\ \vdots \\ v_{n-1} \end{pmatrix}.$$

Conclude that $dV_{n-1}(p)$ is the restriction to M_p of

$$\sum_{i=1}^n (-1)^{i-1} v^i(p) dx^1(p) \wedge \cdots \wedge \widehat{dx^i(p)} \wedge \cdots \wedge dx^n(p).$$

(c) Note that $v_1 \times \cdots \times v_{n-1} = \alpha v(p)$ for some $\alpha \in \mathbb{R}$ (by Problem 5). Show that for $w \in \mathbb{R}^n$ we have

$$(w, v(p)) \cdot (v_1 \times \cdots \times v_{n-1}, v(p)) = (w, v_1 \times \cdots \times v_{n-1}).$$

Conclude that

$$v^i(p) \cdot dV_{n-1}(p) = \text{restriction to } M_p \text{ of} \\ (-1)^{i-1} dx^1(p) \wedge \cdots \wedge \widehat{dx^i(p)} \wedge \cdots \wedge dx^n(p).$$

(d) Let $M \subset \mathbb{R}^n$ be a compact n -dimensional manifold-with-boundary, with v the outward unit normal on ∂M . Denote the volume element of M by dV_n , and that of ∂M by dV_{n-1} . Let $X = \sum_i a^i \partial/\partial x^i$ be a vector field on M . Prove the *Divergence Theorem*:

$$\int_M \operatorname{div} X dV_n = \int_{\partial M} (X, v) dV_{n-1}$$

(the function $\operatorname{div} X$ is defined in Problem 7-27). *Hint*: Consider the form ω on M defined by

$$\omega = \sum_{i=1}^n (-1)^{i-1} a^i dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^n.$$

(e) Let $M \subset \mathbb{R}^3$ be a compact 2-dimensional manifold-with-boundary, with orientation μ , and outward unit normal v . Let T be the vector field on ∂M consisting of positively oriented unit vectors. Denote the volume element of M by dA , and that of ∂M by ds . Let X be a vector field on M . Prove (the original) *Stokes' Theorem*:

$$\int_M (\nabla \times X, v) dA = \int_{\partial M} (X, T) ds$$

($\nabla \times X$ is defined in Problem 7-27).

14. (a) Let V_n be the volume of the unit ball in \mathbb{R}^n . Show that

$$V_n = \int_{-1}^1 (1-x^2)^{(n-1)/2} V_{n-1} dx.$$

(b) If $I_n = \int_{-1}^1 (1 - x^2)^{(n-1)/2} dx$, show that

$$I_n = \frac{n-1}{n} I_{n-2}.$$

(c) Using $V_1 = 2$, $V_2 = \pi$, show that

$$V_n = \begin{cases} \frac{\pi^{n/2}}{(n/2)!} & n \text{ even} \\ \frac{2^{(n+1)/2} \pi^{(n-1)/2}}{1 \cdot 3 \cdot 5 \cdots n} & n \text{ odd.} \end{cases}$$

(In terms of the Γ function, this can be written $\frac{\pi^{n/2}}{\Gamma(1 + n/2)}$.)

(d) Let A_{n-1} be the $(n-1)$ -volume of S^{n-1} . Using the method of proof in Corollary 8-8, but reversing the order of integration, show that

$$V_n = \int_0^1 r^{n-1} A_{n-1} dr = \frac{1}{n} A_{n-1}.$$

(e) Obtain this same result by applying the Divergence Theorem (Problem 13), with $X(p) = p_p$.

15. (a) Let $c: [0, 1] \rightarrow \mathbb{R}^n$ be a differentiable curve, where \mathbb{R}^n has the usual Riemannian metric $(\cdot, \cdot) = \sum_i dx^i \otimes dx^i$. Show that

$$L(c) = \int_0^1 \sqrt{\sum_{i=1}^n [(c^i)'(t)]^2} dt.$$

(b) For the special case $c: [0, 1] \rightarrow \mathbb{R}^2$ given by $c(t) = (t, f(t))$, show that this length,

$$\int_0^1 \sqrt{1 + [f'(t)]^2} dt,$$

is the least upper bound of the lengths of inscribed polygonal curves.

Hint: If the inscribed polygonal curve is determined by the points $(t_i, c(t_i))$ for

a partition $0 = t_0 < \cdots < t_n = 1$ of $[0, 1]$, then we have

$$\begin{aligned} |c(t_i) - c(t_{i-1})| &= \sqrt{(t_i - t_{i-1})^2 + (f(t_i) - f(t_{i-1}))^2} \\ &= \sqrt{(t_i - t_{i-1})^2 + f'(\xi_i)(t_i - t_{i-1})^2} \end{aligned}$$

for some $\xi_i \in [t_{i-1}, t_i]$.

(c) Prove the same result in the general case. *Hint:* Use the results of Problem 8-1, and uniform continuity of $\sqrt{\quad}$ on a compact set.

It is natural to suppose that the area of a surface is, similarly, the least upper bound of the areas of inscribed polygonal surfaces, but as H. Schwarz first observed, this least upper bound is infinite for a bounded portion of a cylinder! To illustrate Schwarz's example I have plagiarized the following picture from a book called *Математический Анализ на Многообразиях*, written by someone called М. Спивак.

To increase the number of triangles, we maintain the hexagonal arrangement, but move the planes of the hexagons closer together, so that the triangles are more nearly in a plane parallel to the bases of the cylinder. In this way, we can increase the number of triangles indefinitely, while the area of each approaches $hl/2$.

The topic of surface area for non-differentiable surfaces is a complex one, which we will not go into here.

16. Let $c: [0, 1] \rightarrow M$ be a curve in a manifold M with a Riemannian metric (\cdot, \cdot) . If $p: [0, 1] \rightarrow [0, 1]$ is a diffeomorphism, show that

$$L(c) = L(c \circ p).$$

17. Show that the metric d on M may be defined using C^∞ , instead of piecewise C^∞ curves. (Show how to round off corners of a piecewise C^∞ path so that the length increases by less than any given $\varepsilon > 0$; remember that the formula for length involves only first derivatives.)

18. (a) Let $B \subset M$ be homeomorphic to the ball $\{p \in \mathbb{R}^n : |p| \leq 1\}$ and let $S \subset M$ be the subset corresponding to $\{p \in \mathbb{R}^n : |p| = 1\}$. Show that $M - S$ is disconnected, by showing that $M - B$ and $B - S$ are disjoint open subsets of $M - S$.

(b) If $p \in B - S$ and $q \in M - B$, show that $d(p, q) \geq \min_{q' \in S} d(p, q')$. Use this fact and Lemma 7' to complete the proof of Theorem 7. (In the theory of infinite dimensional manifolds, these details become quite important, for $M - S$ does *not* have to be disconnected, and Theorem 7 is false.)

19. (a) By applying integration by parts to the equation on pages 318–319, show that

$$\left. \frac{dJ(\bar{\alpha}(u))}{du} \right|_{u=0} = \int_a^b \frac{\partial^2 \alpha}{\partial u \partial t}(0, t) \left[\frac{\partial F}{\partial y}(t, f(t), f'(t)) - \int_a^t \frac{\partial F}{\partial x}(t, f(t), f'(t)) dt \right] dt;$$

this result makes sense even if f is only C^1 .

(b) *Du Bois Reymond's Lemma*. If a continuous function g on $[a, b]$ satisfies

$$\int_a^b \eta'(t)g(t) dt = 0$$

for all C^∞ functions η on $[a, b]$ with $\eta(a) = \eta(b) = 0$, then g is a constant.

Hint: The constant c must be

$$c = \frac{1}{b-a} \int_a^b g(u) du.$$

We clearly have

$$\int_a^b \eta'(t)[g(t) - c] dt = 0,$$

so we need to find a suitable η with $\eta'(t) = g(t) - c$.

(c) Conclude that if the C^1 function f is a critical point of J , then f still satisfies the Euler equations (which are not *a priori* meaningful if f is not C^2).

20. The hyperbolic sine, hyperbolic cosine, and hyperbolic tangent functions \sinh , \cosh , and \tanh are defined by

$$\sinh x = \frac{e^x - e^{-x}}{2}, \quad \cosh x = \frac{e^x + e^{-x}}{2}, \quad \tanh x = \frac{\sinh x}{\cosh x}.$$

(a) Graph \sinh , \cosh , and \tanh .

(b) Show that

$$\cosh^2 - \sinh^2 = 1$$

$$\tanh^2 + 1/\cosh^2 = 1$$

$$\sinh(x + y) = \sinh x \cosh y + \cosh x \sinh y$$

$$\cosh(x + y) = \cosh x \cosh y + \sinh x \sinh y$$

$$\sinh' = \cosh$$

$$\cosh' = \sinh.$$

(c) For those who know about complex power series:

$$\sinh x = \frac{\sin ix}{i}, \quad \cosh x = \cos ix.$$

(d) The inverse functions of \sinh and \tanh are denoted by \sinh^{-1} and \tanh^{-1} , respectively, while \cosh^{-1} denotes the inverse of $\cosh | [0, \infty)$. Show that

$$\sinh(\cosh^{-1} x) = \sqrt{x^2 - 1}$$

$$\cosh(\sinh^{-1} x) = \sqrt{1 + x^2}$$

$$\cosh(\tanh^{-1} x) = \frac{1}{\sqrt{1 - x^2}}$$

$$(\sinh^{-1})'(x) = \frac{1}{\sqrt{1 + x^2}}$$

$$(\cosh^{-1})'(x) = \frac{1}{\sqrt{x^2 - 1}}.$$

21. Consider the problem of finding a surface of revolution joining two circles of radius 1, situated, for convenience, at a and $-a$. We are looking for a function

of the form

$$f(x) = c \cosh \frac{x}{c}$$

where c is supposed to satisfy

$$c \cosh \frac{a}{c} = 1 \quad (c > 0).$$

- (a) There is a unique $y_0 > 0$ with $\tanh y_0 = 1/y_0$. Examine the sign of $1/y - \tanh y$ for $y > 0$.
 (b) Examine the sign of $\cosh y - y \sinh y$ for $y > 0$.
 (c) Let

$$A_a(c) = c \cosh \frac{a}{c} \quad c > 0.$$

Show that A_a has a minimum at a/y_0 , find the value of A_a there, and sketch the graph.

- (d) There exists c with $c \cosh a/c = 1$ if and only if $a \leq y_0/\cosh y_0$. If $a = y_0/\cosh y_0$, then there is a unique such c , namely $c = a/y_0 = 1/\cosh y_0$. If $a < y_0/\cosh y_0$, then there are two such c , with $c_1 < a/y_0 < c_2$. It turns out that the surface for c_2 has smaller area.

- (e) Using Problem 20(d), show that

$$\frac{y_0}{\cosh y_0} = \sqrt{y_0^2 - 1}.$$

[$y_0 \sim 1.2$, so $\sqrt{y_0^2 - 1} \sim .67$.]

[These phenomena can be pictured more easily if we use the notion of an envelope—c.f. Volume III, pp. 176ff. The envelope of the 1-parameter family of curves

$$f_c(x) = c \cosh \frac{x}{c}$$

is determined by solving the equations

$$0 = \frac{\partial f_c(x)}{\partial c} = \cosh \frac{x}{c} - \frac{x}{c} \sinh \frac{x}{c}.$$

We obtain

$$\frac{x}{c} = \pm y_0, \quad y = c \cosh \frac{x}{c} = c \cosh y_0,$$

so the envelope consists of the straight lines

$$y = \pm \frac{\cosh y_0}{y_0} x.$$

The unique member of the family through $(y_0/\cosh y_0, 1)$ is tangent to the envelope at that point. For $a < y_0/\cosh y_0$, the graph of f_{c_1} is tangent to

the envelope at points $P, Q \in (-a, a)$, but the graph of f_{c_2} is tangent to the envelope at points outside $[-a, a]$. The point Q is called **conjugate** to P along the extremal f_{c_1} , and it is shown in the calculus of variations that the existence of this conjugate point implies that the portion of f_{c_1} from P to $(a, 1)$ does *not*

give a local minimum for $\int f\sqrt{1+(f')^2}$. (Compare with the discussion of conjugate points of a geodesic in Volume IV, Chapter 8, and note the remark on pg. V.396.)]

22. All of our illustrations of calculus of variations problems involved an F which does not involve t , so that the Euler equations are actually

$$\frac{\partial F}{\partial x}(f(t), f'(t)) - \frac{d}{dt} \left(\frac{\partial F}{\partial y}(f(t), f'(t)) \right) = 0.$$

(a) Show that for any f and $F: \mathbb{R}^2 \rightarrow \mathbb{R}$ we have

$$\frac{d}{dt} \left(F - f' \frac{\partial F}{\partial y} \right) = f' \left[\frac{\partial F}{\partial x} - \frac{d}{dt} \frac{\partial F}{\partial y} \right],$$

and conclude that the extremals for our problem satisfy

$$F - f' \frac{\partial F}{\partial y} = 0.$$

(b) Apply this to $F(x, y) = x\sqrt{1+y^2}$ to obtain directly the equation $dy/dx = \sqrt{c^2 y^2 - 1}$ which we eventually obtained in our solution to the problem.

23. (a) Let x and x' be two coordinate systems, with corresponding g_{ij} and g'_{ij} for the expression of a Riemannian metric. Show that

$$\begin{aligned} \frac{\partial g'_{\alpha\beta}}{\partial x'^\gamma} &= \sum_{i,j,k=1}^n \frac{\partial g_{ij}}{\partial x^k} \frac{\partial x^k}{\partial x'^\gamma} \frac{\partial x^i}{\partial x'^\alpha} \frac{\partial x^j}{\partial x'^\beta} \\ &\quad + \sum_{i,j=1}^n g_{ij} \left(\frac{\partial x^i}{\partial x'^\alpha} \frac{\partial^2 x^j}{\partial x'^\beta \partial x'^\gamma} + \frac{\partial x^j}{\partial x'^\beta} \frac{\partial^2 x^i}{\partial x'^\alpha \partial x'^\gamma} \right). \end{aligned}$$

(b) For the corresponding $[ij, k]$ and $[\alpha\beta, \gamma]'$, show that

$$[\alpha\beta, \gamma]' = \sum_{i,j,k=1}^n [ij, k] \frac{\partial x^i}{\partial x'^\alpha} \frac{\partial x^j}{\partial x'^\beta} \frac{\partial x^k}{\partial x'^\gamma} + \sum_{i,j=1}^n \frac{\partial x^i}{\partial x'^\gamma} \frac{\partial^2 x^j}{\partial x'^\alpha \partial x'^\beta},$$

so that $[ij, k]$ are not the components of a tensor.

(c) Also show that

$$\Gamma'^\gamma_{\alpha\beta} = \sum_{i,j,k=1}^n \Gamma^k_{ij} \frac{\partial x^i}{\partial x'^\alpha} \frac{\partial x^j}{\partial x'^\beta} \frac{\partial x^k}{\partial x'^\gamma} + \sum_{l=1}^n \frac{\partial^2 x^l}{\partial x'^\alpha \partial x'^\beta} \frac{\partial x'^\gamma}{\partial x^l}.$$

24. Show that any C^∞ structure on \mathbb{R} is diffeomorphic to the usual C^∞ structure. (Consider the arclength function on a geodesic for some Riemannian metric on \mathbb{R} .)

25. Let $(\ , \) = \sum_i dx^i \otimes dx^i$ be the usual Riemannian metric on \mathbb{R}^n , and let $\sum_{i,j} g_{ij} du^i \otimes du^j$ be another metric, where u^1, \dots, u^n again denotes the standard coordinate system on \mathbb{R}^n . Suppose we are told that there is a diffeomorphism $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that $\sum_{i,j} g_{ij} du^i \otimes du^j = f^*(\ , \)$. How can we go about finding f ?

(a) Let $\partial f / \partial u^i = e_i: \mathbb{R}^n \rightarrow \mathbb{R}^n$. If we consider e_i as a vector field on \mathbb{R}^n , show that $f_*(\partial / \partial u^i) = e_i$.

(b) Show that $g_{ij} = (e_i, e_j)$.

(c) To solve for f it is, in theory at least, sufficient to solve for the e_i , and to solve for these we want to find differential equations

$$\frac{\partial e_i}{\partial u^j} = \sum_{r=1}^n A_{ij}^r e_r$$

satisfied by the e_i 's. Show that we must have

$$B_{ij,k} \stackrel{\text{def}}{=} \sum_{r=1}^n g_{kr} A_{ij}^r = \sum_{l=1}^n \frac{\partial^2 f^l}{\partial u^i \partial u^j} \cdot \frac{\partial f^l}{\partial u^k}.$$

(d) Show that

$$\begin{aligned} \frac{\partial g_{ij}}{\partial u^k} &= \sum_{l=1}^n \frac{\partial^2 f^l}{\partial u^i \partial u^k} \frac{\partial f^l}{\partial u^j} + \frac{\partial^2 f^l}{\partial u^j \partial u^k} \frac{\partial f^l}{\partial u^i} \\ &= \sum_{r=1}^n g_{jr} A_{ik}^r + g_{ir} A_{kj}^r \\ &= B_{ik,j} + B_{kj,i}. \end{aligned}$$

(e) By cyclically permuting i, j, k , deduce that

$$B_{ij,k} = [ij, k],$$

so that $A_{ij}^r = \Gamma_{ij}^r$. In *Leçons sur la Géométrie des Espaces de Riemann*, É. Cartan uses this approach to motivate the introduction of the Γ_{ij}^k .

(f) Deduce the result $A_{ij}^r = \Gamma_{ij}^r$ directly from our equations for a geodesic. (Note that the curves obtained by setting all but one f^i constant are geodesics, since they correspond to lines parallel to the x^i -axis.)

26. If $(V', (\cdot, \cdot)')$ and $(V'', (\cdot, \cdot)'')$ are two vector spaces with inner products, we define (\cdot, \cdot) on $V = V' \oplus V''$ by

$$(v' \oplus v'', w' \oplus w'') = (v', w')' + (v'', w'')''.$$

(a) Show that (\cdot, \cdot) is an inner product.

(b) Given Riemannian metrics on M and N , it follows that there is a natural way to put a Riemannian metric on $M \times N$. Describe the geodesics on $M \times N$ for this metric.

27. (a) Let $\gamma: [a, b] \rightarrow M$ be a geodesic, and let $p: [\alpha, \beta] \rightarrow [a, b]$ be a diffeomorphism. Show that $c = \gamma \circ p$ satisfies

$$\frac{d^2 c^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(c(t)) \frac{dc^i}{dt} \frac{dc^j}{dt} = \frac{dc^k}{dt} \frac{p''(t)}{p'(t)}.$$

(b) Conversely, if c satisfies this equation, then γ is a geodesic.

(c) If c satisfies

$$\frac{d^2 c^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(c(t)) \frac{dc^i}{dt} \frac{dc^j}{dt} = \frac{dc^k}{dt} \mu(t) \quad \text{for } \mu: \mathbb{R} \rightarrow \mathbb{R},$$

then c is a reparameterization of a geodesic. (The equation $p''(t) = p'(t)\mu(t)$ can be solved explicitly: $p(t) = \int^t e^{M(s)} ds$, where $M'(s) = \mu(s)$.)

28. Let c be a curve in M with $dc/dt \neq 0$ everywhere, and consider the hypersurfaces

$$\{\exp_{c(t)} v : \|v\| = \text{constant, where } v \in M_{c(t)} \text{ with } (v, dc/dt) = 0\}.$$

Show that for $v \in M_{c(t)}$ with $(v, dc/dt) = 0$, the geodesic $u \mapsto \exp_{c(t)} u \cdot v$ is perpendicular to these hypersurfaces. (Gauss' Lemma is the "special case" where c is constant.)

29. Let $\gamma: [a, b] \rightarrow M$ be a geodesic with $\gamma(a) = p$, and suppose that \exp_p is a diffeomorphism on a neighborhood $\mathcal{O} \subset M_p$ of $\{t\gamma'(0) : 0 \leq t \leq 1\}$. Show that γ is a curve of minimal length between p and $q = \gamma(b)$, among all curves in $\exp(\mathcal{O})$. (Gauss' Lemma still works on $\exp(\mathcal{O})$.)

30. If (\cdot, \cdot) is a Riemannian metric on M and $d: M \times M \rightarrow \mathbb{R}$ is the corresponding metric, then a curve $\gamma: [a, b] \rightarrow M$ with $d(\gamma(a), \gamma(b)) = L(\gamma)$ is a geodesic.

31. Schwarz's inequality for continuous functions states that

$$\left(\int_a^b fg \right)^2 \leq \left(\int_a^b f^2 \right) \left(\int_a^b g^2 \right),$$

with equality if and only if f and g are linearly dependent (over \mathbb{R}).

(a) Prove Schwarz's inequality by imitating the proof of Theorem 1(2).

(b) For any curve γ show that

$$[L_a^b(\gamma)]^2 \leq (b - a) E_a^b(\gamma),$$

with equality if and only if γ is parameterized proportionally to arclength.

(c) Let $\gamma: [a, b] \rightarrow M$ be a geodesic with $L_a^b(\gamma) = d(\gamma(a), \gamma(b))$. If $c(a) = \gamma(a)$ and $c(b) = \gamma(b)$, show that

$$E(\gamma) = \frac{L(\gamma)^2}{b - a} \leq \frac{L(c)^2}{b - a} \leq E(c).$$

Conclude that $E(\gamma) < E(c)$ unless c is also a geodesic with

$$L_a^b(c) = d(c(a), c(b)).$$

In particular, sufficiently small pieces of a geodesic minimize energy.

32. Let p be a point of a manifold M with a Riemannian metric (\cdot, \cdot) . Choose a basis v_1, \dots, v_n of M_p , so that we have a "rectangular" coordinate system χ on M_p given by $\sum_i a^i v_i \mapsto (a^1, \dots, a^n)$; let x be the coordinate system $\chi \circ \exp^{-1}$, defined in a neighborhood U of p .

(a) Show that in this coordinate system we have $\Gamma_{ij}^k(p) = 0$. *Hint:* Recall the equations for a geodesic, and note that a geodesic γ through p is just \exp composed with a straight line through 0 in M_p , so that each γ^k is linear.

(b) Let $r: U \rightarrow \mathbb{R}$ be $r(q) = d(p, q)$, so that $r \circ \gamma = \sum_k (\gamma^k)^2$. Show that

$$\frac{d^2(r \circ \gamma)^2}{dt^2} = 2 \left[\sum_k \left(\frac{d\gamma^k}{dt} \right)^2 - \sum_{i,j,k} \gamma^2 \Gamma_{ij}^k \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} \right].$$

(c) Note that

$$\sum_{i,j} \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} \leq n^2 \sum_k \left(\frac{d\gamma^k}{dt} \right)^2.$$

Using part (a), conclude that if $\|\gamma'(0)\|$ is sufficiently small, then

$$\frac{d^2(r \circ \gamma)^2}{dt^2} > 0,$$

so that $d(r \circ \gamma)^2/dt$ is strictly increasing in a neighborhood of 0.

(d) Let $B_\varepsilon = \{v \in M_p : \|v\| \leq \varepsilon\}$ and $S_\varepsilon = \{v \in M_p : \|v\| = \varepsilon\}$. Show that the following is true for all sufficiently small $\varepsilon > 0$: if γ is a geodesic such that $\gamma(0) \in \exp(S_\varepsilon)$ and such that $\gamma'(0)$ is tangent to $\exp(S_\varepsilon)$, then there is $\delta > 0$ (depending on γ) such that $\gamma(t) \notin \exp(B_\varepsilon)$ for $0 \neq t \in (-\delta, \delta)$. *Hint*: If $\gamma'(0)$ is

tangent to $\exp(S_\varepsilon)$, then $d(r \circ \gamma)/dt = 0$.

(e) Let q and q' be two points with $r(q), r(q') < \varepsilon$ and let γ be the unique geodesic of length $< 2\varepsilon$ joining them. Show that for sufficiently small ε the maximum of $r \circ \gamma$ occurs at either q or q' .

(f) A set $U \subset M$ is **geodesically convex** if every pair $q, q' \in U$ has a unique geodesic of minimum length between them, and this geodesic lies completely in U . Show that $\exp(\{v \in M_p : \|v\| < \varepsilon\})$ is geodesically convex for sufficiently small $\varepsilon > 0$.

(g) Let $f: U \rightarrow \mathbb{R}^n$ be a diffeomorphism of a neighborhood U of $0 \in \mathbb{R}^n$ into \mathbb{R}^n . Show that for sufficiently small ε , the image of the open ε -ball is convex.

33. (a) There is an everywhere differentiable curve $c(t) = (t, f(t))$ in \mathbb{R}^2 such that

$$\lim_{h \rightarrow 0} \frac{\text{length of } c|_{[0, h]}}{|c(h) - c(0)|} \neq 1.$$

Hint: Make c look something like the following picture.

(b) Consider the situation in Corollary 15, except that $c(t) = q$ if and only if $t = a$, and suppose $u'(t) > 0$ for t near 0. If c is C^1 , then $v(t)$ approaches a limit as $t \rightarrow 0$ (even though $v(0)$ is undefined). Show that if c is C^1 , then there is some $K > 0$ such that for all t near 0 we have

$$\left\| \frac{\partial \alpha}{\partial t}(u, t) \right\| \leq Ku \left\| \frac{\partial \alpha}{\partial t}(1, t) \right\| \quad 0 \leq u \leq 1.$$

Hint: In M_q we clearly have

$$\left\| \frac{d(u \cdot v(t))}{dt} \right\| = |u| \cdot \left\| \frac{dv(t)}{dt} \right\|.$$

Since \exp_q is locally a diffeomorphism there are $0 < K_1 < K_2$ such that

$$K_1 \|v\| \leq \|\exp_{q*} v\| \leq K_2 \|v\|$$

for all tangent vectors v at points near q .

(c) Conclude that

$$\lim_{h \rightarrow 0} \frac{L(c|_{[0, h]})}{d(p, c(h))} = \lim_{h \rightarrow 0} \frac{\int_0^h \sqrt{u'(t)^2 + \left\| \frac{\partial \alpha}{\partial t}(u(t), t) \right\|^2} dt}{u(h)} = 1.$$

(d) If c is C^1 , show that $L(c)$ is the least upper bound of inscribed piecewise geodesic curves.

34. (a) Using the methods of Problem 33, show that if c is the straight line joining $v, w \in M_p$, then

$$\lim_{v, w \rightarrow 0} \frac{L(\exp \circ c)}{L(c)} = 1.$$

(b) Similarly, if $\gamma_{v, w}$ is the unique geodesic joining $\exp(v)$ and $\exp(w)$, and $\gamma_{v, w} = \exp \circ c_{v, w}$, then

$$\lim_{v, w \rightarrow 0} \frac{L(\gamma_{v, w})}{L(c_{v, w})} = 1.$$

(c) Conclude that

$$\lim_{v, w \rightarrow 0} \frac{d(\exp v, \exp w)}{\|v - w\|} = 1.$$

35. Let $f: M \rightarrow N$ be an isometry. Show that f is an isometry of the metric space structures determined on M and N by their respective Riemannian metrics.

36. Let M be a manifold with Riemannian metric (\cdot, \cdot) and corresponding metric d . Let $f: M \rightarrow M$ be a map of M onto itself which preserves the metric d .

(a) If γ is a geodesic, then $f \circ \gamma$ is a geodesic.

(b) Define $f': M_p \rightarrow M_{f(p)}$ as follows: For γ a geodesic with $\gamma(0) = p$, let

$$f'(\gamma'(0)) = \left. \frac{df(\gamma(t))}{dt} \right|_{t=0}.$$

Show that $\|f'(X)\| = \|X\|$, and that $f'(cX) = cf'(X)$.

(c) Given $X, Y \in M_p$, use Problem 34 to show that

$$\begin{aligned} \frac{2(X, Y)}{\|X\| \cdot \|Y\|} &= \frac{\|X\|^2 + \|Y\|^2}{\|X\| \cdot \|Y\|} - \frac{\|tX - tY\|^2}{\|tX\| \cdot \|tY\|} \\ &= \frac{\|X\|^2 + \|Y\|^2}{\|X\| \cdot \|Y\|} - \lim_{t \rightarrow 0} \frac{[d(\exp tX, \exp tY)]^2}{\|tX\| \cdot \|tY\|}. \end{aligned}$$

Conclude that $(X, Y)_p = (f'(X), f'(Y))_{f(p)}$, and then that $f'(X + Y) = f'(X) + f'(Y)$.

(d) Part (c) shows that $f': M_p \rightarrow M_{f(p)}$ is a diffeomorphism. Use this to show that f is itself a diffeomorphism, and hence an isometry.

37. (a) For $v, w \in \mathbb{R}^n$ with $w \neq 0$, show that

$$\lim_{t \rightarrow 0} \frac{\|v + tw\| - \|v\|}{t} = \frac{(v, w)}{\|v\|}.$$

The same result then holds in any vector space with a Euclidean metric (\cdot, \cdot) .
Hint: If $\nu: \mathbb{R}^n \rightarrow \mathbb{R}$ is the norm, then the limit is $D\nu(v)(w)$. Alternately, one can use the equation $(u, v) = \|u\| \cdot \|v\| \cdot \cos \theta$ where θ is the angle between u and v .

(b) Conclude that if w is linearly independent of v , then

$$\lim_{t \rightarrow 0} \frac{\|v + tw\| - \|v\| - \|tw\|}{t} \neq 0.$$

(c) Let $\gamma: [0, 1] \rightarrow M$ be a piecewise C^1 critical point for length, and suppose that $\gamma'(t_0^+) \neq \gamma'(t_0^-)$ for some $t_0 \in (0, 1)$. Choose $t_1 < t_0$ and consider the variation α for which $\tilde{\alpha}(u)$ is obtained by following γ up to t_1 , then the unique geodesic from $\gamma(t_1)$ to $\gamma(t_0 + u)$, and finally the rest of γ . Show that if t_1 is

close enough to t_0 , then $dL(\tilde{\alpha}(u))/du|_{u=0} \neq 0$, a contradiction. Thus, critical paths for length cannot have kinks.

38. Consider a cylinder $Z \subset \mathbb{R}^3$ of radius r . Find the metric d induced by the Riemannian metric it acquires as a subset of \mathbb{R}^3 .
39. Consider a cone C (without the vertex), and let L be a generating line. Unfolding $C - L$ onto \mathbb{R}^2 produces a map $f: C - L \rightarrow \mathbb{R}^2$ which is a local

isometry, but which is usually not one-one. Investigate the geodesics on a cone (the number of geodesics between two points depends on the angle of the cone, and some geodesics may come back to their initial point).

40. Let $g: S^n \rightarrow \mathbb{P}^n$ be the map $g(p) = [p] = \{p, -p\}$.
- (a) Show that there is a unique Riemannian metric $\langle \cdot, \cdot \rangle$ on \mathbb{P}^n such that $g^*\langle \cdot, \cdot \rangle$ is the usual Riemannian metric on S^n (the one that makes the inclusion of S^n into \mathbb{R}^{n+1} an isometry).
- (b) Show that every geodesic $\gamma: \mathbb{R} \rightarrow \mathbb{P}^n$ is closed (that is, there is a number a such that $\gamma(t+a) = \gamma(t)$ for all t), and that every two geodesics intersect exactly once.
- (c) Show that there are isometries of \mathbb{P}^n onto itself taking any tangent vector at one point to any tangent vector at any other point.

These results show that \mathbb{P}^n provides a model for “elliptical” non-Euclidean geometry. The sum of the angles in any triangle is $> \pi$.

41. The Poincaré upper half-plane \mathcal{H}^2 is the manifold $\{(x, y) \in \mathbb{R}^2 : y > 0\}$ with the Riemannian metric

$$\langle \cdot, \cdot \rangle = \frac{dx \otimes dx + dy \otimes dy}{y^2}.$$

- (a) Compute that

$$\Gamma_{22}^2 = \Gamma_{12}^1 = \Gamma_{21}^1 = -\frac{1}{y}, \quad \Gamma_{11}^2 = \frac{1}{y}; \quad \text{all other } \Gamma_{ij}^k = 0.$$

(b) Let C be a semi-circle in \mathcal{H}^2 with center at $(0, c)$ and radius R . Considering it as a curve $t \mapsto (t, \gamma(t))$, show that

$$\frac{d^2\gamma(t)}{dt^2} = \frac{-\gamma'(t)}{t - c} - \frac{\gamma'(t)^2}{\gamma(t)}.$$

(c) Using Problem 27, show that all the geodesics in \mathcal{H}^2 are the (suitably parameterized) semi-circles with center on the x -axis, together with the straight lines parallel to the y -axis.

(d) Show that these geodesics have infinite length in either direction, so that the upper half-plane is complete.

(e) Show that if γ is a geodesic and $p \notin \gamma$, then there are infinitely many geodesics through p which do not intersect γ .

(f) For those who know a little about conformal mapping (compare with Problem IV.7-6). Consider the upper half-plane as a subset of the complex numbers \mathbb{C} . Show that the maps

$$f(z) = \frac{az + b}{cz + d} \quad a, b, c, d \in \mathbb{R}, \quad ad - bc > 0$$

are isometries, and that we can take any tangent vector at one point to any tangent vector at any other point by some f_* . Conclude that if length $AB =$ length $A'B'$ and length $AC =$ length $A'C'$ and the angle between the tangent vectors of β and γ at A equals the angle between the tangent vectors of β' and γ' at A' , then length $BC =$ length $B'C'$ and the angles at B and B' and at C and C' are equal ("side-angle-side"). These results show that the Poincaré

upper half-plane is a model for Lobachevskian non-Euclidean geometry. The sum of the angles in any triangle is $< \pi$.

42. Let M be a Riemannian manifold such that every two points of M can be joined by a unique geodesic of minimal length. Does it necessarily follow that the Riemannian manifold M is complete?

43. Let M be a manifold with a Riemannian metric (\cdot, \cdot) , and choose a fixed point $p \in M$. Suppose that every geodesic $\gamma: [a, b] \rightarrow M$ with initial value $\gamma(a) = p$ can be extended to all of \mathbb{R} . Show that the Riemannian manifold M is geodesically complete.

44. Let p be a point in a complete *non-compact* Riemannian manifold M . Prove that there is a geodesic $\gamma: [0, \infty) \rightarrow M$ with the initial value $\gamma(0) = p$, having the property that γ is a minimal geodesic between any two of its points.

45. Let M and N be geodesically complete Riemannian manifolds, and give $M \times N$ the Riemannian metric described in Problem 26. Show that the Riemannian manifold $M \times N$ is also complete.

46. This problem presupposes knowledge of covering spaces. Let $g: M \rightarrow N$ be a covering space, where N is a C^∞ manifold. Then there is a unique C^∞ structure on M which makes g an immersion. If (\cdot, \cdot) is a Riemannian metric on N , then $g^*(\cdot, \cdot)$ is a Riemannian metric on M , and $(M, g^*(\cdot, \cdot))$ is complete if and only if $(N, (\cdot, \cdot))$ is complete.

47. (a) If $M^n \subset N^{n+k}$ is a submanifold of N , show that the normal bundle ν is indeed a k -plane bundle.

(b) Using the notion of Whitney sum \oplus introduced in Problem 3-52, show that

$$\nu \oplus TM \simeq (TN)|_M.$$

48. (a) Show that the normal bundles ν_1, ν_2 of $M^n \subset N^{n+k}$ defined for two different Riemannian metrics are equivalent.

(b) If $\xi = \pi: E \rightarrow M$ is a smooth k -plane bundle over M^n , show that the normal bundle of $M \subset E$ is equivalent to ξ .

49. (a) Given an exact sequence of bundle maps

$$0 \longrightarrow E_1 \xrightarrow{\tilde{f}} E_2 \xrightarrow{\tilde{g}} E_3 \longrightarrow 0$$

as in Problem 3-28, where the bundles are over a smooth manifold M [or, more generally, over a paracompact space], show that $E_2 \simeq E_1 \oplus E_3$.

(b) If $\xi = \pi: E \rightarrow M$ is a smooth bundle, conclude that $TE \simeq \pi^*(\xi) \oplus \pi^*(TM)$.

50. (a) Let M be a non-orientable manifold. According to Problem 3-22 there is $S^1 \subset M$ so that $(TM)|_{S^1}$ is not orientable (the Problem deals with the case where $(TM)|_{S^1}$ is always trivial, but the same conclusions will hold if each $(TM)|_{S^1}$ is orientable; in fact, it is not hard to show that a bundle over S^1 is trivial if and only if it is orientable). Using Problem 47, show that the normal bundle ν of $S^1 \subset M$ is not orientable.
- (b) Use Problem 3-29 to conclude that there is a neighborhood of some $S^1 \subset M$ which is not orientable. (Thus, any non-orientable manifold contains a “fairly small” non-orientable open submanifold.)

CHAPTER 10

LIE GROUPS

This chapter uses, and illuminates, many of the results and concepts of the preceding chapters. It will also play an important role in later Volumes, where we are concerned with geometric problems, because in the study of these problems the groups of automorphisms of various structures play a central role, and these groups can be studied by the methods now at our disposal.

A topological group is a space G which also has a group structure (the product of $a, b \in G$ being denoted by ab) such that the maps

$$\begin{aligned}(a, b) &\mapsto ab && \text{from } G \times G \text{ to } G \\ a &\mapsto a^{-1} && \text{from } G \text{ to } G\end{aligned}$$

are continuous. It clearly suffices to assume instead that the single map $(a, b) \mapsto ab^{-1}$ is continuous. We will mainly be interested in a very special kind of topological group. A Lie group is a group G which is also a manifold with a C^∞ structure such that

$$\begin{aligned}(x, y) &\mapsto xy \\ x &\mapsto x^{-1}\end{aligned}$$

are C^∞ functions. It clearly suffices to assume that the map $(x, y) \mapsto xy^{-1}$ is C^∞ . As a matter of fact (Problem 1), it even suffices to assume that the map $(x, y) \mapsto xy$ is C^∞ .

The simplest example of a Lie group is \mathbb{R}^n , with the operation $+$. The circle S^1 is also a Lie group. One way to put a group structure on S^1 is to consider it as the quotient group \mathbb{R}/\mathbb{Z} , where $\mathbb{Z} \subset \mathbb{R}$ denotes the subgroup of integers. The functions $x \mapsto \cos 2\pi x$ and $x \mapsto \sin 2\pi x$ are C^∞ functions on \mathbb{R}/\mathbb{Z} , and at each point at least one of them is a coordinate system. Thus the map

$$\begin{array}{ccccc}(x, y) & \mapsto & x - y & \mapsto & xy^{-1} \\ \cap & & \cap & & \cap \\ \mathbb{R} \times \mathbb{R} & \longrightarrow & \mathbb{R} & \longrightarrow & S^1 = \mathbb{R}/\mathbb{Z}.\end{array}$$

which can be expressed in coordinates as one of the two maps

$$(x, y) \mapsto \cos 2\pi(x - y) = \cos 2\pi x \cos 2\pi y + \sin 2\pi x \sin 2\pi y$$

$$(x, y) \mapsto \sin 2\pi(x - y) = \sin 2\pi x \cos 2\pi y - \cos 2\pi x \sin 2\pi y,$$

is C^∞ : consequently the map $(x, y) \mapsto xy^{-1}$ from $S^1 \times S^1$ to S^1 is also C^∞ .

If G and H are Lie groups, then $G \times H$, with the product C^∞ structure, and the direct product group structure, is easily seen to be a Lie group. In particular, the torus $S^1 \times S^1$ is a Lie group. The torus may also be described as the quotient group

$$\mathbb{R} \times \mathbb{R} / (\mathbb{Z} \times \mathbb{Z});$$

the pairs (a, b) and (a', b') represent the same element of $S^1 \times S^1$ if and only if $a' - a \in \mathbb{Z}$ and $b' - b \in \mathbb{Z}$.

Many important Lie groups are matrix groups. The **general linear group** $GL(n, \mathbb{R})$ is the group of all non-singular real $n \times n$ matrices, considered as a subset of \mathbb{R}^{n^2} . Since the function $\det: \mathbb{R}^{n^2} \rightarrow \mathbb{R}$ is continuous (it is a polynomial map), the set $GL(n, \mathbb{R}) = \det^{-1}(\mathbb{R} - \{0\})$ is open, and hence can be given the C^∞ structure which makes it an open submanifold of \mathbb{R}^{n^2} . Multiplication of matrices is C^∞ , since the entries of AB are polynomials in the entries of A and B . Smoothness of the inverse map follows similarly from Cramer's Rule:

$$(A^{-1})_{ji} = \det A^{ij} / \det A,$$

where A^{ij} is the matrix obtained from A by deleting row i and column j .

One of the most important examples of a Lie group is the **orthogonal group** $O(n)$, consisting of all $A \in GL(n, \mathbb{R})$ with $A \cdot A^t = I$, where A^t is the transpose of A . This condition is equivalent to the condition that the rows [and columns] of A are orthonormal, which is equivalent to the condition that, with respect to the usual basis of \mathbb{R}^n , the matrix A represents a linear transformation which is an "isometry", i.e., is norm preserving, and thus inner product preserving. Problem 2-33 presents a proof that $O(n)$ is a closed submanifold of $GL(n, \mathbb{R})$, of dimension $n(n-1)/2$. To show that $O(n)$ is a Lie group we must show that the map $(x, y) \mapsto xy^{-1}$ which is C^∞ on $GL(n, \mathbb{R})$, is also C^∞ as a map from $O(n) \times O(n)$ to $O(n)$. By Proposition 2-11, it suffices to show that it is continuous; but this is true because the inclusion of $O(n) \rightarrow GL(n, \mathbb{R})$ is a homeomorphism (since $O(n)$ is a submanifold of $GL(n, \mathbb{R})$). Later in the chapter we will have another way of proving that $O(n)$ is a Lie group, and in particular, a manifold.

The argument in the previous paragraph shows, generally, that if $H \subset G$ is a subgroup of G and also a submanifold of G , then H is a Lie group. (This gives another proof that S^1 is a Lie group, for $S^1 \subset \mathbb{R}^2$ can be considered as the group

of complex numbers of norm 1. Similarly, S^3 is the Lie group of quaternions of norm 1. It is known that these are the only spheres which admit a Lie group structure.) It is possible for a subgroup H of G to be a Lie group with respect to a C^∞ structure that makes it merely an immersed submanifold. For example, if $L \subset \mathbb{R} \times \mathbb{R}$ is a subgroup consisting of all (x, cx) for c irrational, then the

image of L in $S^1 \times S^1 = \mathbb{R} \times \mathbb{R}/(\mathbb{Z} \times \mathbb{Z})$ is a dense subgroup. We define a Lie subgroup H of G to be a subset H of G which is a subgroup of G , and also a Lie group for some C^∞ structure which makes the inclusion map $i: H \rightarrow G$ an immersion. As we have seen, a subgroup which is an (imbedded) submanifold is always a Lie subgroup. It even turns out, after some work (Problem 18), that a subgroup which is an immersed submanifold is always a Lie subgroup, but we will not need this fact.

The group $O(n)$ is disconnected; the two components consist of all $A \in O(n)$ with $\det A = +1$ and $\det A = -1$, respectively. Clearly $SO(n) = \{A \in O(n) : \det A = 1\}$, the component containing the identity I , is a subgroup. This is not accidental.

1. PROPOSITION. If G is a topological group, then the component K containing the identity $e \in G$ is a closed normal subgroup of G . If G is a Lie group, then K is an open Lie subgroup.

PROOF. If $a \in K$, then $a^{-1}K$ is connected, since $b \mapsto a^{-1}b$ is a homeomorphism of K to itself. Since $e = a^{-1}a \in a^{-1}K$, we have $a^{-1}K \subset K$. Since this is true for all $a \in K$, we have $K^{-1}K \subset K$, which proves that K is a subgroup.

For any $b \in G$, it follows similarly that bKb^{-1} is connected. Since $e \in bKb^{-1}$, we have $bKb^{-1} \subset K$, so K is normal. Moreover, K is closed since components are always closed.

If G is a Lie group, then K is also open, since G is locally connected, so K is a submanifold and a subgroup of G . Hence K is a Lie subgroup. ♦

The group $SO(2)$ is just S^1 , which we have already seen is a Lie group. As a final example of a Lie group, we mention $E(n)$, the group of all Euclidean

motions, i.e., isometries of \mathbb{R}^n . A little argument shows (Problem 5) that every element of $E(n)$ can be written uniquely as $A \cdot \tau$ where $A \in O(n)$, and τ is a translation,

$$\tau(x) = \tau_a(x) = x + a.$$

We can give $E(n)$ the C^∞ structure which makes it diffeomorphic to $O(n) \times \mathbb{R}^n$. Now $E(n)$ is not the direct product $O(n) \times \mathbb{R}^n$ as a group, since translations and orthogonal transformations do not generally commute. In fact,

$$A\tau_a A^{-1}(x) = A(A^{-1}x + a) = x + A(a) = \tau_{A(a)}(x),$$

so

$$A\tau_a A^{-1} = \tau_{A(a)}, \quad A\tau_a = \tau_{A(a)}A.$$

Consequently,

$$\begin{aligned} A\tau_a(B\tau_b)^{-1} &= A\tau_a\tau_b B^{-1} = A\tau_{a-b}B^{-1} \\ &= AB^{-1}\tau_{B(a-b)}, \end{aligned}$$

which shows that $E(n)$ is a Lie group. Clearly the component of $e \in E(n)$ is the subgroup of all $A\tau$ with $A \in SO(n)$.

For any Lie group G , if $a \in G$ we define the left and right translations, $L_a: G \rightarrow G$ and $R_a: G \rightarrow G$, by

$$\begin{aligned} L_a(b) &= ab \\ R_a(b) &= ba. \end{aligned}$$

Notice that L_a and R_a are both diffeomorphisms, with inverses $L_{a^{-1}}$ and $R_{a^{-1}}$, respectively. Consequently, the maps

$$\begin{aligned} L_{a*}: G_b &\rightarrow G_{ab} \\ R_{a*}: G_b &\rightarrow G_{ba} \end{aligned}$$

are isomorphisms. A vector field X on G is called *left invariant* if

$$L_{a*}X = X \quad \text{for all } a \in G.$$

Recall this means that

$$L_{a*}X_b = X_{ab} \quad \text{for all } a, b \in G.$$

It is easy to see that this is true if we merely have

$$L_{a*}X_e = X_a \quad \text{for all } a \in G.$$

Consequently, given $X_e \in G_e$, there is a unique left invariant vector field X on G which has the value X_e at e .

2. PROPOSITION. Every left invariant vector field X on a Lie group G is C^∞ .

PROOF. It suffices to prove that X is C^∞ in a neighborhood of e , since the diffeomorphism L_a then takes X to the C^∞ vector field $L_{a*}X$ around a (Problem 5-1). Let (x, U) be a coordinate system around e . Choose a neighborhood V of e so that $a, b \in V$ implies $ab^{-1} \in U$. Then for $a \in V$ we have

$$\begin{aligned} Xx^i(a) &= L_{a*}X_e(x^i) \\ &= X_e(x^i \circ L_a). \end{aligned}$$

Since the map $(a, b) \mapsto ab$ is C^∞ on $V \times V$ we can write

$$x^i(ab) = x^i L_a(b) = f^i(x^1(a), \dots, x^n(a), x^1(b), \dots, x^n(b))$$

for some C^∞ function f^i on $x(V) \times x(V)$. Then

$$\begin{aligned} Xx^i(a) &= X_e(x^i \circ L_a) \\ &= \sum_{j=1}^n c^j \frac{\partial(x^i \circ L_a)}{\partial x^j} \Big|_e \quad \text{where } X_e = \sum_{j=1}^n c^j \frac{\partial}{\partial x^j} \Big|_e \\ &= \sum_{j=1}^n c^j D_{n+j} f^i(x(a), x(e)). \end{aligned}$$

which shows that Xx^i is C^∞ . This implies that X is C^∞ . ♦

3. COROLLARY. A Lie group G always has a trivial tangent bundle (and is consequently orientable).

PROOF. Choose a basis X_{1e}, \dots, X_{ne} for G_e . Let X_1, \dots, X_n be the left invariant vector fields with these values at e . Then X_1, \dots, X_n are clearly everywhere linearly independent, so we can define an equivalence

$$f: TG \rightarrow G \times \mathbb{R}^n$$

by

$$f\left(\sum_{j=1}^n c^j X_j(a)\right) = (a, c^1, \dots, c^n). \quad \diamond$$

A left invariant vector field X is just one that is L_a -related to itself for all a . Consequently, Proposition 6-3 shows that $[X, Y]$ is left invariant if X and Y are. Henceforth we will use X, Y , etc., to denote elements of G_e , and \tilde{X}, \tilde{Y} , etc., to denote the left invariant vector fields with $\tilde{X}(e) = X$, $\tilde{Y}(e) = Y$, etc. We can then define an operation $[\ , \]$ on G_e by

$$[X, Y] = [\tilde{X}, \tilde{Y}](e).$$

The vector space G_e , together with this $[\ , \]$ operation, is called the **Lie algebra** of G , and will be denoted by $\mathcal{L}(G)$. (Sometimes the Lie algebra of G is defined instead to be the set of left invariant vector fields.) We will also use the more customary notation \mathfrak{g} (a German Fraktur g) for $\mathcal{L}(G)$. This notation requires some conventions for particular groups; we write

$$\begin{aligned} \mathfrak{gl}(n, \mathbb{R}) & \quad \text{for the Lie algebra of } \mathrm{GL}(n, \mathbb{R}) \\ \mathfrak{o}(n) & \quad \text{for the Lie algebra of } \mathrm{O}(n). \end{aligned}$$

In general, a **Lie algebra** is a finite dimensional vector space V , with a bilinear operation $[\ , \]$ satisfying

$$\begin{aligned} [X, X] &= 0 \\ [[X, Y], Z] + [[Y, Z], X] + [[Z, X], Y] &= 0 \quad \text{"Jacobi identity"} \end{aligned}$$

for all $X, Y, Z \in V$.

Since the $[\ , \]$ operation is assumed alternating, it is also skew-symmetric, $[X, Y] = -[Y, X]$. Consequently, we call a Lie algebra **abelian** or **commutative** if $[X, Y] = 0$ for all X, Y .

The Lie algebra of \mathbb{R}^n is isomorphic as a vector space to \mathbb{R}^n . Clearly $\mathcal{L}(\mathbb{R}^n)$ is abelian, since the vector fields $\partial/\partial x^i$ are left invariant and $[\partial/\partial x^i, \partial/\partial x^j] = 0$. The Lie algebra $\mathcal{L}(S^1)$ of S^1 is 1-dimensional, and consequently must be abelian. If V_i are Lie algebras with bracket operations $[\ , \]_i$ for $i = 1, 2$, then we can define an operation $[\ , \]$ on the direct sum $V = V_1 \oplus V_2$ ($= V_1 \times V_2$ as a set) by

$$[(X_1, X_2), (Y_1, Y_2)] = ([X_1, Y_1]_1, [X_2, Y_2]_2).$$

It is easy to check that this makes V into a Lie algebra, and that $\mathcal{L}(G \times H)$ is isomorphic to $\mathcal{L}(G) \times \mathcal{L}(H)$ with this bracket operation. Consequently, the Lie algebra $\mathcal{L}(S^1 \times \cdots \times S^1)$ is also abelian.

The structure of $\mathfrak{gl}(n, \mathbb{R})$ is more complicated. Since $\mathrm{GL}(n, \mathbb{R})$ is an open submanifold of \mathbb{R}^{n^2} , the tangent space of $\mathrm{GL}(n, \mathbb{R})$ at the identity I can be

identified with \mathbb{R}^{n^2} . If we use the standard coordinates x^{ij} on \mathbb{R}^{n^2} , then an $n \times n$ (possibly singular) matrix $M = (M_{ij})$ can be identified with

$$M_I = \sum_{i,j} M_{ij} \frac{\partial}{\partial x^{ij}} \Big|_I.$$

Let \tilde{M} be the left invariant vector field on $\mathrm{GL}(n, \mathbb{R})$ corresponding to M . We compute the function $\tilde{M}x^{kl}$ on $\mathrm{GL}(n, \mathbb{R})$ as follows. For every $A \in \mathrm{GL}(n, \mathbb{R})$,

$$\tilde{M}x^{kl}(A) = \tilde{M}_A(x^{kl}) = L_{A*}M_I(x^{kl}) = M_I(x^{kl} \circ L_A).$$

Now the function $x^{kl} \circ L_A: \mathrm{GL}(n, \mathbb{R}) \rightarrow \mathbb{R}$ is the linear function

$$(x^{kl} \circ L_A)(B) = x^{kl}(AB) = \sum_{\alpha=1}^n A_{k\alpha} B_{\alpha l},$$

with (constant) partial derivatives

$$\frac{\partial}{\partial x^{ij}}(x^{kl} \circ L_A) = \begin{cases} A_{ki} & j = l \\ 0 & j \neq l. \end{cases}$$

So

$$\begin{aligned} \tilde{M}x^{kl}(A) &= M_I(x^{kl} \circ L_A) = \sum_{i,j} M_{ij} \frac{\partial}{\partial x^{ij}}(x^{kl} \circ L_A) \\ &= \sum_{i=1}^n M_{il} A_{ki} = \sum_{\alpha=1}^n M_{\alpha l} A_{k\alpha}. \end{aligned}$$

Thus,

$$\frac{\partial}{\partial x^{ij}} \tilde{M}x^{kl} = \begin{cases} M_{jl} & k = i \\ 0 & k \neq i. \end{cases}$$

So if N is another $n \times n$ matrix, we have

$$\begin{aligned} N_I(\tilde{M}x^{kl}) &= \sum_{i,j} N_{ij} \frac{\partial}{\partial x^{ij}}(\tilde{M}x^{kl}) \\ &= \sum_{j=1}^n N_{kj} M_{jl} = (NM)_{kl}. \end{aligned}$$

From this we see that

$$[\tilde{M}, \tilde{N}]_I = \sum_{k,l} (MN - NM)_{kl} \frac{\partial}{\partial x^{kl}} \Big|_I;$$

with $\sin t$ and $-\sin t$ at (i, j) and (j, i) , 1's on the diagonal except at (i, i) and (j, j) , and 0's elsewhere. Then the set of all $A'(0)$ span the skew-symmetric matrices. Hence $O(n)_I$ must consist exactly of skew-symmetric matrices, and $O(n)$ must have dimension $n(n-1)/2$.

We do not need any new calculations to determine the bracket operation in $\mathfrak{o}(n)$. In fact, consider a Lie subgroup H of any Lie group G , and let $i: H \rightarrow G$ be the inclusion. Since $i_*: H_e \rightarrow G_e$ is an isomorphism into, we can identify H_e with a subspace of G_e . Any $X \in H_e$ can be extended to a left invariant vector field \tilde{X} on H and a left invariant vector field \tilde{X} on G . For each $a \in H \subset G$, we have left translations

$$L_a: H \rightarrow H, \quad L_a: G \rightarrow G$$

and

$$L_a \circ i = i \circ L_a.$$

So

$$i_* \tilde{X}(a) = i_* L_{a*} X = L_{a*}(i_* X) = \tilde{X}(a).$$

In other words, \tilde{X} and \tilde{X} are i -related. Consequently, if $Y \in H_e$, then $[\tilde{X}, \tilde{Y}]$ and $[\tilde{X}, \tilde{Y}]$ are i -related, which means that

$$[\tilde{X}, \tilde{Y}](e) = i_*([\tilde{X}, \tilde{Y}](e)).$$

Thus, $H_e \subset G_e = \mathfrak{g}$ is a subalgebra of \mathfrak{g} , that is, H_e is a subspace of \mathfrak{g} which is closed under the $[\ , \]$ operation; moreover, H_e with this induced $[\ , \]$ operation is just $\mathfrak{h} = \mathcal{L}(H)$.

This correspondence between Lie subgroups of G and subalgebras of \mathfrak{g} turns out to work in the other direction also.

4. THEOREM. Let G be a Lie group, and \mathfrak{h} a subalgebra of \mathfrak{g} . Then there is a unique connected Lie subgroup H of G whose Lie algebra is \mathfrak{h} .

PROOF. For $a \in G$, let Δ_a be the subspace of G_a consisting of all $\tilde{X}(a)$ for $X \in \mathfrak{h}$. The fact that \mathfrak{h} is a subalgebra of \mathfrak{g} implies that Δ is an integrable distribution. Let H be the maximal integral manifold of Δ containing e . If $b \in G$, then clearly $L_{b*}(\Delta_a) = \Delta_{ba}$, so L_{b*} leaves the distribution Δ invariant. It follows immediately that L_b permutes the various maximal integral manifolds of Δ among themselves. In particular, if $b \in H$, then $L_{b^{-1}}$ takes H to the maximal integral manifold containing $L_{b^{-1}}(b) = e$, so $L_{b^{-1}}(H) = H$. This implies that H is a subgroup of G . To prove that it is a Lie subgroup we just need to show that $(a, b) \mapsto ab^{-1}$ is C^∞ . Now this map is clearly C^∞ as a map into G . Using Theorem 6-7, it follows that it is C^∞ as a map into H .

The proof of uniqueness is left to the reader. ♦

There is a very difficult theorem of Ado which states that every Lie algebra is isomorphic to a subalgebra of $\text{GL}(N, \mathbb{R})$ for some N . It then follows from Theorem 4 that *every Lie algebra is isomorphic to the Lie algebra of some Lie group*. Later on we will be able to obtain a “local” version of this result. We will soon see to what extent the Lie algebra of G determines G .

We continue the study of Lie groups along the same route used in the study of groups. Having considered subgroups of Lie groups (and subalgebras of their Lie algebras), we next consider, more generally, homomorphisms between Lie groups. If $\phi: G \rightarrow H$ is a C^∞ homomorphism, then $\phi_{*e}: G_e \rightarrow H_e$. For any $a \in G$ we clearly have

$$\phi \circ L_a = L_{\phi(a)} \circ \phi,$$

so if $X \in G_e$, and $\tilde{X} = \widetilde{\phi_{*e}X}$ is the left invariant vector field on H with value $\phi_{*e}X$ at e , then

$$\begin{aligned}\phi_{*a}\tilde{X}(a) &= \phi_{*a}L_{a*}X = L_{\phi(a)*}\phi_{*e}X \\ &= \tilde{X}(\phi(a)).\end{aligned}$$

Thus \tilde{X} and \tilde{Y} are ϕ -related. Consequently, the map $\phi_{*e}: \mathfrak{g} \rightarrow \mathfrak{h}$ is a Lie algebra homomorphism, that is,

$$\begin{aligned}\phi_{*e}(aX + bY) &= a\phi_{*e}X + b\phi_{*e}Y \\ \phi_{*e}[X, Y] &= [\phi_{*e}X, \phi_{*e}Y].\end{aligned}$$

Usually, we will denote ϕ_{*e} simply by $\phi_*: \mathfrak{g} \rightarrow \mathfrak{h}$.

For example, suppose that $G = H = \mathbb{R}$. There are an enormous number of homomorphisms $\phi: \mathbb{R} \rightarrow \mathbb{R}$, because \mathbb{R} is a vector space of uncountable dimension over \mathbb{Q} , and every linear transformation is a group homomorphism. But if ϕ is C^∞ , then the condition

$$\phi(s + t) = \phi(s) + \phi(t)$$

implies that

$$\frac{d\phi(t+s)}{ds} = \frac{d\phi(s)}{ds};$$

evaluating at $s = 0$ gives

$$\phi'(t) = \phi'(0),$$

which means that $\phi(t) = ct$ for some $c (= \phi'(0))$. It is not hard to see that even a continuous ϕ must be of this form (one first shows that ϕ is of this form on the

rational numbers). We can identify $\mathcal{L}(\mathbb{R})$ with \mathbb{R} . Clearly the map $\phi_*: \mathbb{R} \rightarrow \mathbb{R}$ is just multiplication by c .

Now suppose that $G = \mathbb{R}$, but $H = S^1 = \mathbb{R}/\mathbb{Z}$. A neighborhood of the identity $e \in S^1$ can be identified with a neighborhood of $0 \in \mathbb{R}$, giving rise to an identification of $\mathcal{L}(S^1)$ with \mathbb{R} . The continuous homomorphisms $\phi: \mathbb{R} \rightarrow S^1$ are clearly of the form

$$\mathbb{R} \xrightarrow{\times c} \mathbb{R} \longrightarrow \mathbb{R}/\mathbb{Z};$$

once again, $\phi_*: \mathbb{R} \rightarrow \mathbb{R}$ is multiplication by c .

Notice that the only continuous homomorphism $\phi: S^1 \rightarrow \mathbb{R}$ is the 0 map (since $\{0\}$ is the only compact subgroup of \mathbb{R}). Consequently, a Lie algebra homomorphism $\mathfrak{g} \rightarrow \mathfrak{h}$ may not come from any C^∞ homomorphism $\phi: G \rightarrow H$. However, we do have a local result.

5. THEOREM. Let G and H be Lie groups, and $\Phi: \mathfrak{g} \rightarrow \mathfrak{h}$ a Lie algebra homomorphism. Then there is a neighborhood U of $e \in G$ and a C^∞ map $\phi: U \rightarrow H$ such that

$$\phi(ab) = \phi(a)\phi(b) \quad \text{when } a, b, ab \in U,$$

and such that for every $X \in \mathfrak{g}$ we have

$$\phi_{*e}X = \Phi(X).$$

Moreover, if there are two C^∞ homomorphisms $\phi, \psi: G \rightarrow H$ with $\phi_{*e} = \psi_{*e} = \Phi$, and G is connected, then $\phi = \psi$.

PROOF. Let \mathfrak{k} (German Fraktur k) be the subset $\mathfrak{k} \subset \mathfrak{g} \times \mathfrak{h}$ of all $(X, \Phi(X))$, for $X \in \mathfrak{g}$. Since Φ is a homomorphism, \mathfrak{k} is a subalgebra of $\mathfrak{g} \times \mathfrak{h} = \mathcal{L}(G \times H)$. By Theorem 4, there is a unique connected Lie subgroup K of $G \times H$ whose Lie algebra is \mathfrak{k} . If $\pi_1: G \times H \rightarrow G$ is projection on the first factor, and $\omega = \pi_1|_K$, then $\omega: K \rightarrow G$ is a C^∞ homomorphism. For $X \in \mathfrak{g}$ we have

$$\omega_*(X, \Phi(X)) = X,$$

so $\omega_*: K_{(e,e)} \rightarrow G_e$ is an isomorphism. Consequently, there is an open neighborhood V of $(e, e) \in K$ such that ω takes V diffeomorphically onto an open neighborhood U of $e \in G$. If $\pi_2: G \times H \rightarrow H$ is projection on the second factor, we can define

$$\phi = \pi_2 \circ \omega^{-1} \quad \text{on } U.$$

The first condition on ϕ is obvious. As for the second, if $X \in \mathfrak{g}$, then

$$\omega_*(X, \Phi(X)) = X,$$

so

$$\phi_*X = \pi_{2*}(X, \Phi(X)) = \Phi(X).$$

Given $\phi, \psi: G \rightarrow H$, define the one-one map $\theta: G \rightarrow G \times H$ by

$$\theta(a) = (a, \psi(a)).$$

The image G' of θ is a Lie subgroup of $G \times H$ and for $X \in \mathfrak{g}$ we clearly have

$$\theta_*X = (X, \Phi(X)),$$

so $\mathcal{L}(G') = \mathfrak{f}$. Thus $G' = K$, which implies that $\psi(a) = \phi(a)$ for all $a \in G$. ♦

6. COROLLARY. If two Lie groups G and H have isomorphic Lie algebras, then they are locally isomorphic.

PROOF. Given an isomorphism $\Phi: \mathfrak{g} \rightarrow \mathfrak{h}$, let ϕ be the map given by Theorem 5. Since $\phi_{*e} = \Phi$ is an isomorphism, ϕ is a diffeomorphism in a neighborhood of $e \in G$. ♦

Remark: For those who know about simply-connected spaces it is fairly easy (Problem 8) to conclude that two simply-connected Lie groups with isomorphic Lie algebras are actually isomorphic, and that all connected Lie groups with a given Lie algebra are covered by the same simply-connected Lie group.

7. COROLLARY. A connected Lie group G with an abelian Lie algebra is itself abelian.

PROOF. By Corollary 6, G is locally isomorphic to \mathbb{R}^n , so $ab = ba$ for a, b in a neighborhood of e . It follows that G is abelian, since (Problem 4) any neighborhood of e generates G . ♦

8. COROLLARY. For every $X \in G_e$, there is a unique C^∞ homomorphism $\phi: \mathbb{R} \rightarrow G$ such that

$$\left. \frac{d\phi}{dt} \right|_{t=0} = X.$$

FIRST PROOF. Define $\Phi: \mathbb{R} \rightarrow \mathcal{L}(G)$ by

$$\Phi(\alpha) = \alpha X.$$

Clearly Φ is a Lie algebra homomorphism. By Theorem 5, on some neighborhood $(-\varepsilon, \varepsilon)$ of $0 \in \mathbb{R}$ there is a map $\phi: (-\varepsilon, \varepsilon) \rightarrow G$ with

$$\phi(s+t) = \phi(s)\phi(t) \quad |s|, |t|, |s+t| < \varepsilon$$

and

$$\left. \frac{d\phi}{dt} \right|_{t=0} = \phi_* \left(\left. \frac{d}{dt} \right|_{t=0} \right) = X.$$

To extend ϕ to \mathbb{R} we write every t with $|t| \geq \varepsilon$ uniquely as

$$t = k(\varepsilon/2) + r \quad k \text{ an integer, } |r| < \varepsilon/2$$

and define

$$\phi(t) = \begin{cases} \phi(\varepsilon/2) \cdots \phi(\varepsilon/2) \cdot \phi(r) & [\phi(\varepsilon/2) \text{ appears } k \text{ times}] \quad k \geq 0 \\ \phi(-\varepsilon/2) \cdots \phi(-\varepsilon/2) \cdot \phi(r) & [\phi(-\varepsilon/2) \text{ appears } -k \text{ times}] \quad k < 0. \end{cases}$$

Uniqueness also follows from Theorem 5.

SECOND (DIRECT) PROOF. If $f: G \rightarrow \mathbb{R}$ is C^∞ , and $\phi: \mathbb{R} \rightarrow G$ is a C^∞ homomorphism, then

$$\begin{aligned} \frac{d\phi}{dt}(f) &= \lim_{h \rightarrow 0} \frac{f(\phi(t+h)) - f(\phi(t))}{h} \\ &= \lim_{h \rightarrow 0} \frac{f(\phi(t)\phi(h)) - f(\phi(t))}{h} \\ &= \left. \frac{d}{du} \right|_{u=0} f \circ L_{\phi(t)} \circ \phi \\ &= L_{\phi(t)*} \left. \frac{d\phi}{du} \right|_{u=0} (f) \\ &= L_{\phi(t)*} X(f) = \tilde{X}(\phi(t))(f). \end{aligned}$$

Thus ϕ must be an integral curve of \tilde{X} , which proves uniqueness. Conversely, if $\phi: \mathbb{R} \rightarrow G$ is an integral curve of \tilde{X} , then

$$t \mapsto \phi(s) \cdot \phi(t)$$

is an integral curve of \tilde{X} which passes through $\phi(s)$ at time $t = 0$. The same is clearly true for

$$t \mapsto \phi(s+t),$$

so ϕ is a homomorphism. We know that integral curves of \tilde{X} exist locally; they can be extended to all of \mathbb{R} using the method of the first proof. ♦

A homomorphism $\phi: \mathbb{R} \rightarrow G$ is called a **1-parameter subgroup** of G . We thus see that there is a unique 1-parameter subgroup ϕ of G with given tangent vector $d\phi/dt(0) \in G_e$. We have already examined the 1-parameter subgroups of \mathbb{R} . More interesting things happen when we take G to be $\mathbb{R} - \{0\}$, with multiplication as the group operation. Then all C^∞ homomorphisms $\phi: \mathbb{R} \rightarrow \mathbb{R} - \{0\}$, with

$$\phi(s+t) = \phi(s)\phi(t),$$

must satisfy

$$\phi'(t) = \phi'(0)\phi(t)$$

$$\phi(0) = 1.$$

The solutions of this equation are

$$\phi(t) = e^{\phi'(0)t}.$$

Notice that $\mathbb{R} - \{0\}$ is just $GL(1, \mathbb{R})$. All C^∞ homomorphisms $\phi: \mathbb{R} \rightarrow GL(n, \mathbb{R})$ must satisfy the analogous differential equation

$$\begin{aligned} (*) \quad \phi'(t) &= \phi'(0) \cdot \phi(t), \\ \phi(0) &= I, \end{aligned}$$

where \cdot now denotes matrix multiplication. The solutions of these equations can be written formally in the same way

$$(**) \quad \phi(t) = \exp(t\phi'(0)),$$

where exponentiation of matrices is defined by

$$\exp(A) = I + \frac{A}{1!} + \frac{A^2}{2!} + \frac{A^3}{3!} + \cdots.$$

This follows from the facts in Problem 5-6, some of which will be briefly recapitulated here.

If $A = (a_{ij})$ and $|A| = \max |a_{ij}|$, then clearly

$$\begin{aligned} |A+B| &\leq |A| + |B| \\ |AB| &\leq n|A| \cdot |B|; \end{aligned}$$

hence $|A|^k \leq n^{k-1}|A|^k \leq n^k|A|^k$. Consequently,

$$\left| \frac{A^N}{N!} + \cdots + \frac{A^{N+K}}{(N+K)!} \right| \leq \frac{(n|A|)^N}{N!} + \cdots + \frac{(n|A|)^{N+K}}{(N+K)!} \rightarrow 0 \quad \text{as } N \rightarrow \infty.$$

so the series for $\exp(A)$ converges (the $(i, j)^{\text{th}}$ entry of the partial sums converge), and convergence is absolute and uniform in any bounded set. Moreover (see Problem 5-6), if $AB = BA$, then

$$\exp(A + B) = (\exp A)(\exp B).$$

Hence, if $\phi(t)$ is defined by (**), then

$$\begin{aligned}\phi'(t) &= \lim_{h \rightarrow 0} \frac{\exp(t\phi'(0) + h\phi'(0)) - \exp(t\phi'(0))}{h} \\ &= \lim_{h \rightarrow 0} \frac{[\exp(h\phi'(0)) - I]}{h} \exp(t\phi'(0)) \\ &= \lim_{h \rightarrow 0} \frac{\frac{h\phi'(0)}{1!} + \frac{h^2\phi'(0)^2}{2!} + \dots}{h} \exp(t\phi'(0)) \\ &= \phi'(0)\phi(t),\end{aligned}$$

so ϕ does satisfy (*).

For any Lie group G , we now define the “exponential map”

$$\exp: \mathfrak{g} \rightarrow G$$

as follows. Given $X \in \mathfrak{g}$, let $\phi: \mathbb{R} \rightarrow G$ be the unique C^∞ homomorphism with $d\phi/dt(0) = X$. Then

$$\exp(X) = \phi(1).$$

We clearly have

$$\begin{aligned}\exp(t_1 + t_2)X &= (\exp t_1 X)(\exp t_2 X) \\ \exp(-tX) &= (\exp tX)^{-1}.\end{aligned}$$

9. PROPOSITION. The map $\exp: G_e \rightarrow G$ is C^∞ (note that $G_e \approx \mathbb{R}^n$ has a natural C^∞ structure), and 0 is a regular point, so that \exp takes a neighborhood of $0 \in G_e$ diffeomorphically onto a neighborhood of $e \in G$. If $\psi: G \rightarrow H$ is any C^∞ homomorphism, then

$$\exp \circ \psi_* = \psi \circ \exp.$$

$$\begin{array}{ccc} G_e & \xrightarrow{\psi_*} & H_e \\ \exp \downarrow & & \downarrow \exp \\ G & \xrightarrow{\psi} & H \end{array}$$

PROOF. The tangent space $(G_e \times G)_{(X,a)}$ of the C^∞ manifold $G_e \times G$ at the point (X,a) can be identified with $G_e \oplus G_a$. We define a vector field Y on $G_e \times G$ by

$$Y_{(X,a)} = 0 \oplus \tilde{X}(a).$$

Then Y has a flow $\alpha: \mathbb{R} \times (G_e \times G) \rightarrow G_e \times G$, which we know is C^∞ . Since

$$\exp X = \text{projection on } G \text{ of } \alpha(1, 0 \oplus X),$$

it follows that \exp is C^∞ .

If we identify a vector $v \in (G_e)_0$ with G_e , then the curve $c(t) = tv$ in G_e has tangent vector v at 0. So

$$\begin{aligned} \exp_{*0}(v) &= \left. \frac{d \exp(c(t))}{dt} \right|_{t=0} = \left. \frac{d}{dt} \right|_{t=0} \exp(tv) \\ &= v. \end{aligned}$$

So \exp_{*0} is the identity, and hence one-one. Therefore \exp is a diffeomorphism in a neighborhood of 0.

Given $\psi: G \rightarrow H$, and $X \in G_e$, let $\phi: \mathbb{R} \rightarrow G$ be a homomorphism with

$$\left. \frac{d\phi}{dt} \right|_{t=0} = X.$$

Then $\psi \circ \phi: \mathbb{R} \rightarrow H$ is a homomorphism with

$$\left. \frac{d(\psi \circ \phi)}{dt} \right|_{t=0} = \psi_* X.$$

Consequently,

$$\exp(\psi_* X) = \psi \circ \phi(1) = \psi(\exp X). \quad \spadesuit$$

10. COROLLARY. Every one-one C^∞ homomorphism $\phi: G \rightarrow H$ is an immersion (so $\phi(G)$ is a Lie subgroup of H).

PROOF. If $\phi_{*p}(\tilde{X}(p)) = 0$ for some non-zero $X \in \mathfrak{g}$, then also $\phi_{*e}(X) = 0$. But then

$$e = \exp \phi_{*e}(tX) = \phi(\exp(tX)),$$

contradicting the fact that ϕ is one-one. \spadesuit

11. COROLLARY. Every continuous homomorphism $\phi: \mathbb{R} \rightarrow G$ is C^∞ .

PROOF. Let U be a star-shaped open neighborhood of $0 \in G_e$ on which \exp is one-one. For any $a \in \exp(\frac{1}{2}U)$, if $a = \exp(X/2)$ for $X \in U$, then

$$a = \exp(X/2) = [\exp(X/4)]^2, \quad \exp X/4 \in \exp(\tfrac{1}{2}U).$$

So a has a square root in $\exp(\frac{1}{2}U)$. Moreover, if $a = b^2$ for $b \in \exp(\frac{1}{2}U)$, then $b = \exp(Y/2)$ for $Y \in U$, so

$$\exp(X/2) = a = b^2 = [\exp(Y/2)]^2 = \exp Y.$$

Since $X/2, Y \in U$ it follows that $X/2 = Y$, so $X/4 = Y/2$. This shows that every $a \in \exp(\frac{1}{2}U)$ has a unique square root in the set $\exp(\frac{1}{2}U)$.

Now choose $\varepsilon > 0$ so that $\phi(t) \in \exp(\frac{1}{2}U)$ for $|t| \leq \varepsilon$. Let $\phi(\varepsilon) = \exp X$, $X \in \exp(\frac{1}{2}U)$. Since

$$[\phi(\varepsilon/2)]^2 = \phi(\varepsilon) = [\exp X/2]^2,$$

it follows from the above that $\phi(\varepsilon/2) = \exp(X/2)$. By induction we have

$$\phi(\varepsilon/2^n) = \exp(X/2^n).$$

Hence

$$\phi(m/2^n \cdot \varepsilon) = \phi(\varepsilon/2^n)^m = [\exp(X/2^n)]^m = \exp(m/2^n \cdot X).$$

By continuity,

$$\phi(s\varepsilon) = \exp sX \quad \text{for all } s \in [-1, 1]. \quad \spadesuit$$

12. COROLLARY. Every continuous homomorphism $\phi: G \rightarrow H$ is C^∞ .

PROOF. Choose a basis X_1, \dots, X_n for G_e . The map $t \mapsto \phi(\exp tX_i)$ is a continuous homomorphism of \mathbb{R} to H , so there is $Y_i \in H_e$ such that

$$\phi(\exp tX_i) = \exp tY_i.$$

Thus,

$$(*) \quad \phi((\exp t_1 X_1) \cdots (\exp t_n X_n)) = (\exp t_1 Y_1) \cdots (\exp t_n Y_n).$$

Now the map $\psi: \mathbb{R}^n \rightarrow G$ given by

$$\psi(t_1, \dots, t_n) = (\exp t_1 X_1) \cdots (\exp t_n X_n)$$

is C^∞ and clearly

$$\psi_* \left(\frac{\partial}{\partial x^i} \Big|_0 \right) = X_i,$$

so ψ is a diffeomorphism of a neighborhood U of $0 \in \mathbb{R}^n$ onto a neighborhood V of $e \in G$. Then on V ,

$$\phi = (\phi \circ \psi) \circ \psi^{-1},$$

and $(*)$ shows that $\phi \circ \psi$ is C^∞ . So ϕ is C^∞ at e , and thus everywhere. \spadesuit

13. COROLLARY. If G and G' are Lie groups which are isomorphic as topological groups, then they are isomorphic as Lie groups, that is, there is a diffeomorphism between them which is also a group isomorphism.

PROOF. Apply Corollary 11 to the continuous isomorphism and its inverse. ♦

The properties of the particular exponential map

$$\exp: \mathbb{R}^{n^2} (= \mathfrak{gl}(n, \mathbb{R})) \rightarrow \mathrm{GL}(n, \mathbb{R})$$

may now be used to show that $\mathrm{O}(n)$ is a Lie group. It is easy to see that

$$\exp(M^t) = (\exp M)^t.$$

Moreover, since $\exp(M + N) = (\exp M)(\exp N)$ when $MN = NM$, we have

$$(\exp M)(\exp -M) = I.$$

So if M is skew-symmetric, $M = -M^t$, then

$$(\exp M)(\exp M)^t = I,$$

i.e., $\exp M \in \mathrm{O}(n)$. Conversely, any $A \in \mathrm{O}(n)$ sufficiently close to I can be written $A = \exp M$ for some M . Let $A^t = \exp N$. Then $I = A \cdot A^t = (\exp M)(\exp N)$, so $\exp N = (\exp M)^{-1} = \exp(-M)$. For sufficiently small M and N this implies that $N = -M$. So $\exp M^t = A^t = \exp(-M)$; hence $M^t = -M$. It follows that a neighborhood of I in $\mathrm{O}(n)$ is an $n(n-1)/2$ dimensional submanifold of $\mathrm{GL}(n, \mathbb{R})$. Since $\mathrm{O}(n)$ is a subgroup, $\mathrm{O}(n)$ is itself a submanifold of $\mathrm{GL}(n, \mathbb{R})$.

Just as in $\mathrm{GL}(n, \mathbb{R})$, the equation $\exp(X + Y) = \exp X \exp Y$ holds whenever $[X, Y] = 0$ (Problem 13). In general, $[X, Y]$ measures, up to first order, the extent to which this equation fails to hold. In the following Theorem, and in its proof, to indicate that a function $c: \mathbb{R} \rightarrow G_e$ has the property that $c(t)/t^3$ is bounded for small t , we will denote it by $O(t^3)$. Thus $O(t^3)$ will denote different functions at different times.

14. THEOREM. If G is a Lie group and $X, Y \in G_e$, then

- (1) $\exp tX \exp tY = \exp \left\{ t(X + Y) + \frac{t^2}{2}[X, Y] + O(t^3) \right\}$
- (2) $\exp(-tX) \exp(-tY) \exp tX \exp tY = \exp \{ t^2[X, Y] + O(t^3) \}$
- (3) $\exp tX \exp tY \exp(-tX) = \exp \{ tY + t^2[X, Y] + O(t^3) \}.$

PROOF. We have

$$(i) \quad \tilde{X}f(a) = \tilde{X}_a(f) = L_{a*}X(f) = X(f \circ L_a) = \left. \frac{d}{du} \right|_{u=0} f(a \cdot \exp uX).$$

Similarly,

$$(ii) \quad \tilde{Y}f(a) = \left. \frac{d}{du} \right|_{u=0} f(a \cdot \exp uY).$$

For fixed s , let

$$\phi(t) = f(\exp sX \exp tY).$$

Then

$$(iii) \quad \begin{aligned} \phi'(t) &= \frac{d}{dt} f(\exp sX \exp tY) = \left. \frac{d}{du} \right|_{u=0} f(\exp sX \exp tY \exp uY) \\ &= (\tilde{Y}f)(\exp sX \exp tY) \quad \text{by (ii).} \end{aligned}$$

Applying (iii) to $\tilde{Y}f$ instead of f gives

$$(iv) \quad \phi''(t) = [\tilde{Y}(\tilde{Y}f)](\exp sX \exp tY).$$

Now Taylor's Theorem says that

$$\phi(t) = \phi(0) + \phi'(0)t + \frac{\phi''(0)}{2!}t^2 + O(t^3).$$

Suppose that $f(e) = 0$. Then we have

$$(v) \quad \begin{aligned} f(\exp sX \exp tY) &= f(\exp sX) + t(\tilde{Y}f)(\exp sX) \\ &\quad + \frac{t^2}{2}[\tilde{Y}(\tilde{Y}f)](\exp sX) + O(t^3). \end{aligned}$$

Similarly, for any F .

$$\begin{aligned} \frac{d}{ds} F(\exp sX) &= (\tilde{X}F)(\exp sX) \\ \frac{d^2}{ds^2} F(\exp sX) &= [\tilde{X}(\tilde{X}F)](\exp sX) \\ F(\exp sX) &= F(e) + s(\tilde{X}F)(e) + \frac{s^2}{2}[\tilde{X}(\tilde{X}F)](e) + O(s^3). \end{aligned}$$

Substituting in (v) for $F = f$, $F = \tilde{Y}f$, and $F = \tilde{Y}(\tilde{Y}f)$ gives

$$\begin{aligned}
 \text{(vi)} \quad f(\exp sX \exp tY) &= s(\tilde{X}f)(e) + t(\tilde{Y}f)(e) \\
 &\quad + \frac{s^2}{2}[\tilde{X}(\tilde{X}f)](e) + \frac{t^2}{2}[\tilde{Y}(\tilde{Y}f)](e) + st\tilde{X}(\tilde{Y}f)(e) \\
 &\quad + O(s^3) + O(t^3) + O(s^2t) + O(st^2).
 \end{aligned}$$

In particular,

$$\begin{aligned}
 \text{(vii)} \quad f(\exp tX \exp tY) &= t[(\tilde{X} + \tilde{Y})f](e) \\
 &\quad + t^2 \left[\left(\frac{\tilde{X}\tilde{X}}{2} + \tilde{X}\tilde{Y} + \frac{\tilde{Y}\tilde{Y}}{2} \right) f \right](e) + O(t^3).
 \end{aligned}$$

Now for small t we can write

$$\exp tX \exp tY = \exp Z(t)$$

for some C^∞ function Z with values in G_e . Applying Taylor's formula to Z gives

$$Z(t) = tZ_1 + t^2Z_2 + O(t^3),$$

for some $Z_1, Z_2 \in G_e$. If $f(e) = 0$, then clearly $f(A(t) + O(t^3)) = f(A(t)) + O(t^3)$, so by (vi) we have

$$\begin{aligned}
 \text{(viii)} \quad f(\exp Z(t)) &= f(\exp(tZ_1 + t^2Z_2)) + O(t^3) \\
 &= t(\tilde{Z}_1f)(e) + t^2(\tilde{Z}_2f)(e) \\
 &\quad + \frac{t^2}{2}[\tilde{Z}_1(\tilde{Z}_1f)](e) + O(t^3).
 \end{aligned}$$

Since we can take the f 's to be coordinate functions, comparison of (vii) and (viii) gives

$$\begin{aligned}
 \tilde{X} + \tilde{Y} &= \tilde{Z}_1 \\
 \frac{\tilde{Z}_1\tilde{Z}_1}{2} + \tilde{Z}_2 &= \frac{\tilde{X}\tilde{X}}{2} + \tilde{X}\tilde{Y} + \frac{\tilde{Y}\tilde{Y}}{2}.
 \end{aligned}$$

which gives

$$Z_1 = X + Y, \quad Z_2 = \frac{1}{2}[X, Y],$$

thus proving (1).

Equation (2) follows immediately from (1).

To prove (3), again choose f with $f(e) = 0$. Then similar calculations give

$$\begin{aligned}
 \text{(ix)} \quad & f(\exp tX \exp tY \exp(-tX)) \\
 &= t[(\tilde{X} + \tilde{Y} - \tilde{X})f](e) + t^2 \left[\left(\frac{\tilde{X}\tilde{X}}{2} + \frac{\tilde{Y}\tilde{Y}}{2} + \frac{\tilde{X}\tilde{X}}{2} + \tilde{X}\tilde{Y} - \tilde{X}\tilde{X} - \tilde{Y}\tilde{X} \right) \right](e) \\
 &\quad + O(t^3).
 \end{aligned}$$

If we write

$$\exp tX \exp tY \exp(-tX) = \exp(tS_1 + t^2S_2 + O(t^3)),$$

then we also have

$$\begin{aligned}
 \text{(x)} \quad & f(\exp tX \exp tY \exp(-tX)) = f(\exp(tS_1 + t^2S_2)) + O(t^3) \\
 &= t(\tilde{S}_1 f)(e) + t^2(\tilde{S}_2 f)(e) \\
 &\quad + \frac{t^2}{2}[\tilde{S}_1(\tilde{S}_1 f)](e) + O(t^3).
 \end{aligned}$$

Comparing (ix) and (x) gives the desired result. ♦

Notice that formula (2) is a special case of Theorem 5-16 (compare also with Problems 5-16 and 5-18).

The work involved in proving Theorem 14 is justified by its role in the following beautiful theorem.

15. THEOREM. If G is a Lie group and $H \subset G$ is a closed subset which is also a subgroup (algebraically), then H is a Lie subgroup of G . More precisely, there is a C^∞ structure on H , with the relative topology, that makes it a Lie subgroup of G .

PROOF. We attempt to reconstruct the Lie algebra of H as follows. Let $\mathfrak{h} \subset G_e$ be the set of all $X \in G_e$ such that $\exp tX \in H$ for all t .

Assertion 1. Let $X_i \in G_e$ with $X_i \rightarrow X$ and let $t_i \rightarrow 0$ with each $t_i \neq 0$. Suppose $\exp t_i X_i \in H$ for all i . Then $X \in \mathfrak{h}$.

Proof. We can assume $t_i > 0$, since $\exp(-t_i X_i) = (\exp t_i X_i)^{-1} \in H$. For $t > 0$, let

$$k_i(t) = \text{largest integer} \leq \frac{t}{t_i}.$$

Then

$$\frac{t}{t_i} - 1 < k_i(t) \leq \frac{t}{t_i},$$

so

$$t_i k_i(t) \rightarrow t.$$

Now

$$\begin{aligned} \exp(k_i(t)t_i X_i) &= [\exp(t_i X_i)]^{k_i(t)} \in H, \\ k_i(t)t_i X_i &\rightarrow tX. \end{aligned}$$

Thus $\exp tX \in H$, since H is closed and \exp is continuous. We clearly also have $\exp tX \in H$ for $t < 0$, so $X \in \mathfrak{h}$. Q.E.D.

We now claim that $\mathfrak{h} \subset G_e$ is a vector subspace. Clearly $X \in \mathfrak{h}$ implies $sX \in \mathfrak{h}$ for all $s \in \mathbb{R}$. If $X, Y \in \mathfrak{h}$, we can write by (1) of Theorem 14

$$\exp tX \exp tY = \exp\{t(X + Y) + tZ(t)\}$$

where $Z(t) \rightarrow 0$ as $t \rightarrow 0$. Choose positive $t_i \rightarrow 0$ and let $X_i = X + Y + Z(t_i)$. Then *Assertion 1* implies that $X + Y \in \mathfrak{h}$. Alternatively, we can write, for fixed t ,

$$\left(\exp \frac{t}{n} X \exp \frac{t}{n} Y\right)^n = \exp \left\{ t(X + Y) + \frac{t^2}{2n} [X, Y] + O(1/n^2) \right\};$$

taking limits as $n \rightarrow \infty$ gives $\exp t(X + Y) \in H$.

[Similarly, using (2) of Theorem 14 we see that $[X, Y] \in \mathfrak{h}$, so that \mathfrak{h} is a subalgebra, but we will not even use this fact.]

Now let U be an open neighborhood of $0 \in G_e$ on which \exp is a diffeomorphism. Then $\exp(\mathfrak{h} \cap U)$ is a submanifold of G . It clearly suffices to show that if U is small enough, then

$$H \cap \exp(U) = \exp(\mathfrak{h} \cap U).$$

Choose a subspace $\mathfrak{h}' \subset G_e$ complementary to \mathfrak{h} , so that $G_e = \mathfrak{h} \oplus \mathfrak{h}'$.

Assertion 2. The map $\phi: G_e \rightarrow G$ defined by

$$\phi(X + X') = \exp X \exp X' \quad X \in \mathfrak{h}, X' \in \mathfrak{h}'$$

is a diffeomorphism in some neighborhood of 0.

Proof. Choose a basis $X_1, \dots, X_k, \dots, X_n$ of G_e with X_1, \dots, X_k a basis for \mathfrak{h} . Then ϕ is given by

$$\phi\left(\sum_{i=1}^n a_i X_i\right) = \exp\left(\sum_{i=1}^k a_i X_i\right) \exp\left(\sum_{i=k+1}^n a_i X_i\right).$$

Since the map $\sum_{i=1}^n a_i X_i \mapsto (a_1, \dots, a_n)$ is a diffeomorphism of G_e onto \mathbb{R}^n , it suffices to show that

$$\psi(a_1, \dots, a_n) = \exp\left(\sum_{i=1}^k a_i X_i\right) \exp\left(\sum_{i=k+1}^n a_i X_i\right)$$

is a diffeomorphism in a neighborhood of $0 \in \mathbb{R}^n$. This is clear, since

$$\psi_*\left(\frac{\partial}{\partial x^i}\bigg|_0\right) = X_i. \quad \text{Q.E.D.}$$

Assertion 3. There is a neighborhood V' of 0 in \mathfrak{h}' such that $\exp X' \notin H$ if $0 \neq X' \in V'$.

Proof. Choose an inner product on \mathfrak{h}' and let $K \subset \mathfrak{h}'$ be the compact set of all $X' \in \mathfrak{h}'$ with $1 \leq |X'| \leq 2$. If the assertion were false, there would be $X'_i \in \mathfrak{h}'$ with $X'_i \rightarrow 0$ and $\exp X'_i \in H$. Choose integers n_i with

$$n_i X'_i \in K.$$

Choosing a subsequence if necessary, we can assume $X'_i \rightarrow X' \in K$. Since

$$1/n_i \rightarrow 0, \quad \exp(1/n_i)(n_i X'_i) \in H,$$

it follows from *Assertion 1* that $X' \in \mathfrak{h}$, a contradiction. Q.E.D.

We can now complete the proof of the theorem. Choose a neighborhood $U = W \times W'$ of G_e on which \exp is a diffeomorphism, with

W a neighborhood of $0 \in \mathfrak{h}$

W' a neighborhood of $0 \in \mathfrak{h}'$

such that W' is contained in V' of *Assertion 3*, and ϕ of *Assertion 2* is a diffeomorphism on $W \times W'$. Clearly

$$\exp(\mathfrak{h} \cap U) \subset H \cap \exp(U).$$

To prove the reverse inclusion, let $a \in H \cap \exp(U)$. Then

$$a = \exp X \exp X' \quad X \in W, X' \in W'.$$

Since $a, \exp X \in H$ we obtain $\exp X' \in H$, so $0 = X'$, and $a \in \exp(\mathfrak{h} \cap U)$. ♦

Up to now, we have concentrated on the left invariant vector fields, but many properties of Lie groups are better expressed in terms of forms. A form ω is called left invariant if $L_a^*\omega = \omega$ for all $a \in G$. This means that

$$\omega(b) = L_a^*[\omega(ab)].$$

Clearly, a left invariant k -form ω is determined by its value $\omega(e) \in \Omega^k(G_e)$. Hence, if $\omega^1, \dots, \omega^n$ are left invariant 1-forms such that $\omega^1(e), \dots, \omega^n(e)$ span G_e^* , then every left invariant k -form is

$$\sum_{i_1 < \dots < i_k} a_{i_1 \dots i_k} \omega^{i_1} \wedge \dots \wedge \omega^{i_k} = \sum_I A_I \omega^I$$

for certain constants a_I . If $\omega^1(e), \dots, \omega^n(e)$ is the dual basis to $X_1, \dots, X_n \in G_e$, then any C^∞ vector field X can be written

$$X = \sum_{j=1}^n f^j \tilde{X}_j \quad \text{for } C^\infty \text{ functions } f^j.$$

Then

$$\omega^i(X) = f^i,$$

so ω^i is C^∞ . It follows that any left invariant form is C^∞ .

If ω is left invariant, then for $a \in G$ we have

$$L_a^*d\omega = d(L_a^*\omega) = d\omega,$$

so $d\omega$ is also left invariant. The formula on page 215 implies that for a left invariant 1-form ω and left invariant vector fields \tilde{X} and \tilde{Y} we have

$$\begin{aligned} d\omega(\tilde{X}, \tilde{Y}) &= \tilde{X}(\omega(\tilde{Y})) - \tilde{Y}(\omega(\tilde{X})) - \omega([\tilde{X}, \tilde{Y}]) \\ &= -\omega([\tilde{X}, \tilde{Y}]). \end{aligned}$$

Hence

$$(*) \quad d\omega(e)(X, Y) = -\omega(e)([X, Y]),$$

the bracket being the operation in \mathfrak{g} .

The interplay between left invariant and right invariant vector fields is the subject of Problem 11. Here we consider the case of forms.

16. PROPOSITION. Let $\psi: G \rightarrow G$ be $\psi(a) = a^{-1}$.

- (1) A form ω is left invariant if and only if $\psi^*\omega$ is right invariant.
- (2) If $\omega_e \in \Omega^k(G_e)$, then $\psi^*\omega_e = (-1)^k \omega_e$.
- (3) If ω is left and right invariant, then $d\omega = 0$.
- (4) If G is abelian, then \mathfrak{g} is abelian (converse of Corollary 7).

PROOF. (1) Clearly

$$\psi \circ R_b = L_{b^{-1}} \circ \psi,$$

so

$$R_b^* \psi^* = \psi^* L_{b^{-1}}^*.$$

If ω is left invariant, then

$$R_b^*(\psi^*\omega) = \psi^* L_{b^{-1}}^* \omega = \psi^*\omega.$$

so $\psi^*\omega$ is right invariant. The converse is similar.

(2) It clearly suffices to prove this for $k = 1$. So it is enough to show that $\psi_{*e}(X) = -X$ for $X \in G_e$. Now X is the tangent vector at $t = 0$ of the curve $t \mapsto \exp tX$. So $\psi_{*e}X$ is the tangent vector at $t = 0$ of $t \mapsto (\exp tX)^{-1} = \exp(-tX)$; this tangent vector is just $-X$.

(3) If ω is a left and right invariant k -form, then

$$\psi^*(\omega_e) = (-1)^k \omega_e.$$

Since $\psi^*\omega$ and ω are both left invariant, we have

$$\psi^*\omega = (-1)^k \omega.$$

The form $d\omega$ is also left and right invariant, so

$$\psi^*(d\omega) = (-1)^{k+1} d\omega.$$

But

$$\psi^*(d\omega) = d(\psi^*\omega) = d((-1)^k \omega) = (-1)^k d\omega.$$

So $d\omega = 0$.

(4) If G is abelian, then all left invariant 1-forms ω are also right invariant. So $d\omega = 0$ for all left invariant 1-forms. It follows from (*) that $[X, Y] = 0$ for all $X, Y \in \mathfrak{g}$.

Alternate proof of (4). By Theorem 14, if G is abelian, then for $X, Y \in G_e$ we have

$$\frac{t^2}{2}[X, Y] + O(t^3) = \frac{t^2}{2}[Y, X] + O(t^3).$$

Hence

$$\frac{1}{2}[X, Y] + O(t^3)/t^2 = \frac{1}{2}[Y, X] + O(t^3)/t^2.$$

Letting $t \rightarrow 0$, we obtain $[X, Y] = [Y, X]$. ♦

Since $d\omega$ is left invariant for any left invariant ω , it follows that for a basis $\omega^1, \dots, \omega^n$ of invariant 1-forms we can express each $d\omega^k$ in terms of the $\omega^i \wedge \omega^j$. First choose $X_1, \dots, X_n \in G_e$ dual to $\omega^1(e), \dots, \omega^n(e)$. There are constants C_{ij}^k such that

$$[X_i, X_j] = \sum_{k=1}^n C_{ij}^k X_k;$$

clearly we also have

$$[\tilde{X}_i, \tilde{X}_j] = \sum_{k=1}^n C_{ij}^k \tilde{X}_k.$$

The numbers C_{ij}^k are called the **constants of structure** of G (with respect to the basis X_1, \dots, X_n of \mathfrak{g}). From skew-symmetry of $[\ , \]$ and the Jacobi identity we obtain

- (1) $C_{ij}^k = -C_{ji}^k$
- (2) $\sum_{h=1}^n (C_{ij}^h C_{hk}^l + C_{jk}^h C_{hi}^l + C_{ki}^h C_{hj}^l) = 0.$

From (*) on page 394 we obtain

$$d\omega^k = - \sum_{i < j} C_{ij}^k \omega^i \wedge \omega^j = - \frac{1}{2} \sum_{i, j} C_{ij}^k \omega^i \wedge \omega^j.$$

It turns out that (2) is exactly what we obtain from the relation $d^2\omega^k = 0$. Condition (2) is thus an integrability condition. In fact, we can prove (Problem 30) that if C_{ij}^k are constants satisfying (1) and (2), then we can find everywhere linearly independent 1-forms $\omega^1, \dots, \omega^n$ in a neighborhood of $0 \in \mathbb{R}^n$ such that

$$d\omega^k = - \frac{1}{2} \sum_{i, j} C_{ij}^k \omega^i \wedge \omega^j.$$

Moreover, the existence of such ω^i implies (Problem 29) that we can define a multiplication $(a, b) \mapsto ab$ in a neighborhood of 0 which is a group as far as it can be and which has the ω^i as left invariant 1-forms. From this latter fact and (a suitable local version of) Theorem 5 we could immediately deduce the following Theorem, for which we supply an independent proof.

17. THEOREM. Let G be a Lie group with a basis of left invariant 1-forms $\omega^1, \dots, \omega^n$ and constants of structure C_{ij}^k . Let M^n be a differentiable manifold and let $\theta^1, \dots, \theta^n$ be everywhere linearly independent 1-forms on M satisfying

$$d\theta^k = - \sum_{i < j} C_{ij}^k \theta^i \wedge \theta^j.$$

Then for every $p \in M$ there is a neighborhood U and a diffeomorphism $f: U \rightarrow G$ such that

$$\theta^i = f^* \omega^i.$$

PROOF. Let $\pi_1: M \times G \rightarrow M$ and $\pi_2: M \times G \rightarrow G$ be the projections. Let

$$\bar{\theta}^k = \pi_1^* \theta^k, \quad \bar{\omega}^k = \pi_2^* \omega^k.$$

Then

$$\begin{aligned} d(\bar{\theta}^k - \bar{\omega}^k) &= - \sum_{i < j} C_{ij}^k ([\bar{\theta}^i \wedge \bar{\theta}^j] - [\bar{\omega}^i \wedge \bar{\omega}^j]) \\ &= - \sum_{i < j} C_{ij}^k [\bar{\theta}^i \wedge (\bar{\theta}^j - \bar{\omega}^j) + (\bar{\theta}^i - \bar{\omega}^i) \wedge \bar{\omega}^j]. \end{aligned}$$

By Proposition 7-14, $M \times G$ is foliated by n -dimensional manifolds whose tangent spaces at each point are annihilated by all $\bar{\theta}^k - \bar{\omega}^k$. Choose $a \in G$ and let Γ be the folium through (p, a) . Now $\bar{\theta}^1, \dots, \bar{\theta}^n, \bar{\omega}^1, \dots, \bar{\omega}^n$ are linearly independent everywhere; so on $\Gamma_{(p,a)}$, which is the set of vectors in $(M \times G)_{(p,a)}$ where $\bar{\theta}^k - \bar{\omega}^k = 0$, the sets $\bar{\theta}^1, \dots, \bar{\theta}^n$ and $\bar{\omega}^1, \dots, \bar{\omega}^n$ are each linearly independent. Hence $\pi_1: \Gamma \rightarrow M$ and $\pi_2: \Gamma \rightarrow G$ are each diffeomorphisms in some neighborhood of (p, a) . This means that Γ contains the graph of a diffeomorphism f from a neighborhood U of p to a neighborhood of a .

Let $\tilde{f}: U \rightarrow M \times G$ be the map

$$\tilde{f}(q) = (q, f(q)) \in \Gamma.$$

Since $\tilde{\theta}^k - \tilde{\omega}^k = 0$ on Γ , we have

$$\begin{aligned} 0 &= \tilde{f}^*(\tilde{\theta}^k - \tilde{\omega}^k) = \tilde{f}^*\pi_1^*\theta^k - \tilde{f}^*\pi_2^*\omega^k \\ &= (\pi_1 \circ \tilde{f})^*\theta^k - (\pi_2 \circ \tilde{f})^*\omega^k \\ &= \theta^k - f^*\omega^k. \quad \blacklozenge \end{aligned}$$

It is also possible to say by how much any two such maps differ:

18. THEOREM. Let M be a connected manifold, let G be a Lie group, and let $f_1, f_2: M \rightarrow G$ be two C^∞ maps such that

$$f_1^*(\omega) = f_2^*(\omega)$$

for all left invariant 1-forms ω . Then f_1 and f_2 differ by a left translation, that is, there is a (unique) $a \in G$ such that

$$f_2 = L_a \circ f_1.$$

PEDESTRIAN PROOF. Case 1. $M = \mathbb{R}$ and the two maps $\gamma_1, \gamma_2: \mathbb{R} \rightarrow G$ satisfy $\gamma_1(0) = \gamma_2(0)$. We must show that $\gamma_1 = \gamma_2$. For every left invariant 1-form ω we have

$$\begin{aligned} \omega(\gamma_2(t)) \left(\frac{d\gamma_2}{dt} \right) &= \gamma_2^*\omega \left(\frac{d}{dt} \Big|_t \right) = \gamma_1^*\omega \left(\frac{d}{dt} \Big|_t \right) \\ &= \omega(\gamma_1(t)) \left(\frac{d\gamma_1}{dt} \right) \\ &= \left[(L_{\gamma_2(t)\gamma_1(t)^{-1}})^*\omega(\gamma_2(t)) \right] \left(\frac{d\gamma_1}{dt} \right) \\ &= \omega(\gamma_2(t)) \left(\left[L_{\gamma_2(t)\gamma_1(t)^{-1}} \right]_* \frac{d\gamma_1}{dt} \right). \end{aligned}$$

It follows that

$$\frac{d\gamma_2}{dt} = \left[L_{\gamma_2(t)\gamma_1(t)^{-1}} \right]_* \frac{d\gamma_1}{dt}.$$

If we regard γ_1 as given, and write this equation out in a coordinate system, then it becomes an ordinary differential equation for γ_2 (of the type considered

in the Addendum to Chapter 5), so it has a unique solution with the initial condition $\gamma_2(0) = \gamma_1(0)$. But this solution is clearly $\gamma_2 = \gamma_1$.

Case 2. $M = \mathbb{R}$, but the maps γ_1, γ_2 are arbitrary. Choose $a \in G$ so that

$$\gamma_2(0) = a \cdot \gamma_1(0).$$

If ω is a left invariant 1-form, then

$$(L_a \circ \gamma_1)^*(\omega) = \gamma_1^*(L_a^*\omega) = \gamma_1^*(\omega) = \gamma_2^*(\omega).$$

Since $L_a \circ \gamma_1(0) = \gamma_2(0)$, it follows from *Case 1* that $L_a \circ \gamma_1 = \gamma_2$.

Case 3. General case. Let $p_0 \in M$. Choose $a \in G$ so that

$$f_2(p_0) = a \cdot f_1(p_0).$$

For any $p \in M$ there is a C^∞ curve $c: \mathbb{R} \rightarrow M$ with $c(0) = p_0$ and $c(1) = p$. Let $\gamma_i = f_i \circ c$. Then

$$\gamma_2^*(\omega) = c^* f_2^*(\omega) = c^* f_1^*(\omega) = \gamma_1^*(\omega).$$

By *Case 2*, we have

$$\gamma_2(t) = a \cdot \gamma_1(t) \quad \text{for all } t.$$

in particular for $t = 1$, so $f_2(p) = a \cdot f_1(p)$.

ELEGANT PROOF. Let $\pi_i: G \times G \rightarrow G$ be projection on the i^{th} factor. Choose a basis $\omega^1, \dots, \omega^n$ for the left invariant 1-forms. For $(a, b) \in G \times G$, let

$$\Delta_{(a,b)} = \bigcap_{i=1}^n \ker(\pi_1^* \omega^i - \pi_2^* \omega^i).$$

Then Δ is an integrable distribution on $G \times G$. In fact, if $\Delta(G) \subset G \times G$ is the diagonal subgroup $\{(a, a) : a \in G\}$, then the maximal integral manifolds of Δ are the left cosets of $\Delta(G)$. Now define $h: M \rightarrow G \times G$ by

$$h(p) = (f_1(p), f_2(p)).$$

By assumption,

$$h^*(\pi_1^* \omega^i - \pi_2^* \omega^i) = f_1^* \omega^i - f_2^* \omega^i = 0.$$

Since M is connected, it follows that $h(M)$ is contained in some left coset of $\Delta(G)$. In other words, there are $a, b \in G$ with

$$af_1(p) = bf_2(p) \quad \text{for all } p \in M. \quad \spadesuit$$

19. COROLLARY. If G is a connected Lie group and $f: G \rightarrow G$ is a C^∞ map preserving left invariant forms, then $f = L_a$ for a unique $a \in G$.

While left invariant 1-forms play a fundamental role in the study of G , the left invariant n -forms are also very important. Clearly, all left invariant n -forms are a constant multiple of any non-zero one. If σ^n is a left invariant n -form, then σ^n determines an orientation on G , and if $f: G \rightarrow \mathbb{R}$ is a C^∞ function with compact support, we can define

$$\int_G f \sigma^n.$$

Since σ^n is usually kept fixed in any discussion, this is often abbreviated to

$$\int_G f \quad \text{or} \quad \int_G f(a) da.$$

The latter notation has advantages in certain cases. For example, left invariance of σ^n implies that

$$\int_G f(a) da = \int_G f(ba) da.$$

in other words,

$$\int_G f \sigma^n = \int_G g \sigma^n, \quad \text{where } g(a) = f(ba);$$

[note that L_b is an orientation preserving diffeomorphism, so

$$\int_G f \sigma^n = \int_G L_b^*(f \sigma^n) = \int_G (f \circ L_b) L_b^* \sigma^n = \int_G (f \circ L_b) \sigma^n,$$

which proves the formula]. We can, of course, also consider right invariant n -forms. These generally turn out to be quite different from the left invariant n -forms (see the example in Problem 25). But in one case they coincide.

20. PROPOSITION. If G is compact and connected and ω is a left invariant n -form, then ω is also right invariant.

PROOF. Suppose $\omega \neq 0$. For each $a \in G$, the form $R_a^* \omega$ is left invariant, so there is a unique real number $f(a)$ with

$$R_a^* \omega = f(a) \omega.$$

Since $R_a^* \circ R_b^* = (R_{ab})^*$, we have

$$f(ab) = f(ba) = f(a) \cdot f(b).$$

So $f(G) \subset \mathbb{R}$ is a compact connected subgroup of $\mathbb{R} - \{0\}$. Hence $f(G) = \{1\}$. ♦

We can also consider Riemannian metrics on G . In the case of a compact group G there is always a Riemannian metric on G which is both left and right invariant. In fact, if (\cdot, \cdot) is any Riemannian metric we can choose a bi-invariant n -form σ^n and define a bi-invariant $\langle\langle \cdot, \cdot \rangle\rangle$ on G by

$$\langle\langle V, W \rangle\rangle = \int_{G \times G} (L_{a*} R_{b*}(V), L_{a*} R_{b*}(W)) da db.$$

We are finally ready to account for some terminology from Chapter 9.

21. PROPOSITION. Let G be a Lie group with a bi-invariant metric.

- (1) For any $a \in G$, the map $I_a: G \rightarrow G$ given by $I_a(b) = ab^{-1}a$ is an isometry which reverses geodesics through a , i.e., if γ is a geodesic and $\gamma(0) = a$, then $I_a(\gamma(t)) = \gamma(-t)$.
- (2) The geodesics γ with $\gamma(0) = e$ are precisely the 1-parameter subgroups of G , i.e., the maps $t \mapsto \exp(tX)$ for some $X \in \mathfrak{g}$.

PROOF. (1) Since

$$I_e(b) = b^{-1},$$

the map $I_{e*}: G_e \rightarrow G_e$ is just multiplication by -1 (see the proof of Proposition 16(2)), so it is an isometry on G_e . Since

$$I_e = R_{a^{-1}} I_e L_{a^{-1}}$$

for any $a \in G$, the map $I_{e*}: G_a \rightarrow G_{a^{-1}}$ is also an isometry. Clearly I_e reverses geodesics through e .

Since

$$I_a = R_a I_e R_a^{-1},$$

it is clear that I_a is an isometry reversing geodesic through a .

- (2) Let $\gamma: \mathbb{R} \rightarrow G$ be a geodesic with $\gamma(0) = e$. For fixed t , let

$$\tilde{\gamma}(u) = \gamma(t + u).$$

Then $\tilde{\gamma}$ is a geodesic and $\tilde{\gamma}(0) = \gamma(t)$. So

$$\begin{aligned} I_{\gamma(t)} I_e(\gamma(u)) &= I_{\gamma(t)}(\gamma(-u)) = I_{\gamma(t)}(\tilde{\gamma}(-u - t)) \\ &= \tilde{\gamma}(t + u) = \gamma(u + 2t). \end{aligned}$$

But also

$$I_{\gamma(t)} I_e(b) = \gamma(t)b\gamma(t),$$

so

$$\gamma(t)\gamma(u)\gamma(t) = \gamma(u + 2t).$$

It follows by induction that

$$\gamma(nt) = \gamma(t)^n \quad \text{for any integer } n.$$

If $t' = n't$ and $t'' = n''t$ for integers n' and n'' , then

$$\gamma(t' + t'') = \gamma(t)^{n' + n''} = \gamma(t')\gamma(t''),$$

so γ is a homomorphism on \mathbb{Q} . By continuity, γ is a 1-parameter subgroup.

These are the only geodesics, since there are 1-parameter subgroups with any tangent vector at $t = 0$, and geodesics through e are determined by their tangent vectors at $t = 0$. ♦

We conclude this chapter by introducing some neat formalism which allows us to write the expression for $d\omega^k$ in an invariant way that does not use the constants of structure of G . If V is a d -dimensional vector space, we define a V -valued k -form on M to be a function ω such that each $\omega(p)$ is an alternating map

$$\omega(p): \underbrace{M_p \times \cdots \times M_p}_{k \text{ times}} \rightarrow V.$$

If v_1, \dots, v_d is a basis for V , then there are ordinary k -forms $\omega^1, \dots, \omega^d$ such that for $X_1, \dots, X_k \in M_p$ we have

$$\omega(p)(X_1, \dots, X_k) = \sum_{i=1}^d \omega^i(p)(X_1, \dots, X_k) v_i;$$

we will write simply

$$\omega = \sum_{i=1}^d \omega^i \cdot v_i.$$

For any V -valued k -form ω we define a V -valued $(k+1)$ -form $d\omega$ by

$$d\omega = \sum_{i=1}^d d\omega^i \cdot v_i;$$

a simple calculation shows that this definition does not depend on the choice of basis v_1, \dots, v_d for V .

Similarly, suppose $\rho: U \times V \rightarrow W$ is a bilinear map, where U and V have bases u_1, \dots, u_c and v_1, \dots, v_d , respectively. If ω is a U -valued k -form

$$\omega = \sum_{i=1}^c \omega^i \cdot u_i$$

and η is a V -valued l -form

$$\eta = \sum_{j=1}^d \eta^j \cdot v_j,$$

then

$$\sum_{i=1}^c \sum_{j=1}^d \omega^i \wedge \eta^j \cdot \rho(u_i, v_j)$$

is a W -valued $(k+l)$ -form; a calculation shows that this does not depend on the choice of bases u_1, \dots, u_c or v_1, \dots, v_d . We will denote this W -valued $(k+l)$ -form by $\rho(\omega \wedge \eta)$.

These concepts have a natural place in the study of a Lie group G . Although there is no natural way to choose a basis of left invariant 1-forms on G , there is a natural \mathfrak{g} -valued 1-form on G , namely the form ω defined by

$$(*) \quad \omega(a)(\tilde{X}(a)) = X \in \mathfrak{g}.$$

Using the bilinear map $[\cdot, \cdot]: \mathfrak{g} \times \mathfrak{g} \rightarrow \mathfrak{g}$, we have, for any \mathfrak{g} -valued k -form η and any \mathfrak{g} -valued l -form λ on G , a new \mathfrak{g} -valued $(k+l)$ -form $[\eta \wedge \lambda]$ on G .

Now suppose that $X_1, \dots, X_n \in G_e = \mathfrak{g}$ is a basis, and that $\omega^1, \dots, \omega^n$ is a dual basis of left invariant 1-forms. The form ω defined by $(*)$ can clearly be written

$$\omega = \sum_{k=1}^n \omega^k \cdot X_k.$$

Then

$$\begin{aligned} (I) \quad d\omega &= \sum_{k=1}^n d\omega^k \cdot X_k \\ &= \sum_{k=1}^n \left(\sum_{i < j} C_{ij}^k \omega^i \wedge \omega^j \right) \cdot X_k. \end{aligned}$$

On the other hand,

$$[X_i, X_j] = \sum_{k=1}^n C_{ij}^k X_k,$$

so

$$(2) \quad [\omega \wedge \omega] = \sum_{k=1}^n \left(\sum_{i=1}^n \sum_{j=1}^n C_{ij}^k \omega^i \wedge \omega^j \cdot X_k \right).$$

Comparing (1) and (2), we obtain the equations of structure of G :

$$d\omega = -\frac{1}{2}[\omega \wedge \omega].$$

The equations of structure of a Lie group will play an important role in Volume III. For the present we merely wish to point out that the terms $d\omega$ and $[\omega \wedge \omega]$ appearing in this equation can also be defined in an invariant way. For the term $d\omega$ we just modify the formula in Theorem 7-13: If U is a vector field on G and f is a \mathfrak{g} -valued function on G , then (Problem 20) we can define a \mathfrak{g} -valued function $U(f)$ on G . On the other hand, $\omega(U)$ is a \mathfrak{g} -valued function on G . For vector fields U and V we can then define

$$d\omega(U, V) = U(\omega(V)) - V(\omega(U)) - \omega([U, V]).$$

Recall that the value at $a \in G$ of the right side depends only on the values U_a and V_a of U and V at a . If we choose $U = \tilde{X}$, $V = \tilde{Y}$ for some $X, Y \in G_e$, then

$$\begin{aligned} d\omega(a)(\tilde{X}_a, \tilde{Y}_a) &= 0 - 0 - \omega(a)([\tilde{X}, \tilde{Y}]_a) \\ &= -\omega(e)([\tilde{X}, \tilde{Y}]_e) && \text{since } [\tilde{X}, \tilde{Y}] \text{ is left invariant} \\ &= -\omega(e)([X, Y]) && \text{by definition of } [\cdot, \cdot] \text{ in } G_e \\ &= -[X, Y] \\ &= -[\omega(a)(\tilde{X}_a), \omega(a)(\tilde{Y}_a)] \end{aligned} \quad \left. \vphantom{\begin{aligned} d\omega(a)(\tilde{X}_a, \tilde{Y}_a) &= 0 - 0 - \omega(a)([\tilde{X}, \tilde{Y}]_a) \\ &= -\omega(e)([\tilde{X}, \tilde{Y}]_e) \\ &= -\omega(e)([X, Y]) \\ &= -[X, Y] \end{aligned}} \right\} \text{by definition of } \omega.$$

It follows that for any vector fields U and V we have

$$d\omega(U, V) = -[\omega(U), \omega(V)].$$

Problem 20 gives an invariant definition of $\rho(\omega \wedge \eta)$ and shows that this equation is equivalent to the equations of structure.

WARNING: In some books the equation which we have just deduced appears as $d\omega(U, V) = -\frac{1}{2}[\omega(U), \omega(V)]$. The appearance of the factor $\frac{1}{2}$ here has *nothing* to do with the $\frac{1}{2}$ in the other form of the structure equations. It comes about because some books do not use the factor $(k+l)!/k!l!$ in the definition of \wedge . This makes their $\lambda \wedge \eta$ equal to $\frac{1}{2}$ of ours for 1-forms λ and η . Then the definition of $d(\sum \omega_i dx^i)$ as $\sum d\omega_i \wedge dx^i$ makes their $d\omega$ equal to $\frac{1}{2}$ of ours for 1-forms ω .

PROBLEMS

1. Let G be a group which is also a C^∞ manifold, and suppose that $(x, y) \mapsto xy$ is C^∞ .

(a) Find f^{-1} when $f: G \times G \rightarrow G \times G$ is $f(x, y) = (x, xy)$.

(b) Show that (e, e) is a regular point of f .

(c) Conclude that G is a Lie group.

2. Let G be a topological group, and $H \subset G$ a subgroup. Show that the closure \bar{H} of H is also a subgroup.

3. Let G be a topological group and $H \subset G$ a subgroup.

(a) If H is open, then so is every coset gH .

(b) If H is open, then H is closed.

4. Let G be a connected topological group, and U a neighborhood of $e \in G$. Let U^n denote all products $a_1 \cdots a_n$ for $a_i \in U$.

(a) Show that U^{n+1} is a neighborhood of U^n .

(b) Conclude that $\bigcup_n U^n = G$. (Use Problem 3.)

(c) If G is locally compact and connected, then G is σ -compact.

5. Let $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ be distance preserving, with $f(0) = 0$.

(a) Show that f takes straight lines to straight lines.

(b) Show that f takes planes to planes.

(c) Show that f is a linear transformation, and hence an element of $O(n)$.

(d) Show that any element of $E(n)$ can be written $A \cdot \tau$ for $A \in O(n)$ and τ a translation.

6. Show that the tangent bundle TG of a Lie group G can always be made into a Lie group.

7. We have computed that for $M \in \mathfrak{gl}(n, \mathbb{R})$ we have

$$\tilde{M} = \sum_{k,l} \tilde{M} x^{kl} \cdot \frac{\partial}{\partial x^{kl}}, \quad \text{where } \tilde{M} x^{kl}(A) = \sum_{\alpha=1}^n M_{\alpha l} A_{k\alpha}.$$

(a) Show that this means that

$$\tilde{M}(A) = A \cdot M \in \mathbb{R}^{n^2} = \text{GL}(n, \mathbb{R})_A.$$

(It is actually clear *a priori* that \tilde{M} defined in this way is left invariant, for $L_{A*} = L_A$ since L_A is linear.)

(b) Find the right invariant vector field with value M at I .

8. Let G and H be topological groups and $\phi: U \rightarrow H$ a map on a connected open neighborhood U of $e \in G$ such that $\phi(ab) = \phi(a)\phi(b)$ when $a, b, ab \in U$.

(a) For each $c \in G$, consider pairs (V, ψ) , where $V \subset G$ is an open neighborhood of c with $V \cdot V^{-1} \subset U$, and where $\psi: V \rightarrow H$ satisfies $\psi(a) \cdot \psi(b)^{-1} = \phi(ab^{-1})$ for $a, b \in V$. Define $(V_1, \psi_1) \sim (V_2, \psi_2)$ if $\psi_1 = \psi_2$ on some smaller neighborhood of c . Show that the set of all \sim equivalence classes, for all $c \in G$, can be made into a covering space of G .

(b) Conclude that if G is simply-connected, then ϕ can be extended uniquely to a homomorphism of G into H .

9. In Theorem 5, show that ϕ and ψ are equal even if they are defined only on a neighborhood U of $e \in G$, provided that U is connected.

10. Show that Corollary 7 is false if G is not assumed connected.

11. If G is a group, we define the **opposite group** G° to be the same set with the multiplication \star defined by $a \star b = b \cdot a$. If \mathfrak{g} is a Lie algebra, with operation $[\ , \]$, we define the **opposite Lie algebra** \mathfrak{g}° to be the same set with the operation $[X, Y]^\circ = -[X, Y]$.

(a) G° is a group, and if $\psi: G \rightarrow G$ is $a \mapsto a^{-1}$, then ψ is an isomorphism from G to G° .

(b) \mathfrak{g}° is a Lie algebra, and $X \mapsto -X$ is an isomorphism of \mathfrak{g} onto \mathfrak{g}° .

(c) $\mathcal{L}(G^\circ)$ is isomorphic to $[\mathcal{L}(G)]^\circ = \mathfrak{g}^\circ$.

(d) Let $[\ , \]$ be the operation on G_e obtained by using right invariant vector fields instead of left invariant ones. Then $(\mathfrak{g}, [\ , \])$ is isomorphic to $\mathcal{L}(G^\circ)$, and hence to \mathfrak{g}° .

(e) Use this to give another proof that \mathfrak{g} is abelian when G is abelian.

12. (a) Show that

$$\exp \begin{pmatrix} 0 & a \\ -a & 0 \end{pmatrix} = \begin{pmatrix} \cos a & \sin a \\ -\sin a & \cos a \end{pmatrix}.$$

(b) Use the matrices A and B below to show that $\exp(A + B)$ is not generally equal to $(\exp A)(\exp B)$.

$$A = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \quad B = \begin{pmatrix} 0 & 0 \\ -1 & 0 \end{pmatrix}$$

13. Let $X, Y \in G_e$ with $[X, Y] = 0$.

(a) Use Lemma 5-13 to show that $(\exp sX)(\exp tY) = (\exp tY)(\exp sX)$.

(b) More generally, use Theorem 5 to show that \exp is a homomorphism on the subspace of G_e spanned by X and Y . In particular, $\exp(X + Y) = (\exp X)(\exp Y)$.

14. Problem 13 implies that $\exp t(X + Y) = (\exp tX)(\exp tY)$ if $[X, Y] = 0$. A more general result holds. Let X and Y be vector fields on a C^∞ manifold M with corresponding local 1-parameter families of local diffeomorphisms $\{\phi_t\}$, $\{\psi_s\}$. Suppose that $[X, Y] = 0$, and let $\eta_t = \phi_t \circ \psi_t = \psi_t \circ \phi_t$.

(a) Show that

$$\frac{d\eta_t(p)}{dt} = X(\eta_t(p)) + \phi_{t*}(Y(\psi_t(p))).$$

(b) Using Corollary 5-12, show that

$$\frac{d\eta_t(p)}{dt} = X(\eta_t(p)) + Y(\eta_t(p)).$$

In other words, $\{\eta_t\}$ is generated by $X + Y$.

15. (a) If M is a diagonal matrix with complex entries, show that

$$\det \exp M = e^{\text{trace } M}.$$

(b) Show that the same equation holds for all diagonalizable M with complex entries.

(c) Conclude that it holds for all M with complex entries. (The diagonalizable matrices are dense; compare Problem 7-15.)

(d) Using Proposition 9, show that for the homomorphism $\det: \text{GL}(n, \mathbb{R}) \rightarrow \mathbb{R} - \{0\}$, the map $\det_*: \mathfrak{gl}(n, \mathbb{R}) \rightarrow \mathcal{L}(\mathbb{R} - \{0\}) = \mathbb{R}$ is just $M \mapsto \text{trace } M$.

(e) Use this fact to give a fancy proof that $\text{trace } MN = \text{trace } NM$. (Look at $\text{trace}(MN - NM) = \text{trace}[M, N]$.)

(f) Prove the result in part (d) directly, without using (c). (Since \det_* and trace are homomorphisms, it suffices to look at matrices with only one non-zero entry.)

(g) Now use this result and Proposition 9 to give a fancy proof of (c).

16. (a) Let U be a neighborhood of the identity $(1, 0)$ of S^1 (considered as a subset of \mathbb{R}^2). Show that no matter how small U is, there are elements $a \in U$ which have square roots outside U in addition to their square root in U .

(b) Show that for each $n \geq 1$, there is a neighborhood U of $e \in G$ such that every element in U has a unique n^{th} root in U .

(c) For $G = S^1$, show that there is no neighborhood U which has this property for all n .

17. (a) Let (x, V) be a coordinate system around $e \in G$ with $x^i(e) = 0$. Let

$$x^i(ab) = f^i(x^1(a), \dots, x^n(a), x^1(b), \dots, x^n(b))$$

for C^∞ functions f^i . Show that

$$D_j f^i(0) = D_{n+j} f^i(0) = \delta_j^i.$$

(b) If $\alpha, \beta: (-\varepsilon, \varepsilon) \rightarrow G$ are differentiable, show that

$$(\alpha \cdot \beta)'(0) = \alpha'(0) + \beta'(0).$$

(c) Also deduce this result from Theorem 14(1). (Not even the full strength of (1) is needed; it suffices to know that $\exp tX \exp tY = \exp\{t(X+Y) + O(t)\}$. The argument of part (a) is essentially equivalent to the initial part of the deduction of (1).)

18. Let G be a Lie group, and let $H \subset G$ be a subgroup of G (algebraically), such that every $a \in H$ can be joined to e by a C^∞ path lying in H . Let $\mathfrak{h} \subset G_e$ be the set of tangent vectors to all C^∞ paths lying in H .

(a) Show that \mathfrak{h} is a subalgebra of G_e . (Use Theorem 14.)

(b) Let $K \subset G$ be the connected Lie subgroup of G with Lie algebra \mathfrak{h} . Show that $H \subset K$. *Hint:* Join any $a \in H$ to e by a C^∞ curve c , and show that the tangent vectors of c lie in the distribution constructed in the proof of Theorem 4.

(c) Let c_1, \dots, c_k be curves in H with $\{c_i'(0)\}$ a basis for \mathfrak{h} . By considering the map $f(t^1, \dots, t^k) = c_1(t^1) \cdots c_k(t^k)$, show that $K \subset H$. Thus, H is a Lie subgroup of G . It is even true that $H \subset G$ is a Lie subgroup if H is path connected (by not necessarily C^∞ paths); see Yamabe, *On an arcwise connected subgroup of a Lie group*, Osaka Math. J. 2 (1950), 13–14.

(d) If $H \subset G$ is a subgroup and an immersed submanifold, then H is a Lie subgroup.

19. For $a \in G$, consider the map $b \mapsto aba^{-1} = L_a R_a^{-1}(b)$. The map

$$(L_a R_a^{-1})_*: \mathfrak{g} \rightarrow \mathfrak{g}$$

is denoted by $\text{Ad}(a)$; usually $\text{Ad}(a)(X)$ is denoted simply by $\text{Ad}(a)X$.

(a) $\text{Ad}(ab) = \text{Ad}(a) \circ \text{Ad}(b)$. Thus we have a homomorphism $\text{Ad}: G \rightarrow \text{Aut}(\mathfrak{g})$, where $\text{Aut}(\mathfrak{g})$, the automorphism group of \mathfrak{g} , is the set of all non-singular linear transformations of the vector space \mathfrak{g} onto itself (thus, isomorphic to $\text{GL}(n, \mathbb{R})$ if \mathfrak{g} has dimension n). The map Ad is called the **adjoint representation**.

(b) Show that

$$\exp(\text{Ad}(a)X) = a(\exp X)a^{-1}.$$

Hint: This follows immediately from one of our propositions.

(c) For $A \in \mathrm{GL}(n, \mathbb{R})$ and $M \in \mathfrak{gl}(n, \mathbb{R})$ show that

$$\mathrm{Ad}(A)M = AMA^{-1}.$$

(It suffices to show this for M in a neighborhood of 0.)

(d) Show that

$$\mathrm{Ad}(\exp tX)Y = Y + t[X, Y] + O(t^2).$$

(e) Since $\mathrm{Ad}: G \rightarrow \mathfrak{g}$, we have the map

$$\mathrm{Ad}_{*e}: \mathfrak{g} (= G_e) \rightarrow \begin{array}{l} \text{tangent space of } \mathrm{Aut}(\mathfrak{g}) \text{ at the} \\ \text{identity map } 1_{\mathfrak{g}} \text{ of } \mathfrak{g} \text{ to itself.} \end{array}$$

This tangent space is isomorphic to $\mathrm{End}(\mathfrak{g})$, where $\mathrm{End}(\mathfrak{g})$ is the vector space of all linear transformations of \mathfrak{g} into itself. If c is a curve in $\mathrm{Aut}(\mathfrak{g})$ with $c(0) = 1_{\mathfrak{g}}$, then to regard $c'(0)$ as an element of $\mathrm{Aut}(\mathfrak{g})$, we let it operate on $Y \in \mathfrak{g}$ by

$$c'(0)(Y) = \left. \frac{d}{dt} \right|_{t=0} c(Y).$$

(Compare with the case $\mathfrak{g} = \mathbb{R}^n$, $\mathrm{Aut}(\mathfrak{g}) = \mathrm{GL}(n, \mathbb{R})$, $\mathrm{End}(\mathfrak{g}) = n \times n$ matrices.) Use (d) to show that

$$\mathrm{Ad}_{*e}(X)(Y) = [X, Y].$$

(A proof may also be given using the fact that $[\tilde{X}, \tilde{Y}] = L_{\tilde{X}}\tilde{Y}$.) The map $Y \mapsto [X, Y]$ is denoted by $\mathrm{ad} X \in \mathrm{End}(\mathfrak{g})$.

(f) Conclude that

$$\mathrm{Ad}(\exp X) = \exp(\mathrm{ad} X) = 1_{\mathfrak{g}} + \mathrm{ad} X + \frac{(\mathrm{ad} X)^2}{2!} + \cdots.$$

(g) Let G be a connected Lie group and $H \subset G$ a Lie subgroup. Show that H is a normal subgroup of G if and only if $\mathfrak{h} = \mathcal{L}(H)$ is an ideal of $\mathfrak{g} = \mathcal{L}(G)$, that is, if and only if $[X, Y] \in \mathfrak{h}$ for all $X \in \mathfrak{g}$, $Y \in \mathfrak{h}$.

20. (a) Let $f: M \rightarrow V$, where V is a finite dimensional vector space, with basis v_1, \dots, v_d . For $X_p \in M_p$, define $X_p(f) \in V$ by

$$X(f) = \sum_{i=1}^d X_p(f^i) \cdot v_i,$$

where $f = \sum_{i=1}^d f^i \cdot v_i$ for $f^i: M \rightarrow \mathbb{R}$. Show that this definition is independent of the choice of basis v_1, \dots, v_d for V .

- (b) If ω is a V -valued k -form, show that $d\omega$ may be defined invariantly by the formula in Theorem 7-13 (using the definition in part (a)).
- (c) For $\rho: U \times V \rightarrow W$, show that $\rho(\omega \wedge \eta)$ may be defined invariantly by

$$\begin{aligned} \rho(\omega \wedge \eta)(X_1, \dots, X_k, X_{k+1}, \dots, X_{k+l}) \\ = \frac{1}{k!l!} \sum_{\sigma \in S_{k+l}} \text{sgn } \sigma \cdot \rho(\omega(X_{\sigma(1)}, \dots, X_{\sigma(k)}), \eta(X_{\sigma(k+1)}, \dots, X_{\sigma(k+l)})). \end{aligned}$$

Conclude, in particular, that

$$[\omega \wedge \omega](X, Y) = 2[\omega(X), \omega(Y)].$$

- (d) Deduce the structure equations from (b) and (c).

21. (a) If ω is a U -valued k -form and η is a V -valued l -form, and $\rho: U \times V \rightarrow W$, then

$$d(\rho(\omega \wedge \eta)) = \rho(d\omega \wedge \eta) + (-1)^k \rho(\omega \wedge d\eta).$$

- (b) For a \mathfrak{g} -valued k -form ω and l -form η we have

$$[\omega \wedge \eta] = (-1)^{kl+1} [\eta \wedge \omega].$$

- (c) Moreover, if λ is a \mathfrak{g} -valued m -form, then

$$(-1)^{km} [\omega \wedge [\eta \wedge \lambda]] + (-1)^{kl} [\eta \wedge [\lambda \wedge \omega]] + (-1)^{lm} [\lambda \wedge [\eta \wedge \omega]] = 0.$$

22. Let $G \subset GL(n, \mathbb{R})$ be a Lie subgroup. The inclusion map $G \rightarrow GL(n, \mathbb{R}) \rightarrow \mathbb{R}^{n^2}$ will be denoted by P (for "point"). Then dP is an \mathbb{R}^{n^2} -valued 1-form (it corresponds to the identity map of the tangent space of G into itself). We can also consider dP as a matrix of 1-forms; it is just the matrix (dx^{ij}) , where each dx^{ij} is restricted to the tangent bundle of G . We also have the \mathbb{R}^{n^2} -valued 1-form (or matrix of 1-forms) $P^{-1} \cdot dP$, where \cdot denotes matrix multiplication, and P^{-1} denotes the map $A \mapsto A^{-1}$ on G .

- (a) $P^{-1} \cdot dP = \rho(P^{-1} \wedge dP)$, where $\rho: \mathbb{R}^{n^2} \times \mathbb{R}^{n^2} \rightarrow \mathbb{R}^{n^2}$ is matrix multiplication.
- (b) $L_A^* dP = A \cdot dP$. (Use $f^*d = df^*$.)
- (c) $P^{-1} \cdot dP$ is left invariant; and $(dP) \cdot P^{-1}$ is right invariant.
- (d) $P^{-1} \cdot dP$ is the natural \mathfrak{g} -valued 1-form ω on G . (It suffices to check that $P^{-1} \cdot dP = \omega$ at I .)
- (e) Using $dP = P \cdot \omega$, show that $0 = dP \cdot \omega + P \cdot d\omega$, where the matrix of 2-forms $P \cdot d\omega$ is computed by formally multiplying the matrices of 1-forms dP and ω . Deduce that

$$d\omega + \omega \cdot \omega = 0.$$

If ω is the matrix of 1-forms $\omega = (\omega^{ij})$, this says that

$$d\omega^{ij} = - \sum_k \omega^{ik} \wedge \omega^{kj}.$$

Check that these equations are equivalent to the equations of structure (use the form $d\omega(X, Y) = -[\omega(X), \omega(Y)]$.)

23. Let $G \subset \text{GL}(2, \mathbb{R})$ consist of all matrices $\begin{pmatrix} a & b \\ 0 & 1 \end{pmatrix}$ with $a \neq 0$. For convenience, denote the coordinates x^{11} and x^{12} on $\text{GL}(2, \mathbb{R})$ by x and y .

(a) Show that for the natural \mathfrak{g} -valued form ω on G we have

$$\omega = \frac{1}{x} \begin{pmatrix} dx & dy \\ 0 & 0 \end{pmatrix},$$

so that dx/x and dy/x are left invariant 1-forms on G , and a left invariant 2-form is $(dx \wedge dy)/x^2$.

(b) Find the structure constants for these forms.

(c) Show that

$$(dP) \cdot P^{-1} = \frac{1}{x} \begin{pmatrix} dx & -y dx + x dy \\ 0 & 0 \end{pmatrix}$$

and find the right invariant 2-forms.

24. (a) Show that the natural $\mathfrak{gl}(n, \mathbb{R})$ -valued 1-form ω on $\text{GL}(n, \mathbb{R})$ is given by

$$\omega^{ij} = \frac{1}{\det(x^{\alpha\beta})} \sum_{k=1}^n y^{ik} dx^{kj},$$

where

$$(y^{\alpha\beta}) = \det(x^{\alpha\beta}) \cdot (x^{\alpha\beta})^{-1}.$$

(b) Show that both the left and right invariant n^2 -forms are multiples of

$$\frac{1}{(\det(x^{\alpha\beta}))^n} (dx^{11} \wedge \cdots \wedge dx^{n1}) \wedge \cdots \wedge (dx^{1n} \wedge \cdots \wedge dx^{nn}).$$

25. The special linear group $\text{SL}(n, \mathbb{R}) \subset \text{GL}(n, \mathbb{R})$ is the set of all matrices of determinant 1.

(a) Using Problem 15, show that its Lie algebra $\mathfrak{sl}(n, \mathbb{R})$ consists of all matrices with trace = 0.

(b) For the case of $\mathrm{SL}(2, \mathbb{R})$, show that

$$P^{-1} \cdot dP = \begin{pmatrix} v dx - y du & v dy - y dv \\ -u dx + x du & -u dy + x dv \end{pmatrix},$$

where we use x, y, u, v for $x^{11}, x^{12}, x^{21}, x^{22}$. Check that the trace is 0 by differentiating the equation $xv - yu = 1$.

(c) Show that a left invariant 3-form is

$$v dx \wedge du \wedge dy - y dx \wedge du \wedge dv.$$

26. For $M, N \in \mathfrak{o}(n) = \mathcal{L}(\mathrm{O}(n)) = \{M : M = -M^t\}$, define

$$(N, M) = -\mathrm{trace} M \cdot N^t.$$

(a) $(\ , \)$ is a positive definite inner product on $\mathfrak{o}(n)$.

(b) If $A \in \mathrm{O}(n)$, then

$$(\mathrm{Ad}(\bar{A})\bar{M}, \mathrm{Ad}(A)N) = (M, N).$$

($\mathrm{Ad}(A)$ is defined in Problem 19.)

(c) The left invariant metric on $\mathrm{O}(n)$ with value $(\ , \)$ at $\mathrm{O}(n)_I$ is also right invariant.

27. (a) If G is a compact Lie group, then $\exp : \mathfrak{g} \rightarrow G$ is onto. *Hint:* Use Proposition 21.

(b) Let $A \in \mathrm{SL}(2, \mathbb{R})$. Recall that A satisfies its characteristic polynomial, so $A^2 - (\mathrm{trace} A)A + I = 0$. Conclude that $\mathrm{trace} A^2 \geq -2$.

(c) Show that the following element of $\mathrm{SL}(2, \mathbb{R})$ is not A^2 for any A . Conclude that it is not in the image of \exp .

$$\begin{pmatrix} -2 & 0 \\ 0 & -1/2 \end{pmatrix}$$

(d) $\mathrm{SL}(2, \mathbb{R})$ does not have a bi-invariant metric.

28. Let x be a coordinate system around e in a Lie group G , let $\pi_j : G \times G \rightarrow G$ be the projections, and let (y, z) be the coordinate system around (e, e) given by $y^i = x^i \circ \pi_1$, $z^i = x^i \circ \pi_2$. Define $\phi^i : G \times G \rightarrow \mathbb{R}$ by

$$\phi^i(a, b) = x^i(ab),$$

and let X_i be the left invariant vector field on G with

$$X_i(e) = \left. \frac{\partial}{\partial x^i} \right|_e.$$

(a) Show that

$$X_i = \sum_{j=1}^n \psi_i^j \frac{\partial}{\partial x^j},$$

where

$$\psi_i^j(a) = \frac{\partial \phi^j}{\partial x^i}(a, e).$$

(b) Using $L_a L_b = L_{ab}$, show that

$$[L_{a*} X_i(b)](x^l) = [X_i(ab)](x^l).$$

Deduce that

$$X_i(b)(x^l \circ L_a) = \psi_i^l(ab),$$

and then that

$$\sum_{j=1}^n \psi_i^j(b) \cdot \frac{\partial \phi^l}{\partial x^j}(a, b) = \psi_i^l(ab).$$

Letting $\tilde{\psi} = (\tilde{\psi}_j^i)$ be the inverse matrix of $\psi = (\psi_i^j)$, we can write

$$\frac{\partial \phi^l}{\partial x^j}(a, b) = \sum_{i=1}^n \psi_i^l(ab) \cdot \tilde{\psi}_j^i(b).$$

This equation (or any of numerous things equivalent to it) is known as *Lie's first fundamental theorem*. The associativity of G is implicitly contained in it, since we used the fact that $L_a L_b = L_{ab}$.

(c) Prove the *converse of Lie's first fundamental theorem*, which states the following. Let $\phi = (\phi^1, \dots, \phi^n)$ be a differentiable function in a neighborhood of $0 \in \mathbb{R}^{2n}$ [with standard coordinate system $y^1, \dots, y^n, z^1, \dots, z^n$] such that

$$\phi(a, 0) = a \quad \text{for } a \in \mathbb{R}^n.$$

Suppose there are differentiable functions ψ_j^i in a neighborhood of $0 \in \mathbb{R}^n$ [with standard coordinate system x^1, \dots, x^n] such that

$$\psi_j^i(0) = \delta_j^i$$

$$(*) \quad \frac{\partial \phi^l}{\partial z^j}(a, b) = \sum_{i=1}^n \psi_i^l(\phi(a, b)) \cdot \tilde{\psi}_j^i(b) \quad \text{for } (a, b) \text{ in a neighborhood of } 0 \in \mathbb{R}^{2n}.$$

Then $(a, b) \mapsto \phi(a, b)$ is a **local Lie group structure** on a neighborhood of $0 \in \mathbb{R}^n$ (it is associative and has inverses for points close enough to 0, which serves as the identity); the corresponding left invariant vector fields are

$$X_i = \sum_{j=1}^n \psi_i^j \frac{\partial}{\partial x^j}.$$

[To prove associativity, note that

$$\frac{\partial \phi^l(\phi(a, b), z)}{\partial z^j} = \sum_{i=1}^n \psi_i^l(\phi(\phi(a, b), z)) \cdot \tilde{\psi}_j^i(z) \quad \text{by } (*).$$

and then show that $\phi(a, \phi(b, z))$ satisfies the same equation.]

29. *Lie's second fundamental theorem* states that the left invariant vector fields X_i of a Lie group G satisfy

$$[X_i, X_j] = \sum_{k=1}^n C_{ij}^k X_k$$

for certain *constants* C_{ij}^k —in other words, the bracket of two left invariant vector fields is left invariant. The aim of this problem is to prove the *converse of Lie's second fundamental theorem*, which states the following: A Lie algebra of vector fields on a neighborhood of $0 \in \mathbb{R}^n$, which is of dimension n over \mathbb{R} and contains a basis for \mathbb{R}^n_0 , is the set of left invariant vector fields for some local Lie group structure on a neighborhood of $0 \in \mathbb{R}^n$.

(a) Choose X_1, \dots, X_n in the Lie algebra so that $X_i(0) = \partial/\partial x^i|_0$ and set

$$X_i = \sum_{j=1}^n \psi_i^j \frac{\partial}{\partial x^j}.$$

If

$$\omega^i = \sum_{j=1}^n \tilde{\psi}_j^i dx^j,$$

then the ω^i are the dual forms, and consequently

$$d\omega^k = - \sum_{i < j} C_{ij}^k \omega^i \wedge \omega^j \quad C_{ij}^k \text{ constants.}$$

(b) Let $\pi_j: \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ be the projections. Then

$$\pi_2^* \omega^j - \pi_1^* \omega^j = \sum_{l=1}^n (\tilde{\psi}_l^j \circ \pi_2) \left[d(x^l \circ \pi_2) - \sum_{i=1}^n (\psi_i^l \circ \pi_2) \cdot \pi_1^* \omega^i \right].$$

Consequently, the ideal generated by the forms $d(x^l \circ \pi_2) - \sum_{i=1}^n (\psi_i^l \circ \pi_2) \cdot \pi_1^* \omega^i$ is the same as the ideal \mathcal{L} generated by the forms $\pi_2^* \omega^j - \pi_1^* \omega^j$. Using the fact that the C_{jk}^i are constants, show that $d(\mathcal{L}) \subset \mathcal{L}$. Hence $\mathbb{R}^n \times \mathbb{R}^n$ is foliated by n -dimensional manifolds on which the forms $d(x^l \circ \pi_2) - \sum_{i=1}^n (\psi_i^l \circ \pi_2) \cdot \pi_1^* \omega^i$ all vanish.

(c) Conclude, as in the proof of Theorem 17, that for fixed a , there is a function $\Phi_a: \mathbb{R}^n \rightarrow \mathbb{R}^n$ satisfying $\Phi_a(0) = a$ and

$$d\Phi_a^l(b) = \sum_{i=1}^n \psi_i^l(\Phi_a(b)) \cdot \omega^i(b),$$

or equivalently,

$$\frac{\partial \Phi_a^l}{\partial x^j}(b) = \sum_{i=1}^n \psi_i^l(\Phi_a(b)) \cdot \tilde{\psi}_j^i(b).$$

Now set $\phi(a, b) = \Phi_a(b)$, and use the converse of Lie's first fundamental theorem.

30. *Lie's third fundamental theorem* states that the C_{jk}^i satisfy equations (1) and (2) on page 396, i.e., that the left invariant vector fields form a Lie algebra under $[\cdot, \cdot]$. The aim of this problem is to prove the *converse of Lie's third fundamental theorem*, which states that any n -dimensional Lie algebra is the Lie algebra for some local Lie group in a neighborhood of $0 \in \mathbb{R}^n$.

Let C_{ij}^k be constants satisfying equations (1) and (2) on page 396. We would like to find vector fields X_1, \dots, X_n on a neighborhood of $0 \in \mathbb{R}^n$ such that $[X_i, X_j] = \sum_{k=1}^n C_{ij}^k X_k$. Equivalently, we want to find forms ω^i with

$$d\omega^k = - \sum_{i < j} C_{ij}^k \omega^i \wedge \omega^j.$$

Then the result will follow from the converse of Lie's second fundamental theorem.

(a) Let h_r^k be functions on $\mathbb{R} \times \mathbb{R}^n$ such that

$$\frac{\partial h_r^k}{\partial t} = \delta_r^k - \sum_{i,j} C_{ij}^k x^i h_r^j$$

$$h_r^k(0, x) = 0.$$

These are equations "depending on the parameters x " (see Problem 5-5(b)). Note that $h_r^k(t, 0) = \delta_r^k t$, so that $h_r^k(1, 0) = \delta_r^k$. Let σ^k be the 1-form on $\mathbb{R} \times \mathbb{R}^n$ defined by

$$\sigma^k = \sum_r h_r^k dx^r.$$

and write

$$d\sigma^k = \lambda^k + (dt \wedge \alpha^k).$$

where λ^k and α^k do not involve dt . Show that

$$\begin{aligned}\lambda^k &= \sum_{i < j} \left(\frac{\partial h_j^k}{\partial x^i} - \frac{\partial h_i^k}{\partial x^j} \right) dx^i \wedge dx^j \\ \alpha^k &= dx^k - \sum_{i,j} C_{ij}^k x^i \sigma^j.\end{aligned}$$

(b) Show that

$$d\lambda^k = dt \wedge \left(- \sum_{i,j} C_{ij}^k dx^i \wedge \sigma^j - \sum_{i,j} C_{ij}^k x^k \lambda^j \right).$$

(c) Let

$$\theta^k = \lambda^k + \frac{1}{2} \sum_{i,j} C_{ij}^k \sigma^i \wedge \sigma^j.$$

Show that

$$\begin{aligned}d\theta^k &= dt \wedge \left(- \sum_{i,j} C_{ij}^k x^i \lambda^j - \sum_{i,j} \sum_{r,s} C_{ij}^k C_{rs}^i x^r \sigma^s \wedge \sigma^j \right) \\ &\quad + \text{terms not involving } dt.\end{aligned}$$

Using

$$\begin{aligned}\sum_{i,j} \sum_{r,s} C_{ij}^k C_{rs}^i \sigma^s \wedge \sigma^j &= \frac{1}{2} \sum_{i,j} \sum_{r,s} (C_{ij}^k C_{rs}^i - C_{is}^k C_{rj}^i) \sigma^s \wedge \sigma^j \\ &= \frac{1}{2} \sum_{i,j} \sum_{r,s} (C_{ij}^k C_{rs}^i + C_{is}^k C_{jr}^i) \sigma^s \wedge \sigma^j,\end{aligned}$$

and equation (2) on page 396, show that

$$\begin{aligned}d\theta^k &= dt \wedge \left(- \sum_{i,j} C_{ij}^k x^i \lambda^j + \frac{1}{2} \sum_{i,j} \sum_{r,s} C_{ir}^k C_{sj}^i x^r \sigma^s \wedge \sigma^j \right) \\ &\quad + \text{terms not involving } dt.\end{aligned}$$

Finally deduce that

$$d\theta^k = dt \wedge - \sum_{j,l} C_{jl}^k x^j \theta^l + \text{terms not involving } dt.$$

(d) We can write

$$\theta^k = \sum_{i < j} g_{ij}^k dx^i \wedge dx^j.$$

where $g_{ij}^k(0, x) = 0$ (Why?). Using (c), show that

$$\frac{\partial g_{ij}^k}{\partial t} = - \sum_{r,s} C_{rs}^k x^r g_{ij}^s.$$

Conclude that $\theta^k = 0$.

(e) We now have

$$\lambda^k = - \frac{1}{2} \sum_{i,j} C_{ij}^k \sigma^i \wedge \sigma^j.$$

$$d\sigma^k = - \frac{1}{2} \sum_{i,j} C_{ij}^k \sigma^i \wedge \sigma^j + (dt \wedge \alpha^k).$$

Show that the forms $\omega^k(x) = \sigma^k(1, x)$ satisfy

$$d\omega^k = - \frac{1}{2} \sum_{i,j} C_{ij}^k \omega^i \wedge \omega^j.$$

CHAPTER 11

EXCURSION IN THE REALM OF ALGEBRAIC TOPOLOGY

This chapter explores further properties of the de Rham cohomology vector spaces of a manifold. Our main results will be restatements, in terms of the de Rham cohomology, of fundamental properties of the ordinary cohomology which is studied in algebraic topology. Because we deal only with manifolds, many of the proofs become significantly easier. On the other hand, we will be using some of the main tools of algebraic topology, thus retaining much of the flavor of that subject. Along the way we will deduce all sorts of interesting consequences, including a theorem about the possibility of imbedding n -manifolds in \mathbb{R}^{n+1} .

Let M be a manifold with $M = U \cup V$ for open sets $U, V \subset M$. Before examining the cohomology of M we will simply look at the vector space $C^k(M)$ of k -forms on M . Let

$$\begin{array}{ll} i_U: U \rightarrow M & i_V: V \rightarrow M \\ j_U: U \cap V \rightarrow U & j_V: U \cap V \rightarrow V \end{array}$$

be the inclusions. Then we have two linear maps α and β .

$$C^k(M) \xrightarrow{\alpha = i_U^* \oplus i_V^*} C^k(U) \oplus C^k(V) \xrightarrow{\beta = j_U^* - j_V^*} C^k(U \cap V)$$

defined by

$$\alpha(\omega) = (i_U^*(\omega), i_V^*(\omega)) \quad \beta(\lambda_1, \lambda_2) = j_U^*(\lambda_1) - j_V^*(\lambda_2).$$

Here $i_U^*(\omega)$ is just the restriction of ω to U , etc. Clearly $\beta \circ \alpha = 0$. In other words, $\text{image } \alpha \subset \ker \beta$. Moreover, the converse holds: $\ker \beta \subset \text{image } \alpha$. For, if $\beta(\lambda_1, \lambda_2) = 0$, then $\lambda_1 = \lambda_2$ on $U \cap V$, so we can define ω on M to be λ_1 on U and λ_2 on V , and then $\alpha(\omega) = (\lambda_1, \lambda_2)$. The equation $\text{image } \alpha = \ker \beta$ is expressed by saying that the above diagram is exact at the middle vector space. We can extend this diagram by putting the vector space containing only 0 at the

ends; the arrows at either end of the following sequence are the only possible linear maps.

1. LEMMA. The sequence

$$0 \rightarrow C^k(M) \xrightarrow{\alpha} C^k(U) \oplus C^k(V) \xrightarrow{\beta} C^k(U \cap V) \rightarrow 0$$

is exact at all places.

PROOF. It is clear that α is one-one. This is equivalent to exactness at $C^k(M)$, since the image of the first map is $\{0\} \subset C^k(M)$. Similarly, exactness at $C^k(U \cap V)$ is equivalent to β being onto. To prove that β is onto, let $\{\phi_U, \phi_V\}$ be a partition of unity subordinate to $\{U, V\}$. Then $\omega \in C^k(U \cap V)$ is

$$\omega = \beta(\phi_V \omega, -\phi_U \omega),$$

where $\phi_V \omega$ denotes the form equal to $\phi_V \omega$ on $U \cap V$, and equal to 0 on $U - (U \cap V)$. ♦

By putting in the maps d , we can expand our diagram as follows.

$$\begin{array}{ccccccc} & \vdots & & \vdots & & \vdots & \\ & \downarrow & & \downarrow & & \downarrow & \\ 0 & \longrightarrow & C^k(M) & \xrightarrow{\alpha} & C^k(U) \oplus C^k(V) & \xrightarrow{\beta} & C^k(U \cap V) \longrightarrow 0 \\ & & \downarrow d & & \downarrow d \oplus d & & \downarrow d \\ 0 & \longrightarrow & C^{k+1}(M) & \xrightarrow{\alpha} & C^{k+1}(U) \oplus C^{k+1}(V) & \xrightarrow{\beta} & C^{k+1}(U \cap V) \longrightarrow 0 \\ & & \downarrow & & \downarrow & & \downarrow \end{array}$$

so that the rows are all exact. It is easy to check that this diagram commutes, that is, any two compositions from one vector space to another are equal:

$$\begin{array}{lcl} (d \oplus d) \circ \alpha = \alpha \circ d & \xrightarrow{\alpha} \downarrow d \oplus d = d \downarrow \xrightarrow{\alpha} & \\ d \circ \beta = \beta \circ (d \oplus d) & \xrightarrow{\beta} \downarrow d = d \oplus d \downarrow \xrightarrow{\beta} & \end{array}$$

Our first main theorem depends only on the simple algebraic structure inherent in this diagram. To isolate this purely algebraic structure, we make the following definitions. A complex C is a sequence of vector spaces C^k , $k = 0, 1, 2, \dots$, together with a sequence of linear maps

$$d^k: C^k \rightarrow C^{k+1}$$

satisfying $d^{k+1} \circ d^k = 0$, or briefly, $d^2 = 0$. A map $\alpha: C_1 \rightarrow C_2$ between complexes is a sequence of linear maps

$$\alpha^k: C_1^k \rightarrow C_2^k$$

such that the following diagram commutes for all k .

$$\begin{array}{ccc} C_1^k & \xrightarrow{\alpha^k} & C_2^k \\ d_1^k \downarrow & & \downarrow d_2^k \\ C_1^{k+1} & \xrightarrow{\alpha^{k+1}} & C_2^{k+1} \end{array}$$

The most important examples of complexes are obtained by choosing $C^k = C^k(M)$ for some manifold M , with d^k the operator d on k -forms. Another example, implicit in our discussion, is the direct sum $C = C_1 \oplus C_2$ of two complexes, defined by

$$C^k = C_1^k \oplus C_2^k, \quad d^k = d_1^k \oplus d_2^k.$$

For any complex C we can define the cohomology vector spaces of C by

$$H^k(C) = \frac{\ker d^k}{\text{image } d^{k-1}}.$$

Naturally, if $C = \{C^k(M)\}$, then $H^k(C)$ is just $H^k(M)$. If $\alpha: C_1 \rightarrow C_2$ is a map between complexes, then we have a map, also denoted by α ,

$$\alpha: H^k(C_1) \rightarrow H^k(C_2).$$

To define α we note that every element of $H^k(C_1)$ is determined by some $x \in C_1^k$ with $d_1^k(x) = 0$. Commutativity of the above diagram shows that $d_2^k(\alpha^k(x)) = \alpha^{k+1}d_1^k(x) = 0$, so $\alpha^k(x)$ determines an element of $H^k(C_2)$, which we define to be α (the class determined by x). This map is well-defined.

for if we change x to $x + d_1^{k-1}(y)$ for some $y \in C_1^{k-1}$, then $\alpha^k(x)$ is changed to

$$\begin{aligned}\alpha^k(x + d_1^{k-1}(y)) &= \alpha^k(x) + \alpha^k(d_1^{k-1}(y)) \\ &= \alpha^k(x) + d_2^{k-1}(\alpha^{k-1}(y)).\end{aligned}$$

which determines the same element of $H^k(C_2)$. When $C_1^k = C^k(M)$, $C_2^k = C^k(N)$, and $\alpha: C^k(M) \rightarrow C^k(N)$ is f^* for $f: N \rightarrow M$, then this map is just $f^*: H^k(M) \rightarrow H^k(N)$.

Now suppose that we have an exact sequence of complexes

$$0 \rightarrow C_1 \xrightarrow{\alpha} C_2 \xrightarrow{\beta} C_3 \rightarrow 0.$$

which really means a vast commutative diagram in which all rows are exact.

$$(*) \quad \begin{array}{ccccccc} & & \downarrow & & \downarrow & & \downarrow \\ 0 & \longrightarrow & C_1^{k-1} & \xrightarrow{\alpha^{k-1}} & C_2^{k-1} & \xrightarrow{\beta^{k-1}} & C_3^{k-1} \longrightarrow 0 \\ & & \downarrow d_1^{k-1} & & \downarrow d_2^{k-1} & & \downarrow d_3^{k-1} \\ 0 & \longrightarrow & C_1^k & \xrightarrow{\alpha^k} & C_2^k & \xrightarrow{\beta^k} & C_3^k \longrightarrow 0 \\ & & \downarrow d_1^k & & \downarrow d_2^k & & \downarrow d_3^k \\ 0 & \longrightarrow & C_1^{k+1} & \xrightarrow{\alpha^{k+1}} & C_2^{k+1} & \xrightarrow{\beta^{k+1}} & C_3^{k+1} \longrightarrow 0 \\ & & \downarrow & & \downarrow & & \downarrow \end{array}$$

What does this imply about the maps $\alpha: H^k(C_1) \rightarrow H^k(C_2)$ and $\beta: H^k(C_2) \rightarrow H^k(C_3)$? The nicest thing that could happen would be for the following diagram to be exact:

$$0 \rightarrow H^k(C_1) \xrightarrow{\alpha} H^k(C_2) \xrightarrow{\beta} H^k(C_3) \rightarrow 0.$$

This is *not* true. For example, if U and V are overlapping portions of S^2 for which there is a deformation retraction of $U \cap V$ into S^1 , then we have an exact sequence

$$0 \rightarrow C^k(S^2) \rightarrow C^k(U) \oplus C^k(V) \rightarrow C^k(U \cap V) \rightarrow 0.$$

but *not* an exact sequence

$$\begin{array}{ccccccc} 0 & \longrightarrow & H^1(S^2) & \longrightarrow & H^1(U) \oplus H^1(V) & \longrightarrow & H^1(U \cap V) \longrightarrow 0. \\ & & \cong & & \cong & & \cong \\ & & 0 & & 0 & & \mathbb{R} \end{array}$$

Nevertheless, something very nice is true:

2. THEOREM. If $0 \rightarrow C_1 \xrightarrow{\alpha} C_2 \xrightarrow{\beta} C_3 \rightarrow 0$ is a short exact sequence of complexes, then there are linear maps

$$\delta^k : H^k(C_3) \rightarrow H^{k+1}(C_1)$$

so that the following infinitely long sequence is exact (everywhere):

$$\begin{aligned} 0 \longrightarrow H^0(C_1) &\xrightarrow{\alpha} H^0(C_2) \xrightarrow{\beta} H^0(C_3) \xrightarrow{\delta} H^1(C_1) \longrightarrow \dots \\ \dots \longrightarrow H^k(C_1) &\xrightarrow{\alpha} H^k(C_2) \xrightarrow{\beta} H^k(C_3) \xrightarrow{\delta} H^{k+1}(C_1) \longrightarrow \dots \end{aligned}$$

PROOF. Throughout the proof, diagram (*) should be kept at hand. Let $x \in C_3^k$ with $d_3^k(x) = 0$. By exactness of the middle row of (*), there is $y \in C_2^k$ with $\beta^k(y) = x$. Then

$$0 = d_3^k(x) = d_3^k \beta^k(y) = \beta^{k+1} d_2^k(y).$$

So $d_2^k(y) \in \ker \beta^{k+1} = \text{image } \alpha^{k+1}$; thus $d_2^k(y) = \alpha^{k+1}(z)$ for some (unique) $z \in C_1^{k+1}$. Moreover,

$$\alpha^{k+1} d_1^{k+1}(z) = d_2^{k+1} \alpha^{k+1}(z) = d_2^{k+1} d_2^k(y) = 0.$$

Since α^{k+1} is one-one, this implies that $d_1^{k+1}(z) = 0$, so z determines an element of $H^{k+1}(C_1)$; this element is defined to be δ^k of the element of $H^k(C_3)$ determined by x .

In order to prove that δ^k is well-defined, we must check that the result does not depend on the choice of $x \in C_3^k$ representing the element of $H^k(C_3)$. So we have to show that we obtain $0 \in H^{k+1}(C_1)$ if we start with an element of the form $d_3^{k-1}(x')$ for $x' \in C_3^{k-1}$. In this case, let $x' = \beta^{k-1}(y')$. Then

$$x = d_3^{k-1}(x') = d_3^{k-1} \beta^{k-1}(y') = \beta^k d_2^{k-1}(y'),$$

so we choose $d_2^{k-1}(y')$ as y . This means that $d_2^k(y) = 0$, and hence $z = 0$.

It is also necessary to check that our definition is independent of the choice of y with $\beta^k(y) = x$; this is left to the reader.

The proof that the sequence is exact consists of 6 similar diagram chases. We will supply the proof that $\ker \alpha \subset \text{image } \delta$. Let $x \in C_1^k$ satisfy $d_1^k(x) = 0$, and suppose that $\alpha^k(x) \in C_2^k$ represents $0 \in H^k(C_2)$. This means that $\alpha^k(x) = d_2^{k-1}(y)$ for some $y \in C_2^{k-1}$. Now

$$d_3^{k-1} \beta^{k-1}(y) = \beta^k d_2^{k-1}(y) = \beta^k \alpha^k(x) = 0.$$

So $\beta^{k-1}(y)$ represents an element of $H^{k-1}(C_3)$. Moreover, the definition of δ immediately shows that the image of this element under δ is precisely the class represented by x . ♦

It is a worthwhile exercise to check that the main step in the proof of Theorem 8-16 is precisely the proof that $\ker \alpha \subset \text{image } \delta$, together with the first part of the proof that δ is well-defined. All of Theorem 8-16 can be derived directly from the following corollary of Lemma 1 and Theorem 2.

3. THEOREM (THE MAYER-VIETORIS SEQUENCE). If $M = U \cup V$, where U and V are open, then we have an exact sequence (eventually ending in 0's):

$$0 \rightarrow H^0(M) \rightarrow \cdots \rightarrow H^k(M) \rightarrow H^k(U) \oplus H^k(V) \rightarrow H^k(U \cap V) \xrightarrow{\delta} H^{k+1}(M) \rightarrow \cdots$$

As several of the Problems show, the cohomology of nearly everything can be computed by a suitable application of the Mayer-Vietoris sequence. As a simple example, we consider the torus $T = S^1 \times S^1$, and the open sets U and V illustrated below. Since there is a deformation retraction of U and V

onto circles, and a deformation retraction of $U \cap V$ onto 2 circles, the Mayer-Vietoris sequence is

Rather than compute the cohomology of other manifolds, we will use the Mayer-Vietoris sequence to relate the dimensions of $H^k(M)$ to an entirely different set of numbers, arising from a “triangulation” of M , a new structure which we will now define.

The standard n -simplex Δ_n is defined as the set

$$\Delta_n = \left\{ x \in \mathbb{R}^{n+1} : 0 \leq x^i \leq 1 \text{ and } \sum_{i=1}^{n+1} x^i = 1 \right\}.$$

(In Problem 8-5, Δ_n is defined to be a different, although homeomorphic, set.) The subset of Δ_n obtained by setting $n - k$ of the coordinates x^i equal to 0 is homeomorphic to Δ_k , and is called a k -face of Δ_n . If $\Delta \subset M$ is a diffeomorphic image of some Δ_m , then the image of a k -face of Δ_m is called a k -face of Δ . Now by a triangulation of a compact n -manifold M we mean a finite collection $\{\sigma^n_i\}$ of diffeomorphic images of Δ_n which cover M and which satisfy the following condition:

If $\sigma^n_i \cap \sigma^n_j \neq \emptyset$, then for some k the intersection $\sigma^n_i \cap \sigma^n_j$ is a k -face of both σ^n_i and σ^n_j .

It is a difficult theorem that every C^∞ manifold has a triangulation; for a proof see Munkres, *Elementary Differential Topology*, or Whitney, *Geometric Integration*

Theory. Assuming that our manifold M has a triangulation $\{\sigma^n_i\}$ we will call each σ^n_i an n -simplex of the triangulation; any k -face of any σ^n_i will be called a k -simplex of the triangulation. We let α_k be the number of these k -simplexes.

Now let U be the disjoint union of open balls, one within each n -simplex σ^n_i , and let V_{n-1} be the complement of the set consisting of the centers of these balls, so that V_{n-1} is a neighborhood of the union of all $(n-1)$ -simplexes of M . Then

$M = U \cup V_{n-1}$ where $U \cap V_{n-1}$ has the same cohomology as a disjoint union of α_n copies of S^{n-1} . Consider first the case where $n > 2$. The Mayer-Vietoris sequence breaks into pieces:

$$\begin{array}{ccccccc}
 (1) & 0 \longrightarrow & H^0(M) & \longrightarrow & H^0(U) \oplus H^0(V_{n-1}) & \longrightarrow & H^0(U \cap V_{n-1}) \longrightarrow H^1(M) \\
 & & & & \parallel & & \parallel \\
 & & & & 0 & & 0
 \end{array}$$

(2) For $1 < k < n-1$,

$$\begin{array}{ccccccc}
 H^{k-1}(U \cap V_{n-1}) & \longrightarrow & H^k(M) & \longrightarrow & H^k(U) \oplus H^k(V_{n-1}) & \longrightarrow & H^k(U \cap V_{n-1}) \\
 \parallel & & \parallel & & \parallel & & \parallel \\
 0 & & 0 & & 0 & & 0
 \end{array}$$

$$\begin{array}{ccccccc}
 (3) & H^{n-2}(U \cap V_{n-1}) & \longrightarrow & H^{n-1}(M) & \longrightarrow & H^{n-1}(U) \oplus H^{n-1}(V_{n-1}) & \longrightarrow \\
 & \parallel & & \parallel & & \parallel & \\
 & 0 & & 0 & & 0 & \\
 & & & & & & \\
 & \longrightarrow & H^{n-1}(U \cap V_{n-1}) & \longrightarrow & H^n(M) & \longrightarrow & H^n(U) \oplus H^n(V_{n-1}) \\
 & & & & & & \parallel \\
 & & & & & & 0
 \end{array}$$

Applying Proposition 4 to these pieces yields

$$\dim H^k(V_{n-1}) = \dim H^k(M) \quad 0 \leq k \leq n-2$$

$$\dim H^{n-1}(V_{n-1}) = \dim H^{n-1}(M) - \dim H^n(M) + \alpha_n.$$

For the case $n = 2$ we easily obtain the same result without splitting up the sequence. We now introduce the Euler characteristic $\chi(M)$ of M , defined by

$$\chi(M) = \dim H^0(M) - \dim H^1(M) + \dim H^2(M) - \cdots + (-1)^n \dim H^n(M).$$

This makes sense for any manifold in which all $H^k(M)$ are finite dimensional; we anticipate here a later result that $H^k(M)$ is finite dimensional whenever M is compact. The above equations then imply that

$$\begin{aligned} \chi(V_{n-1}) &= \sum_{k=0}^{n-1} (-1)^k \dim H^k(V_{n-1}) \\ &= \sum_{k=0}^{n-2} (-1)^k \dim H^k(M) \\ &\quad + (-1)^{n-1} [\dim H^{n-1}(M) - \dim H^n(M) + \alpha_n] \\ &= \chi(M) - (-1)^n \alpha_n. \end{aligned}$$

or

$$\chi(M) = \chi(V_{n-1}) + (-1)^n \alpha_n.$$

5. THEOREM. For any triangulation of a compact manifold M we have

$$\chi(M) = \alpha_0 - \alpha_1 + \alpha_2 - \cdots + (-1)^n \alpha_n.$$

PROOF. In the manifold V_{n-1} we define a new open set U which consists of a disjoint union of sets diffeomorphic to \mathbb{R}^n , one for each $(n-1)$ -face, joining the balls of the old U .

We will let V_{n-2} be the complement of arcs, in the new U , joining the centers of the balls in the old U .

V_{n-2} is the
complement of

V_{n-2} is the
complement of

An argument precisely like that which proves the equation

$$\chi(M) = \chi(V_{n-1}) + (-1)^n \alpha_n$$

also shows that

$$\chi(V_{n-1}) = \chi(V_{n-2}) + (-1)^{n-1} \alpha_{n-1}.$$

Similarly, we introduce V_{n-3}, \dots, V_0 ; the last of these is a disjoint union of α_0 sets each of which is smoothly contractible to a point. Hence $\chi(V_0) = \alpha_0$, while in all other cases we have

$$\chi(V_k) = \chi(V_{k-1}) + (-1)^k \alpha_k.$$

Combining these equations, we have

$$\begin{aligned} \chi(M) &= \chi(V_{n-1}) + (-1)^n \alpha_n \\ &= \chi(V_{n-2}) + [(-1)^{n-1} \alpha_{n-1} + (-1)^n \alpha_n] \\ &\quad \vdots \\ &= \chi(V_0) + [(-1)^1 \alpha_1 + \dots + (-1)^n \alpha_n] \\ &= \alpha_0 - \alpha_1 + \dots + (-1)^n \alpha_n. \quad \spadesuit \end{aligned}$$

6. COROLLARY (DESCARTES-EULER). If a convex polyhedron has V vertices, E edges, and F faces, then

$$V - E + F = 2.$$

If we turn from H^k to H_c^k we encounter a very different situation. If $U \subset M$ is open, a form ω with compact support $\subset M$ may not restrict to a form with compact support $\subset U$: the inclusion map of U into M is not proper. On the

other hand, if ω is a form with compact support $\subset U$, then ω can be extended to M by letting it be 0 outside U ; we will denote this extended form by

$i_{U'}(\omega).$

If $C_c^k(M)$ denotes the vector space of k -forms with compact support on M , we can define a new sequence.

7. LEMMA. The sequence

$$0 \rightarrow C_c^k(U \cap V) \xrightarrow{j_U' \oplus -j_V'} C_c^k(U) \oplus C_c^k(V) \xrightarrow{i_U' + i_V'} C_c^k(M) \rightarrow 0$$

is exact.

PROOF. It is clear that $j_U' \oplus -j_V'$ is one-one; in fact, each map j_U' and j_V' is one-one.

To prove that $i_U' + i_V'$ is onto, let ω be a k -form with compact support on M , and let $\{\phi_U, \phi_V\}$ be a partition of unity for the cover $\{U, V\}$. Then

$$\omega = \phi_U \omega + \phi_V \omega$$

is clearly the image of $(\phi_U \omega, \phi_V \omega) \in C_c^k(U) \oplus C_c^k(V)$.

It is clear that $\text{image}(j_U' \oplus -j_V') \subset \ker(i_U' + i_V')$. To prove the converse, suppose that

$$(\lambda_1, \lambda_2) \in C_c^k(U) \oplus C_c^k(V) \quad \text{satisfies} \quad i_U'(\lambda_1) + i_V'(\lambda_2) = 0.$$

This means that $\lambda_1 = -\lambda_2$. Since $\text{support } \lambda_1 \subset U$ and $\text{support } \lambda_2 \subset U$, this shows that $\text{support } \lambda_1 \subset U \cap V$ and $\text{support } \lambda_2 \subset U \cap V$. So (λ_1, λ_2) is the image of $\lambda_1 \in C_c^k(U \cap V)$. ♦

8. THEOREM (MAYER-VIETORIS FOR COMPACT SUPPORTS). If the manifold $M = U \cup V$ for U, V open in M , then there is a long exact sequence

$$\cdots \rightarrow H_c^k(U \cap V) \rightarrow H_c^k(U) \oplus H_c^k(V) \rightarrow H_c^k(M) \xrightarrow{\delta} H_c^{k+1}(U \cap V) \rightarrow \cdots$$

PROOF. Apply Theorem 2 to the short exact sequence of complexes given by the Lemma. ♦

This sequence is much harder to work with than the Mayer-Vietoris sequence. For example, suppose we want to find H_c^k for $\mathbb{R}^n - \{0\}$, which is diffeomorphic to $S^{n-1} \times \mathbb{R}$. If we write $S^n = U \cup V$ in the usual way, so that $U \cap V$ is diffeomorphic to $S^{n-1} \times \mathbb{R}$, then $S^n \times \mathbb{R} = (U \times \mathbb{R}) \cup (V \times \mathbb{R})$, where $(U \times \mathbb{R}) \cap (V \times \mathbb{R})$ is diffeomorphic to $S^{n-1} \times \mathbb{R}^2$. The only way to use induction is to find H_c^k for all $S^n \times \mathbb{R}^m$, starting with $S^1 \times \mathbb{R}^m$. The details will be left to the reader; we will merely record one further result, for later use, and then proceed to yet another application of Theorem 2.

9. COROLLARY. If $M = U \cup V$ for U, V open in M , then there is a dual long exact sequence

$$\cdots \rightarrow H_c^{k+1}(U \cap V)^* \rightarrow H_c^k(M)^* \rightarrow [H_c^k(U) \oplus H_c^k(V)]^* \rightarrow H_c^k(U \cap V)^* \rightarrow \cdots$$

PROOF. We just have to show that if the sequence of linear maps

$$W_1 \xrightarrow{\alpha} W_2 \xrightarrow{\beta} W_3$$

is exact at W_2 , then so is the sequence of dual maps and spaces

$$W_3^* \xrightarrow{\beta^*} W_2^* \xrightarrow{\alpha^*} W_1^*.$$

For any $\lambda \in W_3^*$ we have

$$\alpha^* \beta^*(\lambda) = \alpha^*(\lambda \circ \beta) = \lambda \circ (\beta \circ \alpha) = \lambda \circ 0 = 0.$$

So $\alpha^* \circ \beta^* = 0$.

Now suppose $\lambda \in W_2^*$ satisfies $\alpha^*(\lambda) = 0$. Then $\lambda \circ \alpha = 0$. We claim that

$$\begin{array}{ccccc} W_1 & \xrightarrow{\alpha} & W_2 & \xrightarrow{\beta} & W_3 \\ & & \downarrow \lambda & \nearrow \bar{\lambda} & \\ & & \mathbb{R} & & \end{array}$$

there is $\bar{\lambda}: W_3 \rightarrow \mathbb{R}$ with $\lambda = \beta^*(\bar{\lambda})$, i.e., $\lambda = \beta \circ \bar{\lambda}$. Given a $w \in W_3$ which is

of the form $\beta(w')$, we define

$$\bar{\lambda}(w) = \lambda(\beta').$$

This makes sense, for if $\beta(w') = \beta(w'')$, then $w - w'' = \alpha(z)$ for some z , so $\lambda(w) - \lambda(w'') = \lambda\alpha(z) = 0$. This defines $\bar{\lambda}$ on $\beta(W_2) \subset W_3$. Now choose $W \subset W_3$ with $W_3 = \beta(W_2) \oplus W$, and define $\bar{\lambda}$ to be 0 on W . ♦

We now consider a rather different situation. Let $N \subset M$ be a compact submanifold of M . Then $M - N$ is also a manifold. We therefore have the sequence

$$C_c^k(M - N) \xrightarrow{e} C_c^k(M) \xrightarrow{i^*} C^k(N),$$

where e is “extension”. This sequence is *not* exact at $C_c^k(M)$: the kernel of i^* contains all $\omega \in C_c^k(M)$ which are 0 on N , while the image of e contains all $\omega \in C_c^k(M)$ which are 0 in a neighborhood of N .

To circumvent this difficulty, we will have to use a technical device. We appeal first to a result from the Addendum to Chapter 9. There is a compact neighborhood V of N and a map $\pi: V \rightarrow N$ such that V is a manifold-with-boundary, and if $j: N \rightarrow V$ is the inclusion, then $\pi \circ j$ is the identity of N , while $j \circ \pi$ is smoothly homotopic to the identity of V . We now construct a sequence of such neighborhoods $V = V_1 \supset V_2 \supset V_3 \supset \dots$ with $\bigcap_i V_i = N$.

Now consider two forms $\omega_i \in C^k(V_i)$, $\omega_j \in C^k(V_j)$. We will call ω_i and ω_j *equivalent* if there is $l > i, j$ such that

$$\omega_i|_{V_l} = \omega_j|_{V_l}.$$

It is clear that we can make the set of all equivalence classes into a vector space $\mathcal{G}^k(N)$, the “germs of k -forms in a neighborhood of M ”. Moreover, it is easy to define $d: \mathcal{G}^k(N) \rightarrow \mathcal{G}^{k+1}(N)$, so that we obtain a complex \mathcal{G} . Finally, we define a map of complexes

$$C_c^k(M) \xrightarrow{i^*} \mathcal{G}^k(N)$$

in the obvious way: $\omega \mapsto$ the equivalence class of any $\omega|_{V_i}$.

10. LEMMA. The sequence

$$0 \rightarrow C_c^k(M - N) \xrightarrow{e} C_c^k(M) \xrightarrow{i^*} \mathcal{G}^k(N) \rightarrow 0$$

is exact.

PROOF. Clearly e is one-one.

If $\omega \in C_c^k(M - N)$, then $\omega = 0$ in some neighborhood U of N . Since N is compact and $\bigcap_i V_i = N$, there is some i such that $V_i \subset U$, and consequently $\omega = 0$ on V_i . This means that $i^*e(\omega) = 0$. Conversely, suppose $\lambda \in C_c^k(M)$ satisfies $i^*(\lambda) = 0$. By definition of $\mathcal{G}^k(N)$, this means that $\lambda|_{V_i} = 0$ for some i . Hence $\lambda|_{M - N}$ has compact support $\subset M - N$, and $\lambda = e(\lambda|_{M - N})$.

Finally, any element of $\mathcal{G}^k(N)$ is represented by a form η on some V_i . Let $f: M \rightarrow [0, 1]$ be a C^∞ function which is 1 on V_{i+1} , having support $f \subset \text{interior } V_i$. Then $f\eta \in C_c^k(M)$, and $f\eta$ represents the same element of $\mathcal{G}^k(N)$ as η ; consequently this element is $i^*(f\eta)$. ♦

11. LEMMA. The cohomology vector spaces $H^k(\mathcal{G})$ of the complex $\{\mathcal{G}^k(N)\}$ are isomorphic to $H^k(N)$ for all k .

PROOF. This follows easily from the fact that $j^*: H^k(V_i) \rightarrow H^k(N)$ is an isomorphism for each V_i . Details are left to the reader. ♦

12. THEOREM (THE EXACT SEQUENCE OF A PAIR). If $N \subset M$ is a compact submanifold of M , then there is an exact sequence

$$\dots \rightarrow H_c^k(M - N) \rightarrow H_c^k(M) \rightarrow H^k(N) \xrightarrow{\delta} H_c^{k+1}(M - N) \rightarrow \dots$$

PROOF. Apply Theorem 2 to the exact sequence of complexes given by Lemma 10, and then use Lemma 11. ♦

In the proof of this theorem, the de Rham cohomology of the manifold-with-boundary V_i entered only as an intermediary (and we could have replaced the V_i by their interiors). But in the next theorem, which we will need later, it is the object of primary interest.

13. THEOREM. Let M be a manifold-with-boundary, with compact boundary ∂M . Then there is an exact sequence

$$\dots \rightarrow H_c^k(M - \partial M) \rightarrow H_c^k(M) \rightarrow H^k(\partial M) \xrightarrow{\delta} H_c^{k+1}(M - \partial M) \rightarrow \dots$$

PROOF. Just like the proof of Theorem 12, using tubular neighborhoods V_i of ∂M in M . ♦

As a simple application of Theorem 13, we can rederive $H_c^k(\mathbb{R}^n)$ from a knowledge of $H^k(S^{n-1})$, by choosing M to be the closed ball B in \mathbb{R}^n , with $H_c^k(B) \approx H^k(B) = 0$ for $k \neq 0$. The reader may use Theorem 12 to compute $H_c^k(S^n \times \mathbb{R}^m)$, by considering the pair $(S^n \times \mathbb{R}^m, \{p\} \times \mathbb{R}^m)$. Then Theorem 13 may be used to compute the cohomology of $S^n \times S^{m-1} = \partial(S^n \times \text{closed ball in } \mathbb{R}^m)$. For our next application we will seek bigger game.

Let $M \subset \mathbb{R}^{n+1}$ be a compact n -dimensional submanifold of \mathbb{R}^{n+1} (a compact "hypersurface" of \mathbb{R}^{n+1}). Using Theorem 8-17, the sequence of the pair (\mathbb{R}^{n+1}, M) gives

$$\begin{array}{ccccccc} H_c^n(\mathbb{R}^{n+1}) & \longrightarrow & H^n(M) & \xrightarrow{\delta} & H_c^{n+1}(\mathbb{R}^{n+1} - M) & \longrightarrow & H_c^{n+1}(\mathbb{R}^{n+1}) \longrightarrow H^{n+1}(M). \\ \parallel & & & & \cong & & \parallel \\ 0 & & & & \mathbb{R} & & 0 \end{array}$$

It follows that

$$(*) \quad \text{number of components of } \mathbb{R}^{n+1} - M = \dim H^n(M) + 1.$$

But we also know (Problem 8-25) that

$$(**) \quad \text{number of components of } \mathbb{R}^{n+1} - M \geq 2.$$

14. THEOREM. If $M \subset \mathbb{R}^{n+1}$ is a compact hypersurface, then M is orientable, and $\mathbb{R}^{n+1} - M$ has exactly 2 components. Moreover, M is the boundary of each component.

PROOF. From (*) and (**) we obtain

$$\dim H^n(M) + 1 \geq 2.$$

Since $\dim H^n(M)$ is either 0 or 1, we conclude that $\dim H^n(M) = 1$, so M is orientable; then (*) shows that $\mathbb{R}^{n+1} - M$ has exactly two components. The proof in Problem 8-25 shows that every point of M is arbitrarily close to points in different components of $\mathbb{R}^{n+1} - M$, so every point of M is in the boundary of each of the two components. ♦

15. COROLLARY (GENERALIZED $[C^\infty]$ JORDAN CURVE THEOREM). If $M \subset \mathbb{R}^{n+1}$ is a submanifold homeomorphic to S^n , then $\mathbb{R}^{n+1} - M$ has two components, and M is the boundary of each.

16. COROLLARY. Neither the projective plane nor the Klein bottle can be imbedded in \mathbb{R}^3 .

Our next main result will combine some of the theorems we already have. However, there are a number of technicalities involved, which we will have to dispose of first.

Consider a bounded open set $U \subset \mathbb{R}^n$ which is star-shaped with respect to 0. Then U can be described as

$$U = \{tx : x \in S^{n-1} \text{ and } 0 \leq t < \rho(x)\}$$

for a certain function $\rho: S^{n-1} \rightarrow \mathbb{R}$. We will call ρ the radial function of U .

If ρ is C^∞ , then we can prove that U is diffeomorphic to the open ball B of radius 1 in \mathbb{R}^n . The basic idea of the proof is to take $tx \in B$ to $\rho(x)t \cdot x \in U$. This produces difficulties at 0, so a modification is necessary.

17. LEMMA. If the radial function ρ of a star-shaped open set $U \subset \mathbb{R}^n$ is C^∞ , then U is diffeomorphic to the open ball B of radius 1 in \mathbb{R}^n .

PROOF. We can assume, without loss of generality, that $\rho \geq 1$ on S^{n-1} . Let $f: [0, 1] \rightarrow [0, 1]$ be a C^∞ function with

$$\begin{aligned} f &= 0 \text{ in a neighborhood of } 0 \\ f' &\geq 0 \\ f(1) &= 1. \end{aligned}$$

Define $h: B \rightarrow U$ by

$$h(tx) = [t + (\rho(x) - 1)f(t)]x, \quad x \in S^{n-1}, \quad 0 \leq t < 1.$$

Clearly h is a one-one map of B onto U . It is the identity in a neighborhood of 0, so it is C^∞ , with a non-zero Jacobian, at 0. At any other point the same conclusion follows from the fact that $t \mapsto t + (\rho(x) - 1)f(t)$ is a C^∞ function with strictly positive derivative. ♦

In general, the function ρ need not be C^∞ ; it might not even be continuous.

However, the discontinuities of ρ can be of a certain form only.

18. LEMMA. At each point $x \in S^{n-1}$, the radial function ρ of a star-shaped open set $U \subset \mathbb{R}^n$ is “lower semi-continuous”: for every $\varepsilon > 0$ there is a neighborhood W of x in S^{n-1} such that $\rho(y) > \rho(x) - \varepsilon$ for all $y \in W$.

PROOF. Choose $tx \in U$ with $\rho(x) - t < \varepsilon$. Since U is open, there is an open

ball B with $x \in B \subset U$. There is clearly a neighborhood W of x with the property that for $y \in W$ the point ty is in B , and hence in U . This means that for $y \in W$ we have $\rho(y) \geq t > \rho(x) - \varepsilon$. ♦

Even when ρ is discontinuous, it looks as if U should be diffeomorphic to \mathbb{R}^n . Proving this turns out to be quite a feat, and we will be content with proving the following.

19. LEMMA. If U is an open star-shaped set in \mathbb{R}^n , then $H^k(U) \approx H^k(\mathbb{R}^n)$ and $H_c^k(U) \approx H_c^k(\mathbb{R}^n)$ for all k .

PROOF. The proof for H^k is clear, since U is smoothly contractible to a point. We also know that $H_c^n(U) \approx \mathbb{R} \approx H_c^n(\mathbb{R}^n)$. By Theorem 8-17, we just have to show that $H_c^k(U) = 0$ for $0 \leq k < n$.

Let ω be a closed k -form with compact support $K \subset U$. We claim that there is a C^∞ function $\bar{\rho}: S^{n-1} \rightarrow \mathbb{R}$ such that $\bar{\rho} < \rho$ and

$$K \subset V = \{tx : x \in S^{n-1} \text{ and } 0 \leq t < \bar{\rho}(x)\}.$$

This will prove the Lemma, for then V is diffeomorphic to \mathbb{R}^n , and consequently $\omega = d\eta$ where η has compact support contained in V , and hence in U .

For each $x \in S^{n-1}$, choose $t_x < \rho(x)$ such that all points in K of the form ux for $0 \leq u \leq \rho(x)$ actually have $u < t_x$. Since K is closed and ρ is lower semi-

continuous, there is a neighborhood W_x of x in S^{n-1} such that t_x may also be used as t_y for all $y \in W$. Let W_{x_1}, \dots, W_{x_r} cover S^{n-1} , let ϕ_1, \dots, ϕ_r be a partition of unity subordinate to this cover, and define

$$\bar{\rho} = t_{x_1}\phi_1 + \dots + t_{x_r}\phi_r.$$

Any point $x \in S^{n-1}$ is in a certain subcollection of the W_{x_i} , say W_{x_1}, \dots, W_{x_l} for convenience. Then $\rho_{l+1}(x), \dots, \rho_r(x)$ are 0. Each t_{x_1}, \dots, t_{x_l} is $< \rho(x)$. Since $\phi_1(x) + \dots + \phi_l(x) = 1$, it follows that $\bar{\rho}(x) < \rho(x)$. Similarly, $K \subset V$. ♦

We can apply this last Lemma in the following way. Let M be a compact manifold, and choose a Riemannian metric for M . According to Problem 9-32, every point has a neighborhood U which is geodesically convex; we can also choose U so that for any $p \in U$ the map \exp_p takes an open subset of M_p diffeomorphically onto U . Let $\{U_1, \dots, U_r\}$ be a finite cover by such open sets. If any $V = U_{i_1} \cap \dots \cap U_{i_l}$ is non-empty, then V is clearly geodesically convex. If $p \in V$, then \exp_p establishes a diffeomorphism of V with an open star-shaped set in M_p . It follows from Lemma 19 that V has the same H^k and H_c^k as \mathbb{R}^n . In general, a manifold M will be called of **finite type** if there is a finite cover $\{U_1, \dots, U_r\}$ such that each non-empty intersection has the same H^k and H_c^k as \mathbb{R}^n ; such a cover will be called **nice**.

It is fairly clear that if we consider $\mathbb{N} = \{1, 2, 3, \dots\}$ as a subset of \mathbb{R}^2 , then $M = \mathbb{R}^2 - \mathbb{N}$ is not of finite type. To prove this rigorously, we first use the Mayer-Vietoris sequence for $\mathbb{R}^2 = M \cup V$, where V is a disjoint union of balls around $1, 2, 3, \dots$. We obtain

$$\begin{array}{ccccccc}
 H^1(\mathbb{R}^2) & \longrightarrow & H^1(M) \oplus H^1(V) & \longrightarrow & H^1(M \cap V) & \longrightarrow & H^2(\mathbb{R}^2), \\
 \parallel & & \parallel & & & & \parallel \\
 0 & & 0 & & & & 0
 \end{array}$$

where $M \cap V$ has the same H^1 as a disjoint union of infinitely many copies of S^1 ; this shows that $H^1(M)$ is infinite dimensional (see Problem 7 for more information about the cohomology of M). On the other hand,

20. PROPOSITION. If M has finite type, then $H^k(M)$ and $H_c^k(M)$ are finite dimensional for all k .

PROOF. By induction on the number of open sets r in a nice cover. It is clear for $r = 1$. Suppose it is true for a certain r , and consider a nice cover $\{U_1, \dots, U_r, U\}$ of M . Then the theorem is true for $V = U_1 \cup \dots \cup U_r$ and

for U . It is also true for $U \cap V$, since this has the nice cover $\{U \cap U_1, \dots, U \cap U_r\}$. Now consider the Mayer-Vietoris sequence

$$\dots \rightarrow H^{k-1}(U \cap V) \xrightarrow{\delta} H^k(M) \xrightarrow{\alpha} H^k(U) \oplus H^k(V) \rightarrow \dots$$

The map α maps $H^k(M)$ onto a finite dimensional vector space, and the kernel of α is also finite dimensional. So $H^k(M)$ must be finite dimensional.

The proof for $H_c^k(M)$ is similar. ♦

For any manifold M we can define (see Problem 8-31) the **cup product** map

$$H^k(M) \times H^l(M) \xrightarrow{\cup} H^{k+l}(M)$$

by

$$([\omega], [\eta]) \mapsto [\omega \wedge \eta].$$

We can also define

$$H^k(M) \times H_c^l(M) \xrightarrow{\cup} H_c^{k+l}(M)$$

by the same formula, since $\omega \wedge \eta$ has compact support if η does. Now suppose that M^n is connected and oriented, with orientation μ . There is then a unique element of $H_c^n(M)$ represented by any $\eta \in C_c^n(M)$ with

$$\int_{(M, \mu)} \eta = 1.$$

It is convenient to also use μ to denote both this element of $H_c^n(M)$ and the isomorphism $H_c^n(M) \rightarrow \mathbb{R}$ which takes this element to $1 \in \mathbb{R}$. Now every $\alpha \in H^k(M)$ determines an element of the dual space $H_c^{n-k}(M)^*$ by

$$\beta \mapsto \alpha \cup \beta \in H_c^n(M) \xrightarrow{\mu} \mathbb{R}.$$

We denote this element of $H_c^{n-k}(M)^*$ by $PD(\alpha)$, the “Poincaré dual” of α , so that we have a map

$$PD: H^k(M) \rightarrow H_c^{n-k}(M)^*, \quad PD(\alpha)(\beta) = \mu(\alpha \cup \beta).$$

One of the fundamental theorems of manifold theory states that PD is always an isomorphism. We are all set up to prove this fact, but we shall restrict the theorem to manifolds of finite type, in order not to plague ourselves with additional technical details. As with most big theorems of algebraic topology, the main part of the proof is called a Lemma, and the theorem itself is a simple corollary.

21. LEMMA. If $M = U \cup V$ for open sets U and V and PD is an isomorphism for all k on U , V , and $U \cap V$, then PD is also an isomorphism for all k on M .

PROOF. Let $l = n - k$. Consider the following diagram, in which the top row is the Mayer-Vietoris sequence, and the bottom row is the dual of the Mayer-Vietoris sequence for compact supports.

$$\begin{array}{ccccccccc}
 H^{k-1}(U) \oplus H^{k-1}(V) & \longrightarrow & H^{k-1}(U \cap V) & \longrightarrow & H^k(M) & \longrightarrow & H^k(U) \oplus H^k(V) & \longrightarrow & H^k(U \cap V) \\
 \downarrow PD \oplus PD & & \downarrow PD & & \downarrow PD & & \downarrow PD \oplus PD & & \downarrow PD \\
 [H_c^{l+1}(U) \oplus H_c^{l+1}(V)]^* & \longrightarrow & H_c^{l+1}(U \cap V)^* & \longrightarrow & H_c^l(M)^* & \longrightarrow & [H_c^l(U) \oplus H_c^l(V)]^* & \longrightarrow & H_c^l(U \cap V)^*
 \end{array}$$

By assumption, all vertical maps, except possibly the middle one, are isomorphisms. It is not hard to check (Problem 8) that every square in this diagram commutes up to sign, so that by changing some of the vertical isomorphisms to their negatives, we obtain a commutative diagram. We now forget all about our manifold and use a purely algebraic result.

“THE FIVE LEMMA”. Consider the following commutative diagram of vector spaces and linear maps. Suppose that the rows are exact, and that $\phi_1, \phi_2, \phi_4, \phi_5$ are isomorphisms. Then ϕ_3 is also an isomorphism.

$$\begin{array}{ccccccccc}
 V_1 & \xrightarrow{\alpha_1} & V_2 & \xrightarrow{\alpha_2} & V_3 & \xrightarrow{\alpha_3} & V_4 & \xrightarrow{\alpha_4} & V_5 \\
 \downarrow \phi_1 & & \downarrow \phi_2 & & \downarrow \phi_3 & & \downarrow \phi_4 & & \downarrow \phi_5 \\
 W_1 & \xrightarrow{\beta_1} & W_2 & \xrightarrow{\beta_2} & W_3 & \xrightarrow{\beta_3} & W_4 & \xrightarrow{\beta_4} & W_5
 \end{array}$$

PROOF. Suppose $\phi_3(x) = 0$ for some $x \in V_3$. Then $\beta_3\phi_3(x) = 0$, so $\phi_4\alpha_3(x) = 0$. Hence $\alpha_3(x) = 0$, since ϕ_4 is an isomorphism. By exactness at V_3 , there is $y \in V_2$ with $x = \alpha_2(y)$. Thus $0 = \phi_3(x) = \phi_3\alpha_2(y) = \beta_2\phi_2(y)$. Hence $\phi_2(y) = \beta_1(z)$ for some $z \in W_1$. Moreover, $z = \phi_1(w)$ for some $w \in V_1$. Then

$$\phi_2(y) = \beta_1(z) = \beta_1\phi_1(w) = \phi_2\alpha_1(w),$$

which implies that $y = \alpha_1(w)$. Hence

$$x = \alpha_2(y) = \alpha_2(\alpha_1(w)) = 0.$$

So ϕ_3 is one-one.

The proof that ϕ_3 is onto is similar, and is left to the reader. This proves the original Lemma. ♦

22. THEOREM (THE POINCARÉ DUALITY THEOREM). If M is a connected oriented n -manifold of finite type, then the map

$$PD: H^k(M) \rightarrow H_c^{n-k}(M)^*$$

is an isomorphism for all k .

PROOF. By induction on the number r of open sets in a nice cover of M . The theorem is clearly true for $r = 1$. Suppose it is true for a certain r , and consider a nice cover $\{U_1, \dots, U_r, U\}$ of M . Let $V = U_1 \cup \dots \cup U_r$. The theorem is true for U , V , and for $U \cap V$ (as in the proof of Proposition 19). By the Lemma, it is true for M . This completes the induction step. ♦

23. COROLLARY. If M is a connected oriented n -manifold of finite type, then $H^k(M)$ and $H_c^{n-k}(M)$ have the same dimension.

PROOF. Use the Theorem and Proposition 19, noting that V^* is isomorphic to V if V is finite dimensional. ♦

Even though the Poincaré Duality Theorem holds for manifolds which are not of finite type, Corollary 23 does not. In fact, Problem 7 shows that $H^1(\mathbb{R}^2 - \mathbb{N})$ and $H_c^1(\mathbb{R}^2 - \mathbb{N})$ have different (infinite) dimensions.

24. COROLLARY. If M is a compact connected orientable n -manifold, then $H^k(M)$ and $H^{n-k}(M)$ have the same dimension.

25. COROLLARY. If M is a compact orientable odd-dimensional manifold, then $\chi(M) = 0$.

PROOF. In the expression for $\chi(M)$, the terms $(-1)^k \dim H^k(M)$ and

$$(-1)^{n-k} \dim H^{n-k}(M) = (-1)^{k+1} \dim H^{n-k}(M)$$

cancel in pairs. ♦

A more involved use of Poincaré duality will eventually allow us to say much more about the Euler characteristic of any compact connected oriented manifold M^n . We begin by considering a smooth k -dimensional orientable vector bundle $\xi = \pi: E \rightarrow M$ over M . Orientations μ for M and ν for ξ give an orientation $\mu \oplus \nu$ for the $(n+k)$ -manifold E , since E is locally a product. If $\{U_1, \dots, U_r\}$ is a nice cover of M by geodesically convex sets so small that each bundle $\xi|_{U_i}$ is trivial, then a slight modification of the proof for Lemma 19

shows that $\{\pi^{-1}(U_1), \dots, \pi^{-1}(U_r)\}$ is a nice cover of E , so E is a manifold of finite type. Notice also that for the maps

$$M \begin{array}{c} \xrightarrow{s = 0\text{-section}} \\ \xleftarrow{\pi} \end{array} E$$

we have

$$\pi \circ s = \text{identity of } M$$

$$s \circ \pi \quad \text{is smoothly homotopic to identity of } E,$$

so $\pi^*: H^l(M) \rightarrow H^l(E)$ is an isomorphism for all l . The Poincaré duality theorem shows that there is a unique class $U \in H_c^k(E)$ such that

$$\pi^*\mu \cup U = \mu \oplus \nu \in H_c^{n+k}(E).$$

This class U is called the **Thom class** of ξ . Our first goal will be to find a simpler property to characterize U .

Let $F_p = \pi^{-1}(p)$ be the fibre of ξ over any point $p \in M$, and let $j_p: F_p \rightarrow E$ be the inclusion map. Since j_p is proper, there is an element $j_p^*U \in H_c^k(F_p)$. On the other hand, the orientation ν for ξ determines an orientation ν_p for F_p , and hence an element $\nu_p \in H_c^k(F_p)$.

26. THEOREM. Let (M, μ) be a compact connected oriented manifold, and $\xi = \pi: E \rightarrow M$ an oriented k -plane bundle over M with orientation ν . Then the Thom class U is the unique element of $H_c^k(E)$ with the property that for all $p \in M$ we have $j_p^*U = \nu_p$. (This condition means that

$$\int_{(F_p, \nu_p)} j_p^*\omega = 1,$$

where U is the class of the closed form ω .)

PROOF. Pick some closed form $\omega \in C_c^k(E)$ representing U , and let $\eta \in C^n(M)$ be a form representing μ , so that $\int_{(M, \mu)} \eta = 1$. Our definition of U states that

$$(1) \quad \int_E \pi^*\eta \wedge \omega = 1.$$

Let $A \subset M$ be an open set which is diffeomorphic to \mathbb{R}^n , so that A is smoothly contractible to any point $p \in A$. Also choose A so that there is an equivalence

$$f: \pi^{-1}(A) \rightarrow A \times \mathbb{R}^k.$$

This equivalence allows us to identify $\pi^{-1}(A)$ with $A \times F_p$. Under this identification, the map $j_p: F_p \rightarrow \pi^{-1}(A)$ corresponds to the map $e \mapsto (p, e)$ for $e \in F_p$, which we will continue to denote by j_p . We will also use $\pi_2: A \times F_p \rightarrow F_p$ to denote projection on the second factor.

Let $\| \cdot \|$ be a norm on F_p . By choosing a smaller A if necessary, we can assume that there is some $K > 0$ such that, under the identification of $\pi^{-1}(A)$ with $A \times F_p$, the support of $\omega|_{\pi^{-1}(A)}$ is contained in $\{(q, e) : q \in A, \|e\| < K\}$.

Using the fact that A is smoothly contractible to p , it is easy to see that there is a smooth homotopy $H: (A \times F_p) \times [0, 1] \rightarrow A \times F_p$ such that

$$\begin{aligned} H(e, 0) &= e \\ H(e, 1) &= (p, \pi_2(e)) = j_p(\pi_2(e)); \end{aligned}$$

we just pull the fibres along the smooth homotopy which makes A contractible

to e . For the H constructed in this way it follows that

$$H(e, t) \notin \text{support } \omega \text{ if } \|e\| \geq K.$$

Consequently, the form $H^*\omega$ on $(A \times F_p) \times [0, 1]$ has support contained in $\{(q, e, t) : \|e\| < K\}$. A glance at the definition of I (page 224) shows that the

form $IH^*\omega$ on $A \times F_p$ has support contained in $\{(q, e) : \|e\| < K\}$. Theorem 7-14 shows that

$$\begin{aligned}(j_p \circ \pi_2)^*\omega - \omega &= i_1^*(H^*\omega) - i_0^*(H^*\omega) \\ &= d(IH^*\omega) + I(dH^*\omega) \\ &= d(IH^*\omega).\end{aligned}$$

Thus

$$(2) \quad \pi_2^*j_p^*\omega - \omega = d\lambda, \quad \text{support } \lambda \subset \{(q, e) : \|e\| < K\}.$$

So

$$(3) \quad \int_{A \times F_p} \pi^*\eta \wedge \omega = \int_{A \times F_p} \pi^*\eta \wedge \pi_2^*j_p^*\omega - \int_{A \times F_p} \pi^*\eta \wedge d\lambda.$$

Now, on the one hand we have (Problem 8-17)

$$(4) \quad \int_{A \times F_p} \pi^*\eta \wedge \pi_2^*j_p^*\omega = \int_A \pi^*\eta \cdot \int_{F_p} j_p^*\omega.$$

On the other hand, we claim that the last integral in (3) is 0. To prove this, it clearly suffices to prove that the integral is 0 over $A' \times F_p$ for any closed ball $A' \subset A$. Since

$$\pi^*\mu \wedge d\lambda = \pm d(\pi^*\mu \wedge \lambda),$$

we have

$$\begin{aligned}(5) \quad \int_{A' \times F_p} \pi^*\mu \wedge d\lambda &= \pm \int_{A' \times F_p} d(\pi^*\mu \wedge \lambda) && \text{where } \pi^*\mu \wedge \lambda \text{ has} \\ & && \text{compact support on} \\ & && A' \times F_p \text{ by (2)} \\ &= \pm \int_{\partial A' \times F_p} \pi^*\mu \wedge \lambda && \text{by Stokes' Theorem} \\ &= 0.\end{aligned}$$

because the form $\pi^*\mu \wedge \lambda$ is clearly 0 on $\partial A' \times F_p$ (since $\partial A'$ is $(n-1)$ -dimensional).

Combining (3), (4), (5) we see that

$$\int_{A \times F_p} \pi^*\eta \wedge \omega = \int_A \pi^*\eta \cdot \int_{F_p} j_p^*\omega.$$

This shows that $\int_{F_p} j_p^* \omega$ is independent of p , for $p \in A$. Using connectedness, it is easy to see that it is independent of p for all $p \in M$, so we will denote it simply by $\int_F j^* \omega$. Thus

$$\int_{\pi^{-1}(A)} \pi^* \eta \wedge \omega = \int_A \pi^* \eta \cdot \int_F j^* \omega.$$

Comparing with equation (1), and utilizing partitions of unity, we conclude that

$$\int_F j^* \omega = 1,$$

which proves the first part of the theorem.

Now suppose we have another class $U' \in H_c^k(E)$. Since

$$H_c^k(E) \approx H^n(E) \approx H^n(M) \approx \mathbb{R},$$

it follows that $U' = cU$ for some $c \in \mathbb{R}$. Consequently,

$$j_p^* U' = j_p^* cU = c \cdot v_p.$$

Hence U' has the same property as U only if $c = 1$. ♦

The Thom class U of $\xi = \pi: E \rightarrow M$ can now be used to determine an element of $H^k(M)$. Let $s: M \rightarrow E$ be any section; there always is one (namely, the 0-section) and any two are clearly smoothly homotopic. We define the Euler class $\chi(\xi) \in H^k(M)$ of ξ by

$$\chi(\xi) = s^* U.$$

Notice that if ξ has a non-zero section $s: M \rightarrow E$, and $\omega \in C_c^k(E)$ represents U , then a suitable multiple $c \cdot s$ of s takes M to the complement of support ω . Hence, in this case

$$\chi(\xi) = (c \cdot s)^* U = 0.$$

The terminology “Euler class” is connected with the special case of the bundle TM , whose sections are, of course, vector fields on M . If X is a vector field on M which has an isolated 0 at some point p (that is, $X(p) = 0$, but $X(q) \neq 0$ for $q \neq p$ in a neighborhood of p), then, quite independently of our previous considerations, we can define an “index” of X at p . Consider first a vector

field X on an open set $U \subset \mathbb{R}^n$ with an isolated zero at $0 \in U$. We can define a function $f_X: U - \{0\} \rightarrow S^{n-1}$ by $f_X(p) = X(p)/|X(p)|$. If $i: S^{n-1} \rightarrow U$ is $i(p) = \varepsilon p$, mapping S^{n-1} into U , then the map $f_X \circ i: S^{n-1} \rightarrow S^{n-1}$ has a certain degree; it is independent of ε , for small ε , since the maps $i_1, i_2: S^{n-1} \rightarrow U$ corresponding to ε_1 and ε_2 will be smoothly homotopic. This degree is called the index of X at 0.

Now consider a diffeomorphism $h: U \rightarrow V \subset \mathbb{R}^n$ with $h(0) = 0$. Recall that h_*X is the vector field on V with

$$(h_*X)(y) = h_*(X_{h^{-1}(y)}).$$

Clearly 0 is also an isolated zero of h_*X .

27. LEMMA. If $h: U \rightarrow V \subset \mathbb{R}^n$ is a diffeomorphism with $h(0) = 0$, and X has an isolated 0 at 0, then the index of h_*X at 0 equals the index of X at 0.

PROOF. Suppose first that h is orientation preserving. Define

$$H: \mathbb{R}^n \times [0, 1] \rightarrow \mathbb{R}^n$$

by

$$H(x, t) = \begin{cases} h(tx) & 0 < t \leq 1 \\ Dh(0)(x) & t = 0. \end{cases}$$

This is a smooth homotopy; to prove that it is smooth at 0 we use Lemma 3-2 (compare Problem 3-32). Each map $H_t = x \mapsto H(x, t)$ is clearly a diffeomorphism, $0 \leq t \leq 1$. Note that $H_1 \in \text{SO}(n)$, since h is orientation preserving. There is also a smooth homotopy $\{H_t\}$, $1 \leq t \leq 2$ with each $H_t \in \text{SO}(n)$ and $H_2 = \text{identity}$, since $\text{SO}(n)$ is connected. So (see Problem 8-25), the map h is smoothly homotopic to the identity, via maps which are diffeomorphisms. This shows that f_{h_*X} is smoothly homotopic to f_X on a sufficiently small region of $\mathbb{R}^n - \{0\}$. Hence the degree of $f_{h_*X} \circ i$ is the same as the degree of $f_X \circ i$.

To deal with non-orientation preserving h , it obviously suffices to check the theorem for $h(x) = (x^1, \dots, x^{n-1}, -x^n)$. In this case

$$f_{h_*X} = h \circ f_X \circ h^{-1},$$

which shows that $\text{degree } f_{h_*X} \circ i = \text{degree } f_X \circ i$. ♦

As a consequence of Lemma 27, we can now define the index of a vector field on a manifold. If X is a vector field on a manifold M , with an isolated zero at $p \in M$, we choose a coordinate system (x, U) with $x(p) = 0$, and define the index of X at p to be the index of x_*X at 0.

28. THEOREM. Let M be a compact connected manifold with an orientation μ , which is, by definition, also an orientation for the tangent bundle $\xi = \pi: TM \rightarrow M$. Let $X: M \rightarrow TM$ be a vector field with only a finite number of zeros, and let σ be the sum of the indices of X at these zeros. Then

$$\chi(\xi) = \sigma \cdot \mu \in H^n(M).$$

PROOF. Let p_1, \dots, p_r be the zeros of X . Choose disjoint coordinate systems $(U_1, x_1), \dots, (U_r, x_r)$ with $x_i(p_i) = 0$, and let

$$B_i = x_i^{-1}(\{p \in \mathbb{R}^n : |p| \leq 1\}).$$

If $\omega \in C_c^n(E)$ is a closed form representing the Thom class U of ξ , then we are trying to prove that

$$\int_{(M, \mu)} X^*(\omega) = \sigma.$$

We can clearly suppose that $X(q) \notin \text{support } \omega$ for $q \notin \bigcup_i B_i$. So

$$\int_M X^*(\omega) = \sum_{i=1}^r \int_{B_i} X^*(\omega);$$

thus it suffices to prove that

$$(*) \quad \int_{B_i} X^*(\omega) = \text{index of } X \text{ at } p_i.$$

It will be convenient to drop the subscript i from now on.

We can assume that TM is trivial over B , so that $\pi^{-1}(B)$ can be identified with $B \times M_p$. Let j_p and π_2 have the same meaning as in the proof of Theorem 26. Also choose a norm $\| \cdot \|$ on M_p . We can assume that under the identification of $\pi^{-1}(B)$ with $B \times M_p$, the support of $\omega|_{\pi^{-1}(B)}$ is contained in $\{(q, v) : q \in A, \|v\| \leq 1\}$. Recall from the proof of Theorem 26 that

$$\pi_2^* j_p^* \omega - \omega = d\lambda \quad \text{support } \lambda \subset \{(q, v) : \|v\| \leq 1\}.$$

Since we can assume that $X(q) \notin \text{support } \lambda$ for $q \in \partial B$, we have

$$\begin{aligned} (1) \quad \int_B X^*(\omega) &= \int_B X^* \pi_2^* (j_p^* \omega) - \int_B X^*(d\lambda) \\ &= \int_B X^* \pi_2^* (j_p^* \omega) - \int_{\partial B} X^*(\lambda) \quad \text{by Stokes' Theorem} \\ &= \int_B X^* \pi_2^* (j_p^* \omega). \end{aligned}$$

On the manifold M_p we have

$$j_p^* \omega = d\rho \quad \begin{array}{l} \rho \text{ an } (n-1)\text{-form on } M_p \\ \text{(with non-compact support).} \end{array}$$

If $D \subset M_p$ is the unit disc (with respect to the norm $\| \cdot \|$) and S^{n-1} denotes $\partial D \subset M_p$, then

$$\begin{aligned} (2) \quad \int_{S^{n-1}} \rho &= \int_{\partial D} \rho = \int_D d\rho \\ &= \int_D j_p^* \omega \\ &= 1. \quad \begin{array}{l} \text{by Theorem 26, and the fact} \\ \text{that support } j_p^* \omega \subset D. \end{array} \end{aligned}$$

Now, for $q \in B - \{p\}$, we can define

$$\bar{X}(q) = X(q)/|X(q)|,$$

and $\bar{X}: \partial B \rightarrow TM$ is smoothly homotopic to $X: \partial B \rightarrow TM$. So

$$\begin{aligned} (3) \quad \int_B X^* \pi_2^* (j_p^* \omega) &= \int_B X^* \pi_2^* d\rho \\ &= \int_{\partial B} X^* \pi_2^* \rho \quad \text{by Stokes' Theorem} \\ &= \int_{\partial B} \bar{X}^* \pi_2^* \rho \\ &= \int_{\partial B} (\pi_2 \circ \bar{X})^* \rho. \end{aligned}$$

From the definition of the index of a vector field, together with equation (2), it follows that

$$(4) \quad \int_{\partial B} (\pi_2 \circ \bar{X})^* \rho = \text{index of } X \text{ at } p.$$

Equations (1), (3), (4) together imply (*). ♦

29. COROLLARY. If X and Y are two vector fields with only finitely many zeros on a compact orientable manifold, then the sum of the indices of X equals the sum of the indices of Y .

At the moment, we do not even know that there is a vector field on M with finitely many zeros, nor do we know what this constant sum of the indices is (although our terminology certainly suggests a good guess). To resolve these questions, we consider once again a triangulation of M . We can then find a vector field X with just one zero in each k -simplex of the triangulation. We begin by drawing the integral curves of X along the 1-simplexes, with a zero at each 0-simplex and at one point in each 1-simplex. We then extend this picture

to include the integral curves of X on the 2-simplexes, producing a zero at one

point in each of them. We then continue similarly until the n -simplexes are filled.

30. THEOREM (POINCARÉ-HOPF). The sum of the indices of this vector field (and hence of any vector field) on M is the Euler characteristic $\chi(M)$. Thus, for $\xi = \pi : TM \rightarrow M$ we have $\chi(\xi) = \chi(M) \cdot \mu$.

PROOF. At each 0-simplex of the triangulation, the vector field looks like

with index 1.

Now consider the vector field in a neighborhood of the place where it is zero on a 1-simplex. The vector field looks like a vector field on $\mathbb{R}^n = \mathbb{R}^1 \times \mathbb{R}^{n-1}$ which points directly inwards on $\mathbb{R}^1 \times \{0\}$ and directly outwards on $\{0\} \times \mathbb{R}^{n-1}$.

For $n = 2$, the index is clearly -1 . To compute the index in general, we note that f_X takes the “north pole” $N = (0, \dots, 0, 1)$ to itself and no other point goes to N . By Theorem 8-12 we just have to compute $\text{sign}_N f_X$. Now at N we can pick projection on $\mathbb{R}^{n-1} \times \{0\}$ as the coordinate system. Along the inverse image of the x^1 -axis the vector field looks exactly like figure (a) above, where we already know the degree is -1 , so f_{X*} takes the subspace of S^{n-1}_N consisting of tangent vectors to this curve into the same subspace, in an orientation reversing way. Along the inverse image of the x^2, \dots, x^{n-1} -axes the vector field looks like

so f_{X*} takes the corresponding subspaces of S^{n-1}_N into themselves in an orientation preserving way. Thus $\text{sign}_N f_X = -1$, which is therefore the index of the vector field.

In general, near a zero within a k -simplex, X looks like a vector field on $\mathbb{R}^n = \mathbb{R}^k \times \mathbb{R}^{n-k}$ which points directly inwards on $\mathbb{R}^k \times \{0\}$ and directly outwards on $\{0\} \times \mathbb{R}^{n-k}$. The same argument shows that the index is $(-1)^k$.

Consequently, the sum of the indices is

$$\alpha_0 - \alpha_1 + \alpha_2 - \dots = \chi(M). \quad \spadesuit$$

We end this chapter with one more observation, which we will need in the last chapter of Volume V! Let $\xi = \pi: E \rightarrow M$ be a smooth oriented k -plane bundle over a compact connected oriented n -manifold M , and let (\cdot, \cdot) be a Riemannian metric for ξ . Then we can form the “associated disc bundle” and “associated sphere bundle”

$$D = \{e : (e, e) \leq 1\}$$

$$S = \{e : (e, e) = 1\}.$$

It is easy to see that D is a compact oriented $(n+k)$ -manifold, with $\partial D = S$; moreover, the D constructed for any other Riemannian metric is diffeomorphic to this one. We let $\pi_0: S \rightarrow M$ be $\pi|_S$.

31. THEOREM. A class $\alpha \in H^k(M)$ satisfies $\pi_0^*(\alpha) = 0$ if and only if α is a multiple of $\chi(\xi)$.

PROOF. Consider the following picture. The top row is the exact sequence

$$\begin{array}{ccccc}
 H_c^k(D - S) & \xrightarrow{e} & H^k(D) & \xrightarrow{i^*} & H^k(S) \\
 & \searrow s^* & \downarrow \bar{s}_* \parallel (\pi|D)^* & \nearrow \pi_0^* & \\
 & & H^k(M) & &
 \end{array}$$

for (D, S) given by Theorem 13. The map $s: M \rightarrow D - S$ is the 0-section, while $\bar{s}: M \rightarrow D$ is the same 0-section. Note that everything commutes.

$$\begin{aligned}
 \pi_0^* &= i^* \circ (\pi|D)^* && \text{since } \pi_0 = (\pi|D) \circ i, \\
 s^* &= \bar{s}_* \circ e && \text{since extending a form to } D \\
 &&& \text{does not affect its value on } s(M),
 \end{aligned}$$

and that

$$\bar{s}^* \circ (\pi|D)^* = \text{identity of } H^k(M),$$

since $(\pi|D) \circ \bar{s}$ is smoothly homotopic to the identity.

Now let $\alpha \in H^k(M)$ satisfy $\pi_0^*(\alpha) = 0$. Then $i^*(\pi|D)^*\alpha = 0$, so $(\pi|D)^*\alpha \in \text{image } e$. Since $D - S$ is diffeomorphic to E , and every element of $H_c^k(D - S)$ is a multiple of the Thom class U of ξ , we conclude that

$$(\pi|D)^*\alpha = c \cdot e(U) \quad \text{for some } c \in \mathbb{R}.$$

Hence

$$\begin{aligned}
 \alpha &= \bar{s}^*(\pi|D)^*\alpha = c \cdot \bar{s}^*(e(U)) = c \cdot s^*U \\
 &= c \cdot \chi(\xi).
 \end{aligned}$$

The proof of the converse is similar. ♦

PROBLEMS

1. Find $H^k(S^1 \times \cdots \times S^1)$ by induction on the number n of factors. [Answer: $\dim H^k = \binom{n}{k}$.]

2. (a) Use the Mayer-Vietoris sequence to determine $H^k(M - \{p\})$ in terms of $H^k(M)$, for a connected manifold M .

(b) If M and N are two connected n -manifolds, let $M \# N$ be obtained by joining M and N as shown below. Find the cohomology of $M \# N$ in terms of that of M and N .

(c) Find χ for the n -holed torus. [Answer: $2 - 2n$.]

3. (a) Find $H^k(\text{Möbius strip})$.

(b) Find $H^k(\mathbb{P}^2)$.

(c) Find $H^k(\mathbb{P}^n)$. (Use Problem 1-15(b); it is necessary to consider whether a neighborhood of \mathbb{P}^{n-1} in \mathbb{P}^n is orientable or not.) [Answer: $\dim H^k(\mathbb{P}^n) = 1$ if k even and $\leq n$, $= 0$ otherwise.]

(d) Find $H^k(\text{Klein bottle})$.

(e) Find the cohomology of $M \# (\text{Möbius strip})$ and $M \# (\text{Klein bottle})$ if M is the n -holed torus.

4. (a) The figure below is a triangulation of a rectangle. If we perform the indicated identifications of edges we do *not* obtain a triangulation of the torus. Why not?

(b) The figure below does give a triangulation of the torus when sides are identified. Find α_0 , α_1 , α_2 for this triangulation; compare with Theorem 5 and Problem 1.

5. (a) For any triangulation of a compact 2-manifold M , show that

$$3\alpha_2 = 2\alpha_1$$

$$\alpha_1 = 3(\alpha_0 - \chi(M))$$

$$\frac{\alpha_0(\alpha_0 - 1)}{2} \geq \alpha_1$$

$$\alpha_0 \geq \frac{1}{2}(7 + \sqrt{49 - 24\chi(M)}).$$

(b) Show that for triangulations of S^2 and the torus $T^2 = S^1 \times S^1$ we have

$$S^2 : \quad \alpha_0 \geq 4 \quad \alpha_1 \geq 6 \quad \alpha_2 \geq 4$$

$$T^2 : \quad \alpha_0 \geq 7 \quad \alpha_1 \geq 21 \quad \alpha_2 \geq 14.$$

Find triangulations for which these inequalities are all equalities.

6. (a) Find $H_c^k(S^n \times \mathbb{R}^m)$ by induction on n , using the Mayer-Vietoris sequence for compact supports.

(b) Use the exact sequence of the pair $(S^n \times \mathbb{R}^m, \{p\} \times \mathbb{R}^m)$ to compute the same vector spaces.

(c) Compute $H^k(S^n \times S^{m-1})$, using Theorem 13.

7. (a) The vector space $H^1(\mathbb{R}^2 - \mathbb{N})$ may be described as the set of all sequences of real numbers. Using the exact sequence of the pair $(\mathbb{R}^2, \mathbb{N})$, show that $H_c^1(\mathbb{R}^2 - \mathbb{N})$ may be considered as the set of all real sequences $\{a_n\}$ such that $a_n = 0$ for all but finitely many n .

(b) Describe the map $PD: H^1(\mathbb{R}^2 - \mathbb{N}) \rightarrow H_c^1(\mathbb{R}^2 - \mathbb{N})^*$ in terms of these descriptions of $H^1(\mathbb{R}^2 - \mathbb{N})$ and $H_c^1(\mathbb{R}^2 - \mathbb{N})$, and show that it is an isomorphism.

(c) Clearly $H_c^1(\mathbb{R}^2 - \mathbb{N})$ has a countable basis. Show that $H^1(\mathbb{R}^2 - \mathbb{N})$ does not. *Hint:* If $v_i = \{a_i^j\} \in H^1(\mathbb{R}^2 - \mathbb{N})$, choose $(b_1, b_2) \in \mathbb{R}^2$ linearly independent of (a_1^1, a_1^2) ; then choose $(b_3, b_4, b_5) \in \mathbb{R}^3$ linearly independent of both (a_1^3, a_1^4, a_1^5) and (a_2^3, a_2^4, a_2^5) ; etc.

8. Show that the squares in the diagram in the proof of Lemma 21 commute, except for the square

$$\begin{array}{ccc} H^{k-1}(U \cap V) & \longrightarrow & H^k(M) \\ \downarrow PD & & \downarrow PD \\ H_c^{l+1}(U \cap V)^* & \longrightarrow & H_c^l(M)^* \end{array}$$

which commutes up to the sign $(-1)^k$. (It will be necessary to recall how various maps are defined, which is a good exercise; the only slightly difficult maps are the ones involved in the above diagram.)

9. (a) Let $M = M_1 \cup M_2 \cup M_3 \cup \dots$ be a disjoint union of oriented n -manifolds. Show that $H_c^k(M) \approx \bigoplus_i H_c^k(M_i)$, this “direct sum” consisting of all sequences $(\alpha_1, \alpha_2, \alpha_3, \dots)$ with $\alpha_i \in H_c^k(M_i)$ and all but finitely many $\alpha_i = 0 \in H_c^k(M_i)$.
 (b) Show that $H^k(M) \approx \prod_i H^k(M_i)$, this “direct product” consisting of all sequences $(\alpha_1, \alpha_2, \alpha_3, \dots)$ with $\alpha_i \in H^k(M_i)$.
 (c) Show that if the Poincaré duality theorem holds for each M_i , then it holds for M .
 (d) The figure below shows a decomposition of a triangulated 2-manifold into three open sets U_0 , U_1 , and U_2 . Use an analogous decomposition in n dimensions to prove that Poincaré duality holds for any triangulated manifold.

U_0 is union of shaded 
 U_1 is union of unshaded 

U_2 is union of shaded 

10. Let $\xi = \pi: E \rightarrow M$ and $\xi' = \pi': E' \rightarrow M$ be oriented k -plane bundles over a compact oriented manifold M , and (\tilde{f}, f) a bundle map from ξ' to ξ which is an isomorphism on each fibre.

- (a) If $U \in H_c^k(E)$ and $U' \in H_c^k(E')$ are the Thom classes, then $\tilde{f}^*(U) = U'$.
 (b) $f^*(\chi(\xi)) = \chi(\xi')$. (Using the notation of Problem 3-23, we have $f^*(\chi(\xi)) = \chi(f^*(\xi))$.)

11. (a) Let $\xi = \pi: E \rightarrow M$ be an oriented k -plane bundle over an oriented manifold M , with Thom class U . Using Poincaré duality, prove the Thom Isomorphism Theorem: The map $H^l(E) \rightarrow H_c^{l+k}(E)$ given by $\alpha \mapsto \alpha \cup U$ is an isomorphism for all l .

(b) Since we can also consider U as being in $H^k(E)$, we can form $U \cup U \in H_c^{2k}(E)$. Using anticommutativity of \wedge , show that this is 0 for k odd. Conclude that U represents $0 \in H^k(E)$, so that $\chi(\xi) = 0$. It follows, in particular, that $\chi(\xi) = 0$ when $\xi = \pi: TM \rightarrow M$ for M of odd dimension, providing another proof that $\chi(M) = 0$ in this case.

12. If a vector field X has an isolated singularity at $p \in M^n$, show that the index of $-X$ at p is $(-1)^n$ times the index of X at p . This provides another proof that $\chi(M) = 0$ for odd n .

13. (a) Let $p_1, \dots, p_r \in M$. Using Problem 8-26, show that there is a subset $D \subset M$ diffeomorphic to the closed ball, such that all $p_i \in \text{interior } D$.

(b) If M is compact, then there is a vector field X on M with only one singularity.

(c) It is a fact that a C^∞ map $f: S^{n-1} \rightarrow S^{n-1}$ of degree 0 is smoothly homotopic to a constant map. Using this, show that if $\chi(M) = 0$, then there is a nowhere 0 vector field on M .

(d) If M is connected and not compact, then there is a nowhere 0 vector field on M . (Begin with a triangulation to obtain a vector field with a discrete set of zeros. Join these by a ray going to infinity, enclose this ray in a cone, and push everything off to infinity.)

(e) If M is a connected manifold-with-boundary, with $\partial M \neq \emptyset$, then there is a nowhere zero vector field on M .

14. This Problem proves de Rham's Theorem. Basic knowledge of singular cohomology is required. We will denote the group of singular k -chains of X by $S_k(X)$. For a manifold M , we let $S_k^\infty(M)$ denote the C^∞ singular k -chains, and let $i: S_k^\infty(M) \rightarrow S_k(M)$ be the inclusion. It is not hard to show that there is a chain map $\tau: S_k(M) \rightarrow S_k^\infty(M)$ so that $\tau \circ i = \text{identity of } S_k^\infty(M)$, while $i \circ \tau$ is chain homotopic to the identity of $S_k(M)$ [basically, τ is approximation by a C^∞ chain]. This means that we obtain the correct singular cohomology of M if we consider the complex $\text{Hom}(S_k^\infty(M), \mathbb{R})$.

(a) If ω is a closed k -form on M , let $Rh(\omega) \in \text{Hom}(S_k^\infty(M), \mathbb{R})$ be

$$Rh(\omega)(c) = \int_c \omega.$$

Show that Rh is a chain map from $\{C^k(M)\}$ to $\{\text{Hom}(S_k^\infty(M), \mathbb{R})\}$. (*Hint: Stokes' Theorem.*) It follows that there is an induced map Rh from the de Rham cohomology of M to the singular cohomology of M .

(b) Show that Rh is an isomorphism on a smoothly contractible manifold (Lemmas 17, 18, and 19 will not be necessary for this.)

(c) Imitate the proof of Theorem 21, using the Mayer-Vietoris sequence for singular cohomology, to show that if Rh is an isomorphism for U , V , and $U \cap V$, then it is an isomorphism for $U \cup V$.

(d) Conclude that Rh is an isomorphism if M is of finite type. (Using the method of Problem 9, it follows that Rh is an isomorphism for any triangulated manifold.)

(e) Check that the cup product defined using \wedge corresponds to the cup product defined in singular cohomology.

APPENDIX A

CHAPTER 1

Following the suggestions in this chapter, we will now define a manifold to be a topological space M such that

- (1) M is Hausdorff,
- (2) For each $x \in M$ there is a neighborhood U of x and an integer $n \geq 0$ such that U is homeomorphic to \mathbb{R}^n .

Condition (1) is necessary, for there is even a 1-dimensional “manifold” which is not Hausdorff. It consists of $\mathbb{R} \cup \{*\}$ where $* \notin \mathbb{R}$, with the following topology: A set U is open if and only if

- (1) $U \cap \mathbb{R}$ is open,
- (2) If $* \in U$, then $(U \cap \mathbb{R}) \cup \{0\}$ is a neighborhood of 0 (in \mathbb{R}).

Thus the neighborhoods of $*$ look just like neighborhoods of 0. This space may also be obtained by identifying all points except 0 in one copy of \mathbb{R} with the corresponding point in another copy of \mathbb{R} . Although non-Hausdorff manifolds are important in certain cases, we will not consider them.

We have just seen that the Hausdorff property is not a “local property”, but local compactness is, so every manifold is locally compact. Moreover, a Hausdorff locally compact space is regular, so every manifold is regular. (By the way, this argument does not work for “infinite dimensional” manifolds, which are locally like Banach spaces; these need not be regular even if they are Hausdorff.) On the other hand, there are manifolds which are not normal (Problem 6). Every manifold is also clearly locally connected, so every component is open, and thus a manifold itself. Before exhibiting non-metrizable manifolds, we first note that almost all “nice” properties of a manifold are equivalent.

THEOREM. The following properties are equivalent for any manifold M :

- (a) Each component of M is σ -compact.
- (b) Each component of M is second countable (has a countable base for the topology).
- (c) M is metrizable.
- (d) M is paracompact.

(In particular, a compact manifold is metrizable.)

FIRST PROOF. (a) \Rightarrow (b) follows immediately from the simple proposition that a σ -compact locally second countable space is second countable.

(b) \Rightarrow (c) follows from the Urysohn metrization theorem.

(c) \Rightarrow (d) because any metric space is paracompact (Kelley, *General Topology*, pg. 160). The second proof does not rely on this difficult theorem.

(d) \Rightarrow (a) is a consequence of the following.

LEMMA. A connected, locally compact, paracompact space is σ -compact.

Proof. There is a locally finite cover of the space by open sets with compact closure. If U_0 is one of these, then \bar{U}_0 can intersect only a finite number U_1, \dots, U_{n_1} of the others. Similarly $\bar{U}_0 \cup \bar{U}_1 \cup \dots \cup \bar{U}_{n_1}$ intersects only $U_{n_1+1}, \dots, U_{n_2}$; and so on. The union

$$\bar{U}_0 \cup \dots \cup \bar{U}_{n_1} \cup \dots \cup \bar{U}_{n_2} \cup \dots = U_0 \cup \dots \cup U_{n_1} \cup \dots \cup U_{n_2} \cup \dots$$

is clearly open. It is also closed, for if x is in the closure, then x must be in the closure of a finite union of these U_i , because x has a neighborhood which intersects only finitely many. Thus x is in the union.

Since the space is connected, it equals this countable union of compact sets.

This proves the Lemma and the Theorem.

SECOND PROOF. (a) \Rightarrow (b) \Rightarrow (c) and (d) \Rightarrow (a) as before.

(c) \Rightarrow (a) is Theorem 1-2.

(a) \Rightarrow (d). Let $M = C_1 \cup C_2 \cup \dots$, where each C_i is compact. Clearly C_1 has an open neighborhood U_1 with compact closure. Then $\bar{U}_1 \cup C_2$ has an open neighborhood U_2 with compact closure. Continuing in this way, we obtain open sets U_i with \bar{U}_i compact and $\bar{U}_i \subset U_{i+1}$, whose union contains all C_i , and hence is M . It is easy to show from this that M is paracompact. ♦

It turns out that there are even 1-manifolds which are not paracompact. The construction of these examples requires the ordinal numbers, which are briefly explained here. (Ordinal numbers will not be needed for a 2-dimensional example to come later.

ORDINAL NUMBERS

Recall that an **ordering** $<$ on a set A is a relation such that

- (1) $a < b$ and $b < c$ implies $a < c$ for all $a, b, c \in A$ (transitivity)

(2) For all $a, b \in A$, one and only one of the following holds:

- (i) $a = b$
 - (ii) $a < b$
 - (iii) $b < a$ (also written $a > b$)
- (trichotomy).

An ordered set is just a pair $(A, <)$ where $<$ is an ordering on A . Two ordered sets $(A, <)$ and $(B, <)$ are order isomorphic if there is a one-one onto function $f: A \rightarrow B$ such that $a < b$ implies $f(a) < f(b)$; the map f itself is called an order isomorphism, and f^{-1} is easily seen to be an order isomorphism also.

An ordering $<$ on A is a well-ordering if every non-empty subset $B \subset A$ has a *first* element, that is, an element b such that $b \leq b'$ for all $b' \in B$. Some well-ordered sets are illustrated below; in this scheme we do not list any of the $<$ relations which are consequences of the ones already listed.

$$\begin{array}{ll} \emptyset & \\ \{0\} & \\ 0 < 1 & (A = \{0, 1\}) \\ 0 < 1 < 2 & (A = \{0, 1, 2\}) \\ 0 < 1 < 2 < 3 & \text{etc.} \\ \vdots & \\ 0 < 1 < 2 < 3 < \dots & \\ 0 < 1 < 2 < \dots < \omega & (\omega \text{ is some set } \neq 0, 1, 2, 3, \dots) \\ & (\omega + 1 \text{ is, for the present,} \\ 0 < 1 < 2 < \dots < \omega < \omega + 1 & \text{just a set distinct from} \\ & \text{those already mentioned}) \\ \vdots & \\ 0 < 1 < 2 < \dots < \omega < \omega + 1 < \omega + 2 < \dots & \\ 0 < 1 < 2 < \dots < \omega < \omega + 1 < \omega + 2 < \dots < \omega \cdot 2 & \\ \vdots & \\ 0 < 1 < 2 < \dots < \omega < \omega + 1 < \omega + 2 < \dots < \omega \cdot 2 < \omega \cdot 2 + 1 < \dots & \\ 0 < 1 < 2 < \dots < \omega < \omega + 1 < \omega + 2 < \dots < \omega \cdot 2 < \omega \cdot 2 + 1 < \dots < \omega & \\ \vdots & \\ 0 < 1 < 2 < \dots < \omega < \dots < \omega \cdot 2 < \dots < \omega \cdot 3 < \dots < \dots & \\ 0 < 1 < 2 < \dots < \omega < \dots < \omega \cdot 2 < \dots < \omega \cdot 3 < \dots < \dots < \omega^2 & \end{array}$$

Any subset of a well-ordered set is, of course, also a well-ordered set with the same ordering. In particular, a subset B of a well-ordered set A is called an (initial) segment if $b \in B$ and $a < b$ imply $a \in B$. It is easy to see that if B is a segment of A , then either $B = A$ or else there is some $a \in A$ such that

$$B = \{a' \in A : a' < a\};$$

in fact, a is the first element of $A - B$. Notice that each set on our list is a segment of the succeeding ones. It is not hard to see that no two sets on our list are order isomorphic. For example,

$$0 < 1 < \dots < \omega \quad \text{and} \quad 0 < 1 < \dots < \omega < \omega + 1$$

are not order isomorphic because the second has both a last and a next to last element, while the first does not. But there is a much more general proposition which will settle all cases at once:

1. PROPOSITION. If $B \neq A$ is a segment of A , then B is not order isomorphic to A . In fact, the only order isomorphism from B to a segment of A is the identity.

PROOF. If $f: B \rightarrow B' \subset A$ is an order isomorphism and B' is a segment of A , then for the first element b of B (and hence of A) we clearly must have $f(b) = b$. Then $f(b')$ must be b' , where b' is the second element. And so on, even for the " ω^{th} " element (the first one after the first, second, third, etc.)! The way we prove this rigorously is amazingly simple: If $f(b) \neq b$ for some $b \in B$, just consider the first element of $\{b \in B : f(b) \neq b\}$; an outright contradiction appears almost immediately. ♦

Proposition 1 has a companion, which makes the study of well-ordered sets simply delightful.

2. PROPOSITION. If $(A, <)$ and $(B, <)$ are well-ordered sets, then one is order isomorphic to a segment of the other.

PROOF. We match the first element of A with the first of B , the second with the second, ..., the " ω^{th} " with the " ω^{th} ", etc., until we run out of one set. To do this rigorously, consider order isomorphisms from segments of A onto segments of B . It is easy to show that any two such order isomorphisms agree on the smaller of their two domains (just consider the smallest element where

they don't). So all such order isomorphisms can be put together to give another, which is clearly the largest of all. If it is defined on all of A we are done. If it is not, then its range must be all of B (or we could easily extend it) and we are still done. ♦

Suppose we define a relation $<$ between well-ordered sets by stipulating that $(A, <) < (B, <)$ when $(A, <)$ is order isomorphic to a proper segment of $(B, <)$. Transitivity of $<$ is obvious, and Propositions 1 and 2 show that we almost have trichotomy. "Almost", because the condition " $(A, <) = (B, <)$ " must be replaced by " $(A, <) \text{ order isomorphic to } (B, <)$ ". To obviate this difficulty we need only work with order isomorphism classes of well-ordered sets, instead of with the well-ordered sets themselves. These order isomorphism classes are called **ordinal numbers**. They are beautiful.*

3. PROPOSITION. $<$ is a well-ordering of the ordinal numbers.

PROOF. Given a non-empty set \mathcal{A} of ordinal numbers, let $(A, <)$ be a well-ordered set representing one of its elements α . To produce a smallest element of \mathcal{A} we can obviously ignore elements $\geq \alpha$. Every element $< \alpha$ is represented by an ordered set which is order isomorphic to some proper segment of A : each of these is the segment consisting of elements of A less than some $a \in A$. Consider the least of these a 's. It determines a segment which represents some $\beta \in \mathcal{A}$. This β is the smallest element of \mathcal{A} . ♦

Notice that if α is an ordinal number, represented by a well-ordered set $(A, <)$, then the well-ordered set of all ordinals $\beta < \alpha$ has a particularly simple representation: it is order isomorphic to the set $(A, <)$! Roughly speaking: An ordinal number is order isomorphic to the set of all ordinals less than it.

If α is an ordinal number, we will denote by $\alpha + 1$ the smallest ordinal after α (if α is represented by the well-ordered set $(A, <)$, then $\alpha + 1$ is represented by a well-ordered set with just one more element, larger than all members of A). Notice that some ordinals are not of the form $\alpha + 1$ for any α ; these are called **limit ordinals**, while those of the form $\alpha + 1$ are called **successor**

*Only one feature mars the beauty of the ordinal numbers as presented here. Each ordinal number is a horribly large set; it would be much nicer to choose one specific well-ordered set from each order isomorphism class, and define these specific sets to be the ordinal numbers. There is a particularly elegant way to do this, due to von Neumann, which can be found in the Appendix to Kelley, *General Topology*.

ordinals. We will also denote some ordinals by the symbols appearing before: $0, 1, 2, 3, \dots, \omega, \omega + 1, \dots$, etc.

Our list of well-ordered sets only begins to suggest the complexity which well-ordered sets can achieve. With a little thought, one can see how the symbols $\omega^3, \omega^4, \dots$ would appear (symbols like $\omega^3 + \omega^2 \cdot 3 + \omega \cdot 4 + 6$ would be used somewhere between ω^3 and ω^4): after all these one would need

$$\omega^\omega, \omega^{\omega^\omega}, \dots$$

and after all these the symbol ε_0 pops up. After

$$\varepsilon_0^2, \varepsilon_0^3, \dots, \varepsilon_0^\omega, \dots, \varepsilon_0^{\omega^\omega}, \dots, \varepsilon_0^{\omega^{\omega^\omega}}, \dots,$$

one comes to

$$\varepsilon_1, \varepsilon_2, \dots, \varepsilon_\omega, \dots, \varepsilon_{\omega^\omega}, \dots, \varepsilon_{\varepsilon_0}, \dots, \varepsilon_{\varepsilon_{\varepsilon_0}}, \dots;$$

and this is only the beginning!

All the well-ordered sets mentioned so far are *countable*. There are indeed an enormous number of countable well-ordered sets:

4. PROPOSITION. Let Ω be the collection of all countable ordinals (ordinals represented by a countable well-ordered set). Then Ω is uncountable.

PROOF. By Proposition 3, $(\Omega, <)$ is a well-ordered set. If it were countable, it would represent a countable ordinal $\alpha \in \Omega$. By the remark after Proposition 3, this would mean that Ω is order isomorphic to the collection of ordinals $< \alpha$, i.e., to a proper segment of itself, contradicting* Proposition 1. ♦

We have thus established the existence of an uncountable ordinal. Our specific example, represented by Ω , is clearly the first uncountable ordinal; any member of Ω is countable, and consequently has only countably many predecessors. (It is hopeless to try to “reach” Ω by continuing the listing of well-ordered sets begun above, for one would have to go uncountably far, and encounter sets with an uncountable number of degrees of complexity. A leap of faith is required.)

Although the countable ordinals exhibit uncountably many degrees of complexity, they are each simple in one way:

* By deleting the words countable and uncountable in this proof one obtains the “Burali-Forti Paradox”: the set *Ord* of all ordinal numbers is well-ordered, so it represents an ordinal $\alpha \in \text{Ord}$, and hence is order isomorphic to an initial segment of *Ord*. For a resolution of this paradox, see Kelley’s Appendix.

5. PROPOSITION. If $\alpha \in \Omega$ is a limit ordinal, then there is a sequence $\beta_1 < \beta_2 < \beta_3 < \dots < \alpha$, such that every $\beta < \alpha$ satisfies $\beta < \beta_n$ for some n (we say that $\{\beta_n\}$ is “cofinal” in α).

PROOF. Since α is countable, *all* its members can be listed (in not-necessarily increasing order) $\gamma_1, \gamma_2, \gamma_3, \dots$. Let $\beta_1 = \gamma_1$ and let β_{n+1} be the first γ in the list which comes after β_n . ♦

6. COROLLARY. If $\alpha \in \Omega$, then α is represented by some well-ordered subset of \mathbb{R} . However, no subset of \mathbb{R} is order isomorphic to Ω .

PROOF. Suppose there were one, and hence a smallest, $\alpha \in \Omega$ not represented by some subset of \mathbb{R} . It cannot happen that $\alpha = \beta + 1$, for then β would be represented by a subset of \mathbb{R} , thus also by a subset of $(-\infty, 0)$ and α could be represented by a subset of \mathbb{R} . So by Proposition 5, there is a sequence $\beta_1 < \beta_2 < \beta_3 < \dots < \alpha$ cofinal in α . Then β_i is represented by a subset of $(-\infty, i)$, and we can easily arrange that the subset representing β_i is a segment of the subset representing β_j for $i < j$. The union of all these sets would then represent α , a contradiction.

If a subset of \mathbb{R} were order isomorphic to Ω , then there would be uncountably many disjoint intervals in \mathbb{R} , namely those between the points representing α and $\alpha + 1$ for all $\alpha \in \Omega$. This is impossible. ♦

The first example of a non-metrizable manifold is defined in terms of Ω . Consider $\Omega \times [0, 1)$, with the order $<$ defined as follows:

$$(\alpha, s) < (\beta, t) \quad \text{if } \alpha < \beta \text{ or if } \alpha = \beta \text{ and } s < t.$$

This can be pictured as follows:

The set $\Omega \times [0, 1)$ with the order topology (a subbase consists of sets of the form $\{x : x < x_0\}$ and $\{x : x > x_0\}$) is called the closed long ray (with “origin” $(0, 0)$), and $L^+ = \Omega \times [0, 1) - \{(0, 0)\}$ is the (open) long ray. The disjoint union of two copies of the closed long ray with their origins identified is the long line L . To distinguish L^+ and L , the names “half-long line” and “long line” may also be used. The Corollary to Proposition 5 implies easily that the long ray and the long line are 1-dimensional manifolds; aside from the line and the circle, there are no other connected 1-manifolds.

Quite a few new 2-manifolds can now be constructed:

$$\begin{array}{ll}
 L^+ \times S^1 & \text{(half-long cylinder),} \\
 L^+ \times \mathbb{R} & \text{(half-long strip),} \\
 L \times L & \text{(big plane),} \\
 L^+ \times L^+ & \text{(big quadrant).}
 \end{array}
 \qquad
 \begin{array}{ll}
 L \times S^1 & \text{(long cylinder),} \\
 L \times \mathbb{R} & \text{(long strip),} \\
 L \times L^+ & \text{(big half-plane),}
 \end{array}$$

Identifying all points $((0, 0), \theta)$ in the product of the closed long ray and S^1 produces another 2-manifold, which might be called the "big disc".

There is another way of producing a non-metrizable 2-manifold which does not use Ω at all. We begin with the open upper half-plane $\mathbb{R}_+^2 = \{(x, y) \in \mathbb{R}^2 : y > 0\}$ and another copy $\mathbb{R}^2 \times \{0\}$ of the plane; we will denote this set by \mathbb{R}_0^2 , and denote the point $(x, y, 0)$ by $(x, y)_0$. Define a map $f_0: (\mathbb{R}_0^2)_+ \rightarrow \mathbb{R}_+^2$ by

$$f_0((x, y)_0) = (xy, y).$$

Consider the disjoint union of \mathbb{R}_+^2 and \mathbb{R}_0^2 , with $p \in (\mathbb{R}_0^2)_+$ and $f_0(p) \in \mathbb{R}_+^2$ identified. This is a Hausdorff manifold; the following diagram shows two open sets homeomorphic to \mathbb{R}^2 . The manifold itself is, in fact, homeomorphic

to \mathbb{R}^2 ; we could have thrown away \mathbb{R}_+^2 to begin with since it is identified by a homeomorphism with $(\mathbb{R}_0^2)_+$.

But consider now, for each $a \in \mathbb{R}$, another copy of \mathbb{R}^2 , say $\mathbb{R}^2 \times \{a\}$, which we will denote by \mathbb{R}_a^2 . Define $f_a: (\mathbb{R}_a^2)_+ \rightarrow \mathbb{R}_+^2$ by

$$f_a((x, y)_a) = (a + xy, y).$$

In the disjoint union of \mathbb{R}_+^2 and *all* \mathbb{R}_a^2 , $a \in \mathbb{R}$ we wish to identify each $p \in (\mathbb{R}_a^2)_+$ with $f_a(p) \in \mathbb{R}_+^2$. We may dispense with \mathbb{R}_+^2 completely, and in the disjoint union of all \mathbb{R}_a^2 identify each $(x, y)_a$ and $(x', y')_b$ for which $y = y' > 0$ and $xy + a = x'y' + b$. The equivalence classes, of course, are a space homeomorphic to \mathbb{R}_+^2 , so we will consider \mathbb{R}_+^2 a subset of the resulting space. This space is still a Hausdorff manifold, but it cannot be second countable, for it has an uncountable discrete subset, namely the set $\{(0, 0)_a\}$. This manifold, the **Prüfer manifold**, and related manifolds, have some very strange properties, developed in the problems.

PROBLEMS

1. (a) A well-ordered set cannot contain a decreasing infinite sequence $x_1 > x_2 > x_3 > \cdots$.
- (b) If we denote $(\alpha + 1) + 1$ by $\alpha + 2$, $(\alpha + 2) + 1$ by $\alpha + 3$, etc., then any α equals $\beta + n$ for a unique limit ordinal β and integer $n \geq 0$. (Thus one can define *even* and *odd* ordinals.)
2. Let c be a “choice function”, i.e., $c(A)$ is defined for each set $A \neq \emptyset$, and $c(A) \in A$ for all A . Given a set X , a well-ordering $<$ on a subset Y of X will be called “distinguished” if for all $y \in Y$,

$$y = c(Y - \{y' \in Y : y' < y\}).$$

- (a) Show that of any two distinguished well-orderings, one is an extension of the other.
- (b) Show that there is a well-ordering on X . (Zorn's Lemma may be deduced from this fact fairly easily.)
- (c) Given two sets, show that one of them is equivalent to (can be put in one-one correspondence with) a subset of the other.
- (d) Show that on any infinite set there is a well-ordering which represents a limit ordinal.
- (e) From (d), and Problem 1, show that if X and Y are disjoint equivalent infinite sets, then $X \cup Y$ is equivalent to Y .

3. (a) L^+ and L are not metrizable.
- (b) If $x_1 \leq x_2 \leq x_3 \leq \cdots$ is a sequence in L^+ , then $\{x_n\}$ converges to some point. Consequently, any sequence has a convergent subsequence (but L^+ is not compact!).

- (c) If $\{x_n\}$ and $\{y_n\}$ are sequences in L^+ with $x_n \leq y_n \leq x_{n+1}$ for all n , then both sequences converge to the same point.
- (d) L^+ (and also L) are normal. (Use (c)).
- (e) More generally, any order topology is normal (completely different proof).
- (f) If $f: L^+ \rightarrow \mathbb{R}$ is continuous, and $r > s$, then one of the sets $f^{-1}((-\infty, s])$ and $f^{-1}([r, \infty))$ is countable.
- (g) If $f: L^+ \rightarrow \mathbb{R}$ is continuous, then f is eventually constant.
4. (a) L^+ is not contractible. *Hint:* Given $H: L^+ \times [0, 1] \rightarrow L^+$ with $H(x, 0) = x$ for all x , show that for every t we have $\{H(x, t)\} = L^+$.
- (b) $\pi_1(L^+) = \pi_1(L) = 0$. Similarly for $L^+ \times \mathbb{R}$, $L \times \mathbb{R}$, $L \times L$, $L \times L^+$, $L^+ \times L^+$.
- (c) $\pi_1(L^+ \times S^1) = \pi_1(L \times S^1) = \mathbb{Z}$.
5. (a) L^+ and L are not homeomorphic. *Hint:* Imitating Problem 1-19, define “paracompact ends”.
- (b) $L^+ \times \mathbb{R}$ and $L \times \mathbb{R}$ are not homeomorphic; $L^+ \times S^1$ and $L \times S^1$ are not homeomorphic.
- (c) Of the 2-manifolds constructed from L^+ or L with $\pi_1 = 0$ and one paracompact end, only $L^+ \times \mathbb{R}$ has the homotopy type of L^+ .
- (d) The Stone-Čech compactifications of $L \times L$, $L^+ \times L$, $L^+ \times L^+$, and the big disc are all distinct. (Using Problem 3(g), one can explicitly construct these Stone-Čech compactifications).
6. (a) Show that the Prüfer manifold P is Hausdorff.
- (b) P does not have a countable dense subset.
- (c) Let U be an open set in \mathbb{R}_+^2 which is the union of “wedges” centered at $(a, 0)$ for every irrational a . Show that U includes a whole rectangle of the form

$(a, b) \times (0, \varepsilon)$. *Hint:* Let $A_n = \{a : \text{the wedge centered at } a \text{ has width } \geq 1/n\}$. Since $\mathbb{R} = \mathbb{Q} \cup \bigcup_n A_n$, some A_n is not nowhere dense.

(d) Let $C_1, C_2 \subset P$ be

$$C_1 = \{(0, 0)_a : a \text{ irrational}\}$$

$$C_2 = \{(0, 0)_a : a \text{ rational}\}.$$

Show that C_1 and C_2 are closed, but that they are not contained in disjoint open sets.

(e) Define $H: P \times [0, 1] \rightarrow P$ by

$$H((x, y)_a, s) = \begin{cases} \left(x \sqrt{\frac{1-s+sy}{1+sy}}, y \sqrt{\frac{1+sy}{1-s+sy}} \right)_a & \text{if } y > 0 \\ \left(x \sqrt{1-s^2}, y \sqrt{1-s^2} \right)_a & \text{if } y \leq 0. \end{cases}$$

Show that H is well-defined and that $H(p, 1) \in \mathbb{R}_+^2 \cup \{(0, 0)_a\}$ for all $p \in P$. Conclude that P is contractible.

(f) $P - \{(x, y)_a : y < 0\}$ is a manifold-with-boundary P' , whose boundary is a disjoint union of uncountably many copies of \mathbb{R} .

(g) The disjoint union of two copies of P' , with corresponding points on the boundary identified, is a manifold which is not metrizable, but which has a countable dense subset. Its fundamental group is uncountable.

7. It is known that every second countable contractible 2-manifold is S^2 or \mathbb{R}^2 . Hence the result of constructing the Prüfer manifold using only copies \mathbb{R}_a^2 for rational a must be homeomorphic to \mathbb{R}^2 . Describe a homeomorphism of this manifold onto \mathbb{R}^2 .

8. Let M be a connected Hausdorff manifold which is not a point.

(a) If $A \subset M$ has cardinality \mathfrak{c} (the cardinality of \mathbb{R}), then the closure \bar{A} has cardinality \mathfrak{c} .

(b) If $C \subset M$ is closed and has cardinality \mathfrak{c} , then C has an open neighborhood with cardinality \mathfrak{c} .

(c) Let $p \in M$. There is a function $f: \Omega \rightarrow (\text{set of subsets of } M)$ such that $f(\alpha)$ has cardinality \mathfrak{c} for all $\alpha \in \Omega$, and such that

$$f(0) = \{p\}$$

$$f(\alpha) \text{ is an open neighborhood of the closure of } \bigcup_{\beta < \alpha} f(\beta).$$

(Consider functions defined on initial segments of Ω with these same properties, and apply Zorn's Lemma. Alternatively, one can require $f(\alpha)$ to be the result of applying the choice function to the set of all open neighborhoods of the closure

of $\bigcup_{\beta < \alpha} f(\beta)$ with cardinality \mathfrak{c} . Then there is a unique f with the required properties. This is an example of defining a function by “transfinite induction”.)

(d) A function $f: \Omega \rightarrow (\text{set of subsets of } [0, 1])$ with the properties of the function in part (c) is eventually constant.

(e) M has cardinality \mathfrak{c} . (Given $p' \in M$, consider an arc from p to p' .)

9. (a) A connected 1-manifold whose topology is the order topology for some order, is homeomorphic to either the real line, the long line, or the half-long line.

(b) Every 1-manifold M contains a maximal open submanifold N whose topology is the order topology for some order.

(c) If M is connected and $N \neq M$, then M is homeomorphic to S^1 .

CHAPTER 2

The long ray L^+ can be given a C^∞ structure, and even a C^ω structure. To see this we need the result of Problem 9-24—any C^∞ [or C^ω] structure on a manifold M homeomorphic to \mathbb{R} is diffeomorphic to \mathbb{R} with the usual structure. This implies that it is also diffeomorphic to $(0, 1)$, and consequently that the structure on M can be extended if M is a proper subset of L^+ . An easy application of Zorn's Lemma then shows that C^∞ and C^ω structures exist on L^+ .

I do not know whether all C^∞ structures on L^+ are diffeomorphic. It is known that there are uncountably many inequivalent C^ω structures on L^+ . If $p \in L^+$, and L^+_p denotes all points $\leq p$, then $L^+ - L^+_p$ is clearly homeomorphic to L^+ . If \mathcal{O} is a C^ω structure for L^+ , then it yields a C^ω structure for $L^+ - L^+_p$, and hence for L^+ . These are all distinct, in other words, there is no C^ω map

$$f: L^+ - L^+_p \rightarrow L^+ - L^+_q \quad q > p$$

with a C^ω inverse. In fact, we must have $f(q) > q$, and then it is easy to see

that we must also have $f(f(q)) > f(q)$, $f(f(f(q))) > f(f(q))$, etc. The increasing sequence $q, f(q), f(f(q)), \dots$ has a limit point $x_0 \in L^+ - L^+_p$, and $f(x_0) = x_0$. Now f cannot be the identity on all points $> x_0$ (for then it would be the identity everywhere, since it is C^ω). So for some $q_1 > x_0$ we have $f(q_1) \neq q_1$; we can assume $f(q_1) > q_1$, since we can consider f^{-1} in the contrary case. Reasoning as before, we obtain $x_1 > x_0$ with $f(x_1) = x_1$. Continuing in this way, we obtain $x_0 < x_1 < x_2 < \dots$ with $f(x_n) = x_n$. This sequence has a limit in $L^+ - L^+_p$, but this implies that $f(x) = x$ for all x , a contradiction.

A C^ω structure exists on the Prüfer manifold; this follows immediately from the fact that the maps f_a , used for identifying points in various $(\mathbb{R}^2_0)_+$ with points in \mathbb{R}^2_+ , are all C^ω . I do not know whether every 2-manifold has a C^∞ structure.

Using the C^ω structure on L^+ , we can get a C^ω structure on $L^+ \times L^+$. However, the method used for obtaining a C^ω structure on L^+ will not yield a *complex analytic structure* on $L^+ \times L^+$; the problem is that a complex analytic structure on \mathbb{R}^2 may be conformally equivalent to the disc, and hence extendable, but it

may also be equivalent to the complex plane, and not extendable. In fact, it is a classical theorem of Rado that every Riemannian surface (2-manifold with a complex analytic structure) is second countable. On the other hand, a modification of the Prüfer manifold yields a non-metrizable manifold of complex dimension 2. References to these matters are to be found in

Calabi and Rosenlicht, *Complex Analytic Manifolds without Countable Base*, Proc. Amer. Math. Soc. 4 (1953), pp. 335–340.

PROBLEMS

10. Prove that for $q > p$ there is no non-constant C^ω map $f: L^+ - L^+_p \rightarrow L^+ - L^+_q$.
11. Let (Y, ρ) be a metric space and let $f: X \rightarrow Y$ be a continuous locally one-one map, where X is Hausdorff, connected, locally connected, and locally compact.
 - (a) Every two points $x, y \in X$ are contained in a compact connected $C \subset X$.
 - (b) Let $d(x, y)$ be the greatest lower bound of the diameters of $f(C)$ (in the ρ -metric) for all compact connected C containing x and y . Show that d is a metric on X which gives the same topology for X .
12. Of the various manifolds mentioned in the previous section, try to determine which can be immersed in which.

CHAPTER 6

Problem A-6(g) describes a non-paracompact 2-manifold in which two open half-planes are a dense set. We will now describe a 3-dimensional version with a twist.

Let $A = \{(x, y, z) \in \mathbb{R}^3 : y \neq 0\}$, and for each $a \in \mathbb{R}$ let \mathbb{R}_a^3 be a copy of \mathbb{R}^3 , points in \mathbb{R}_a^3 being denoted by $(x, y, z)_a$. In the disjoint union of A and all \mathbb{R}_a^3 , $a \in \mathbb{R}$ we identify

$$\begin{aligned} (x, y, z)_a & \text{ for } y > 0 & \text{ with } & (a + yx, y, z + a) \\ (x, y, z)_a & \text{ for } y < 0 & \text{ with } & (a + yx, y, z - a). \end{aligned}$$

The equivalence classes form a 3-dimensional Hausdorff manifold M . On this manifold there is an obvious function “ z ”, and the sets $z = \text{constant}$ form a foliation of M by a 2-dimensional manifold N . The remarkable fact about this 2-dimensional manifold N is that it is connected. For, the set of points $(x, y, c) \in A$ with $y > 0$ is identified with the set of points $(x, y, c - a)_a \in \mathbb{R}_a^3$ with $y > 0$. Now the folium containing $\{(x, y, c - a)_a\}$ contains the points $(x, y, c - a)_a$ with $y < 0$, and these are identified with the set of points $(x, y, c - 2a) \in A$ with $y < 0$. Since we can choose $a = c/2$, we see that all leaves of the foliation are the same as the leaf containing $\{(x, y, 0) : y < 0\} \subset A$.

This example is due to M. Kneser, *Beispiel einer dimensionserhöhenden analytischen Abbildung zwischen überabzählbaren Mannigfaltigkeiten*. Archiv. Math. 11 (1960), pp. 280–281.

CHAPTERS 7, 9, 10

1. We have seen that any paracompact C^∞ manifold has a Riemannian metric. The converse also holds, since a Riemannian metric determines an ordinary metric.

2. Problem A-11 implies that a manifold N immersed in a paracompact manifold M is paracompact, but a much easier proof is now available: Let (\cdot, \cdot) be a Riemannian metric on M ; if $f: N \rightarrow M$ is an immersion, then N has the Riemannian metric $f^*(\cdot, \cdot)$.

We can now dispense with the argument in the proof of Theorem 6-6 which was used to show that each folium of a distribution on a metrizable manifold is also metrizable, for the folium is a submanifold, and hence paracompact.

3. Since there is no Riemannian metric on a non-paracompact manifold M , the tangent bundle TM cannot be trivial. Thus the tangent bundle of the long line is not trivial, nor is the tangent bundle of the Prüfer manifold, even though the Prüfer manifold is contractible. (On the other hand, a basic result about bundles says that a bundle over a paracompact contractible space is trivial. Compare pg. V.272.)

4. The tangent bundle of the long line L is clearly orientable, so there *cannot* be a nowhere zero 1-form ω on L , for ω and the orientation would determine a nowhere zero vector field, contradicting the fact that the tangent bundle is not trivial. Thus, Theorem 7-9 fails for L . Notice also that if M is non-paracompact, then TM is definitely not equivalent to T^*M , since an equivalence would determine a Riemannian metric. So there are at least two inequivalent non-trivial bundles over M .

5. Although the results in the Addendum to Chapter 9 can be extended to closed, not necessarily compact, submanifolds, they cannot be extended to non-paracompact manifolds, as can be seen by considering the 0-dimensional submanifold $\{(0,0)_a\}$ of the Prüfer manifold.

6. A Lie group is automatically paracompact, since its tangent bundle is trivial. More generally, a locally compact connected topological group is σ -compact (Problem 10-4).

7. It is not clear that a non-paracompact manifold cannot have an indefinite metric (a non-degenerate inner product on each tangent space). This will be proved in Volume II (Chapter 8, Addendum 1).

PROBLEM

13. Is there a nowhere zero 2-form on the various non-paracompact 2-manifolds which have been described?

These books were typeset using Donald E. Knuth's \TeX typesetting system, together with Berthold Horn's DVIPSONE PostScript driver. The figures were produced with Adobe Illustrator, and new or modified fonts were created using Fontographer.

The text font is 11 point Monotype Baskerville—though the em-dash has been modified—together with its italic. The elegant swashes of the italic *y* and *f* cause problems in words like *topology* and *apology*, so a special *gy* ligature was added; special *gg* and *gf* ligatures were also required.

Although a Baskerville bold face is unhistorical, bold type was useful in special circumstances—mainly for indicating **defined terms**. The bold face supplied by Monotype, even the “semi-bold”, is obtrusively **extended**, so a non-extended version was created.

The somewhat bold appearance of chapter headings, in 16 point type, results from the linear scaling, as well as the fact that the upper case Baskerville letters are of somewhat heavier weight than the lower case. On the other hand, the tall initial letters beginning each chapter were designed specially, since simple scaling would have made them unpleasantly heavy.

A thicker set of numerals was constructed for use with the upper case lettering in chapter headings and statements of theorems, and special parentheses and other punctuation symbols were also required. Numerous other modifications of this sort, including additional kerns and alterations of set widths, were made for various purposes.

The mathematics fonts are a variation of the *MathTime* fonts, now based on the Monotype Times New Roman family, together with the Monotype Times N R Seven and Times Small Text families—presumably these three families are based on the original designs for Times New Roman, which was created in three essential sizes: 9, 7 and $5\frac{1}{2}$ point.

The italic fonts of these three families were used as the basis for creating the three separate “math italic” fonts—for use at ordinary size, in superscripts, and in second order superscripts. The proportions and weights for these were then used for the three sizes of the symbol font and the other mathematics fonts, including bold symbols, script letters, and additional special symbols, as well as for the extension font and its bold version.

The bold letters for mathematics come directly from the bold fonts of the Times families, while blackboard bold letters were made by hollowing out these bold letters. The Adobe Mathematical Pi 2 font was used for the ordinary sized German Fraktur letters, with suitably modified versions used for superscripts.

The covers, painted by the author in his spare moments, are loosely based on Samuel Taylor Coleridge's poem *The Rime of the Ancient Mariner*.

CORRECTIONS FOR VOLUME I

pg. 3, line 3—: change $\bar{d}_i(x, y) < 1$ to $\bar{d}_i(x, y) \leq 1$.

pg. 14: relabel the lower left part of the central figure as

pg. 19: replace the next-to-last paragraph with the following: .

The set of points in a manifold-with-boundary that do not have a neighborhood homeomorphic to \mathbb{R}^n (but only one homeomorphic to \mathbb{H}^n) is called the **boundary** of M and is denoted by ∂M . Equivalently, $x \in \partial M$ if and only if there is a neighborhood V of x and a homeomorphism $\phi : V \rightarrow \mathbb{H}^n$ such that $\phi(x) = 0$. If M is actually a manifold, then $\partial M = \emptyset$, and ∂M itself is always a manifold (without boundary).

pg. 22: Replace the top left figure with

pg. 43: Replace the last line and displayed equation with the following:

Since rank $f = k$ in a neighborhood of p , the lower rectangle in the matrix

$$\left(\frac{\partial(v^i \circ f)}{\partial x^j} \right) = \begin{pmatrix} \begin{matrix} 1 & & \\ & \ddots & \\ & & 1 \end{matrix} & 0 \\ \times & \begin{matrix} D_{k+1}\psi^{k+1} \dots D_{k+1}\psi^m \\ \vdots \\ D_n\psi^{k+1} \dots D_n\psi^m \end{matrix} \end{pmatrix}$$

pg. 60, Problem 30: Change part (f) and add part (g):

(f) If M is a connected manifold, there is a proper map $f : M \rightarrow \mathbb{R}$; the function f can be made C^∞ if M is a C^∞ manifold.

(g) The same is true if M has at most countably many components.

pg. 61, Problem 32: For clarity, restate part (c) as follows:

(c) This is false if $f : M_1 \rightarrow \mathbb{R}$ is replaced with $f : M_1 \rightarrow N$ for a disconnected manifold N .

pg. 70: Replace the last two lines of page 70 and the first two lines of page 71 with the following:

theorem of topology). If there were a way to map $T(M, i)$, fibre by fibre, homeomorphically onto $M \times \mathbb{R}^2$, then each v_p would correspond to $(p, v(p))$ for some $v(p) \in \mathbb{R}^2$, and we could continuously pick $w(p) \in \mathbb{R}^2$, corresponding to a dashed vector, by using the criterion that $w(p)$ should make a positive angle with $v(p)$.

pg. 78: the third display should read:

$$0 = \ell(0) = \ell(fh) = f(p)\ell(h) + h(p)\ell(f) = 0 + \ell(f).$$

pg. 103, Problem 29(d). Add the hypothesis that M is orientable.

pg. 117: After the next to last display, $\bar{A}(X_1, \dots, X_k)(p) = A(p)(X_1(p), \dots, X_k(p))$, add:

If A is C^∞ , then \bar{A} is C^∞ , in the sense that $\bar{A}(X_1, \dots, X_k)$ is a C^∞ function for all C^∞ vector fields X_1, \dots, X_k .

pg. 118: Add the following to the statement of the theorem: If \mathcal{A} is C^∞ , then A is also.

pg. 119: Add the following at the end of the proof:

Smoothness of A follows from the fact that the function $A_{i_1 \dots i_k}$ is $\mathcal{A}(\partial/\partial x_{i_1}, \dots, \partial/\partial x_{i_k})$.

pg. 131, Problem 9: Let F be a covariant functor from \mathbf{V} ,

pg. 133. Though there is considerable variation in terminology, what are here called “odd scalar densities” should probably simply be called “scalar densities”; what are called “even scalar densities” might best be called “signed scalar densities”.

In part (c) of Problem 10, we should be considering the h of part (a), not the h of part (b)! Thus conclude that the bundle of signed scalar densities (*not* the scalar densities) is not trivial if M is not orientable.

pg. 134. Extending the changed terminology from pg. 133, we should probably speak of the bundle of “signed tensor densities of type $\binom{k}{l}$ and weight w ” (though sometimes the term relative tensor is used instead, restricting densities to those of weight 1), when the transformation rule involves $(\det A)^w$, omitting the modifier “signed” when it involves $|\det A|^w$.

pg. 143. The hypothesis of Theorem 3 should be changed so that it reads:

Let $x \in U$ and let α_1, α_2 be two maps on some open interval I such that $\alpha_1(I), \alpha_2(I) \subset U$,

$$\alpha_i'(t) = f(\alpha_i(t)) \quad i = 1, 2$$

and

$$\alpha_1(t_0) = \alpha_2(t_0) \quad \text{for some } t_0 \in I.$$

And the first sentence of the proof should be deleted.

pg. 177. Problem 17, part (d) should begin:

(d) Let $f: M \rightarrow N$, and suppose that $f_{*p} = 0$. For $X_p, Y_p \in M_p$ and

pg. 198. In Problem 5, we must also assume that each $\Delta_i \oplus \Delta_j$ is integrable.

pg. 226. In the comutative diagram, the lower right entry should be “ I -forms on N ”.

pg. 233. The reference “pg. V.375” refers to pg. 375 of Volume V.

pg. 237. In Problem 26, replace parts (b) and (c) with:

(b) Determine the i^{th} component of $v_1 \times \dots \times v_{n-1}$ in terms of the $(n-1) \times (n-1)$ submatrices of the matrix

$$\begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix}.$$

In particular, for \mathbb{R}^3 , show that

$$v \times w = (v^2 w^3 - v^3 w^2, v^3 w^1 - v^1 w^3, v^1 w^2 - v^2 w^1).$$

pg. 292. In Problem 20, the condition $U_i \cap U_j \neq \emptyset$ should be $U_i \cap U_{i+1} \neq \emptyset$.

pg. 408. Problem 16 (b) should read: “For any Lie group G , show that . . .”.

pp. 408–410. For consistency with standard usage, Aut should be replaced with Aut , and then replace *End* with *End*. In part (g) of Problem 19, add the hypothesis that H is a connected Lie subgroup.

pg. 411. The display in Problem 21, part (c) should read:

$$(-1)^{km}[\omega \wedge [\eta \wedge \lambda]] + (-1)^{ki}[\eta \wedge [\lambda \wedge \omega]] + (-1)^{lm}[\lambda \wedge [\omega \wedge \eta]] = 0.$$

PREFACE

Though this volume begins the study of modern differential geometry in earnest, it ends just when we have gotten to the fanciest definition of a connection, but have hardly begun to start spouting theorems. A glance at the Table of Contents will show that the semi-historical path promised in Volume I really has been followed. The most decisive encounters with classical differential geometry occur in Chapters 3 and 4, which present the classical papers and then explain them. While it is possible to get through this volume without reading any of the classical works themselves, the easy way out certainly misses all the fun!

There are no Problem sets in this volume, which is a shame, but much of the material doesn't lend itself to problems, and even if it did, I would have gone berserk trying to produce them in any reasonable length of time. As compensation for the lack of Problems, the final volume contains a comprehensive bibliography of the literature of Differential Geometry, including texts where problems may be found.

TABLE OF CONTENTS

Although the chapters are not divided into sections,
the listing for each chapter gives some indication
which topics are treated, and on what pages.

CHAPTER 1. CURVES IN THE PLANE AND IN SPACE

Curvature of plane curves	1
Convex curves	12
Curvature and torsion of space curves	24
The Serret-Frenet formulas	34
The natural form on a Lie group	36
Classification of plane curves under the group of special affine motions	39
Classification of curves in \mathbb{R}^n	44

CHAPTER 2. WHAT THEY KNEW ABOUT SURFACES BEFORE GAUSS

Euler's Theorem	50
Meusnier's Theorem	52

CHAPTER 3. THE CURVATURE OF SURFACES IN SPACE

A. HOW TO READ GAUSS	55
B. GAUSS' THEORY OF SURFACES	
The Gauss map	112
Gaussian curvature	114
The Weingarten map; the first and second fundamental forms . . .	122
The Theorema Egregium	129
Geodesics on a surface	134
The metric in geodesic polar coordinates	136
The integral of the curvature over a geodesic triangle	141

Addendum. The formula of Bertrand and Puiseux; Diquet's formula	145
--	-----

CHAPTER 4. THE CURVATURE OF HIGHER DIMENSIONAL MANIFOLDS

A. AN INAUGURAL LECTURE	149
“On the Hypotheses which lie at the Foundations of Geometry” . . .	151
B. WHAT DID RIEMANN SAY?	163
The form of the metric in Riemannian normal coordinates	166
C. A PRIZE ESSAY	181
D. THE BIRTH OF THE RIEMANN CURVATURE TENSOR	
Necessary conditions for a metric to be flat	184
The Riemann curvature tensor	189
Sectional Curvature	194
The Test Case; first version	197
Addendum. Finsler metrics	200

CHAPTER 5. THE ABSOLUTE DIFFERENTIAL CALCULUS (THE RICCI CALCULUS); OR, THE DEBAUCH OF INDICES

Covariant derivatives	209
Ricci's Lemma	213
Ricci's identities	214
The curvature tensor	215
The Test Case; second version	217
Classical connections	221
The torsion tensor	221
Geodesics	223
Bianchi's identities	224

CHAPTER 6. THE ∇ OPERATOR

Kozul connections	227
Covariant derivatives	229
Parallel translation	234
The torsion tensor	236
The Levi-Civita connection	238

The curvature tensor	239
The Test Case; third version	241
Bianchi's identities	244
Geodesics	246
The First Variation Formula	247
Addendum 1. Connections with the same geodesics	249
Addendum 2. Riemann's invariant definition of the curvature tensor	254

CHAPTER 7. THE REPÈRE MOBILE (THE MOVING FRAME)

Moving frames	259
The structural equations of Euclidean space	261
The structural equations of a Riemannian manifold	267
The Test Case; fourth version	268
Adapted frames	270
The structural equations in polar coordinates	272
The Test Case; fifth version	274
The Test Case; sixth version	275
"The curvature determines the metric"	277
The 2-dimensional case	279
Cartan connections	281
Covariant derivatives and the torsion and curvature tensors	285
Bianchi's identities	288
Addendum 1. Manifolds of constant curvature	290
Schur's Theorem	291
The form of the metric in normal coordinates	295
Addendum 2. Conformally equivalent manifolds	296
Addendum 3. É. Cartan's treatment of normal coordinates	302

CHAPTER 8. CONNECTIONS IN PRINCIPAL BUNDLES

Principal bundles	305
Lie groups acting on manifolds	309
A new definition of Cartan connections	311
Ehresmann connections	315
Lifts	317
Parallel translation and covariant derivatives	319

The covariant differential and the curvature form	324
The dual form and the torsion form	324
The structural equations	327
The torsion and curvature tensors	329
The Test Case; seventh version	333
Bianchi's identities	334
Summary	337
Addendum 1. The tangent bundle of $F(M)$	342
Addendum 2. Complete connections	344
Addendum 3. Connections in vector bundles	346
Addendum 4. Flat connections	349
NOTATION INDEX	351
INDEX	355

DIFFERENTIAL GEOMETRY

VOLUME TWO

CHAPTER 1

CURVES IN THE PLANE AND IN SPACE

Volume I of these notes represents the “differential” part of differential geometry. In this volume we finally get down to some geometry. For the present we are going to study only the simplest geometric objects, curves, and at first our approach will be terribly geometric. Nevertheless, the results of this chapter span a couple hundred years, and we will end with some very modern looking constructions.

We begin by considering only curves in the plane, and we further restrict our attention to curves $c: [a, b] \rightarrow \mathbb{R}^2$ which are *immersions*, i.e., which satisfy $c'(t) = dc/dt \neq 0$ for all $t \in [a, b]$. For these curves, the arclength function $s: [a, b] \rightarrow \mathbb{R}$,

$$s(t) = \int_a^t |c'(u)| du,$$

is a diffeomorphism $s: [a, b] \rightarrow [0, L]$, where $L = \text{length of } c$. The curve $\gamma = c \circ s^{-1}$ is then a reparameterization of c ; clearly γ is parameterized by arclength, $|\gamma'(s)| = 1$. We have just introduced a convention to be used throughout the chapter: for curves $\gamma: [a, b] \rightarrow \mathbb{R}^2$ with unit tangent vectors, we will usually denote a typical point in $[a, b]$ by s , even at the risk of confusing it with the arclength function defined above. We also emphasize that throughout this chapter $\gamma'(s)$ just denotes a vector in \mathbb{R}^3 , not a tangent vector in $\mathbb{R}^3_{\gamma(s)}$, even though we will often draw it that way.

For an immersed curve $c: [a, b] \rightarrow \mathbb{R}^2$, we would like a way of measuring the amount that c is “curving” at any point. No matter how vague this, as yet

intuitive, term may be, we will surely all agree that

- (a) a straight line is not curving at all,
- (b) a circle of radius $R > r$ is curving less than the circle of radius r .

If we have to attach a numerical measure of curvature to these particular curves, it seems reasonable to define the curvature of a straight line at any point to be 0, and to define the curvature of a circle of radius r to be $1/r$ at any point.

From these special cases we want to develop a definition that works for any curve. We take as a clue the procedure which we use in a similar, but simpler, case. We can easily define what we mean by the *direction* of a curve $c: [a, b] \rightarrow \mathbb{R}^2$ at any time t . This direction is determined by the tangent line at $c(t)$, which is the limit of lines through $c(t)$ and $c(t')$ as $t' \rightarrow t$. This limit exists if $c'(t)$

exists and is non-zero. If, moreover, c' is continuous at t , then this limit line can be described as the limit, as $t_1, t_2 \rightarrow t$, of the line through $c(t_1)$ and $c(t_2)$; for this line is parallel to the tangent through $c(\xi)$ for some ξ between t_1 and t_2 .

In order to determine the curvature of a curve we follow an analogous procedure. We find the circle which passes through three points $c(t_1), c(t_2), c(t_3)$ and then see if this circle approaches a limiting circle as $t_1, t_2, t_3 \rightarrow t$. If it does, we can define the curvature of c at t to be the reciprocal of the radius of this circle.

Before proving a precise theorem, we simply try to determine the position of this circle, assuming it does exist. This can be done as follows. First of all, since c is an immersion, it is locally one-one, so for distinct t_1, t_2, t_3 near t , the points $c(t_1), c(t_2), c(t_3)$ are distinct. To be specific, let us say that $t_1 < t_2 < t_3$. Suppose also that $c(t_1), c(t_2), c(t_3)$ do not lie on a straight line, so that there is a unique circle through these three points, with center $C(t_1, t_2, t_3)$. Consider the function

$$t \mapsto \langle c(t) - C(t_1, t_2, t_3), c(t) - C(t_1, t_2, t_3) \rangle.$$

At t_1, t_2, t_3 this function has the same value, the square of the radius of the circle through $c(t_1), c(t_2), c(t_3)$. So its derivative must be 0 at points $\xi_1 \in (t_1, t_2)$ and $\xi_2 \in (t_2, t_3)$:

$$(1) \quad 0 = \langle c'(\xi_i), c(\xi_i) - C(t_1, t_2, t_3) \rangle, \quad \xi_i \in (t_i, t_{i+1}), \quad i = 1, 2.$$

Similarly, the function $t \mapsto \langle c'(t), c(t) - C(t_1, t_2, t_3) \rangle$ must have derivative 0 at some point $\eta \in (\xi_1, \xi_2)$:

$$(2) \quad \langle c''(\eta), c(\eta) - C(t_1, t_2, t_3) \rangle = -\langle c'(\eta), c'(\eta) \rangle.$$

Now, if the points $C(t_1, t_2, t_3)$ approach a point C as $t_1, t_2, t_3 \rightarrow t$, and if c'' is continuous, then (1) and (2) clearly imply that

$$(1') \quad \langle c'(t), c(t) - C \rangle = 0$$

$$(2') \quad \langle c''(t), c(t) - C \rangle = -\langle c'(t), c'(t) \rangle.$$

The first of these equations shows that the circle through $c(t)$ with center C must be tangent to c at $c(t)$, which is certainly to be expected. Thus C is already

restricted to lie along a certain line. If $c''(t)$ is not a multiple of $c'(t)$, the second equation then determines C , since it tells us the inner product of $c(t) - C$ with $c''(t)$. If $c''(t)$ is a multiple of $c'(t)$, then we obtain the contradiction

$$0 \neq -\langle c'(t), c'(t) \rangle = \langle c''(t), c(t) - C \rangle = \text{constant} \cdot \langle c'(t), c(t) - C \rangle = 0.$$

In other words, if $c''(t)$ is a multiple of $c'(t)$, this limiting position cannot exist.

Although equations (1'), (2') could be solved for C , we can make things a lot easier for ourselves by considering a curve c parameterized by arclength, so that $|c'(s)| = 1$. (This means that $c'(s)$ always lies on the unit circle $S^1 \subset \mathbb{R}^2$, even though we often picture it instead as a tangent vector.) Now the equation

$$\langle c'(s), c'(s) \rangle = 1$$

can be differentiated to give

$$(*) \quad \langle c''(s), c'(s) \rangle = 0.$$

In other words, $c''(s)$ is always perpendicular to $c'(s)$. In particular, $c''(s)$ is a multiple of $c'(s)$ only when $c''(s) = 0$. Equations (1') and (*) show that $c''(s)$ and $c(s) - C$ are both perpendicular to $c'(s)$. If $c''(s) \neq 0$, then we can write $c(s) - C = a \cdot c''(s)$. Substituting in (2') gives

$$a \cdot \langle c''(s), c''(s) \rangle = -\langle c'(s), c'(s) \rangle = -1.$$

Since we also have

$$|c(s) - C| = |a| \cdot |c''(s)|,$$

we easily deduce that

$$|c(s) - C| = \frac{1}{|c''(s)|}.$$

In other words, our circle is perpendicular to c at $c(s)$, and has radius $1/|c''(s)|$. Its curvature, and hence the curvature of c at s , is thus $|c''(s)|$. We are ready to reverse the order of this reasoning, and take care of details which we have ignored.

1. **THEOREM.** Let $c: [a, b] \rightarrow \mathbb{R}^3$ be a C^2 curve parameterized by arclength. If $c''(s) \neq 0$, then for s_1, s_2, s_3 sufficiently close to s , the points $c(s_1), c(s_2), c(s_3)$ do not lie on a straight line. As $s_1, s_2, s_3 \rightarrow s$ the unique circle through the points $c(s_i)$ approaches a circle passing through $c(s)$, whose radius is $1/|c''(s)|$, and whose center lies on the line through $c(s)$ perpendicular to the tangent line through $c(s)$. If $c''(s) = 0$, then, even if the points $c(s_i)$ do not lie on a line, the circles through them do not approach a limiting circle.

PROOF. We first show that if $c''(s) \neq 0$, then the points $c(s_1), c(s_2), c(s_3)$ cannot lie on a line for s_1, s_2, s_3 arbitrarily close to s . Whenever the points $c(s_i)$ lie on a line, for $s_1 < s_2 < s_3$, there are points $\xi_1 \in (s_1, s_2)$ and $\xi_2 \in (s_2, s_3)$ where the tangent lines are parallel to this line (Cauchy mean value theorem).

This means that the curve c' in S^1 has $c'(\xi_1) = c'(\xi_2)$. For ξ_1 and ξ_2 close enough to s , the image $c'([\xi_1, \xi_2])$ can't be the whole of S^1 . So there is a point $\eta \in (\xi_1, \xi_2)$ where $c'(\eta)$ is furthest from $c'(\xi_i)$ in some direction along the circle. It follows that $c''(\eta) = 0$. This cannot happen for η arbitrarily close to s , so the points $c(s_1), c(s_2), c(s_3)$ cannot lie on a line for s_1, s_2, s_3 arbitrarily close to s .

Now let C be the unique point satisfying

$$(*) \quad \begin{aligned} \langle c'(s), c(s) - C \rangle &= 0 \\ \langle c''(s), c(s) - C \rangle &= -\langle c'(s), c'(s) \rangle = -1. \end{aligned}$$

For $s_1 < s_2 < s_3$ close to s , let $C(s_1, s_2, s_3)$ be the center of the unique circle through the points $c(s_i)$. We have already seen that

$$\begin{aligned} \langle c'(\xi), c(\xi) - C(s_1, s_2, s_3) \rangle &= 0 & \xi \in (s_1, s_3) \\ \langle c''(\eta), c(\eta) - C(s_1, s_2, s_3) \rangle &= -\langle c'(\eta), c'(\eta) \rangle = -1 & \eta \in (s_1, s_3). \end{aligned}$$

Since $c'(\xi) \rightarrow c'(s)$ and $c''(\eta) \rightarrow c''(s)$ as $s_i \rightarrow s$, comparison of these equations with $(*)$ shows that $C(s_1, s_2, s_3)$ must approach C .

We have already shown that if $c''(s) = 0$, then $C(s_1, s_2, s_3)$ cannot approach a limiting position as $s_i \rightarrow s$. ♦

The circle determined in Theorem 1 is called the **osculating circle** of c at s (“osculate” means to kiss). It is clearly the circle which best approximates the

curve c at $c(s)$. This suggests that we define $|c''(s)|$ to be the curvature of c at s ; even for $c''(s) = 0$ this gives the result we would like. With this definition, curvature would always be non-negative, but we can modify the definition slightly so that we obtain a signed curvature. We will henceforth use the notation $\mathbf{t}(s)$ for $c'(s)$, the unit tangent vector of c at s . We use this notation only for curves parameterized by arclength; recall once again that $\mathbf{t}(s) \in S^1$, even though we usually draw it as an element of $\mathbb{R}^3_{c(s)}$. We then define $\mathbf{n}(s)$, the unit normal at s , to be the unit vector such that $\mathbf{n}(s)$ is perpendicular to $\mathbf{t}(s)$, and $[\mathbf{t}(s), \mathbf{n}(s)]$ is the standard orientation of \mathbb{R}^2 . Thus $\mathbf{n}(s) = (-\mathbf{t}^2(s), \mathbf{t}^1(s))$. Now we define

the **curvature** $\kappa(s)$ of c at s by the equation

$$\mathbf{t}'(s) = \kappa(s) \cdot \mathbf{n}(s).$$

Notice that

$$|\kappa(s)| = |\mathbf{t}'(s)| = |c''(s)|,$$

so that $1/|\kappa(s)|$ is the radius of the osculating circle at s , for $\kappa(s) \neq 0$. The

significance of the sign of κ is indicated in the figure below.

For any curve c we can define a curve \bar{c} “going in the opposite direction” by $\bar{c}(s) = c(-s)$. If we use $\bar{\mathbf{t}}(s)$ for $\bar{c}'(s)$, then clearly

$$\begin{aligned}\bar{\mathbf{t}}(s) &= -\mathbf{t}(-s), & \text{hence } \bar{\mathbf{n}}(s) &= -\mathbf{n}(-s) \\ \bar{\mathbf{t}}'(s) &= \mathbf{t}'(-s).\end{aligned}$$

This shows that the curvature $\bar{\kappa}(s)$ of \bar{c} at s is

$$\bar{\kappa}(s) = -\kappa(-s).$$

One can see this change of sign in the figure above. Traversing the left curve in the opposite direction, and turning the figure upside down, one obtains the curve on the right.

This relation can also be seen from explicit formulas for κ , which are sometimes useful to have. To write these, we abandon our usual practice of indicating component functions with superscripts, and instead write $c(s) = (c_1(s), c_2(s))$. We have, of course, $|\kappa(s)| = \sqrt{(c_1''(s))^2 + (c_2''(s))^2}$, but we can also develop a formula for $\kappa(s)$ itself. Since $|\kappa(s)|$ is the length of $c''(s)$, which is perpendicular to the unit vector $c'(s)$, clearly $|\kappa(s)|$ is also the area of the rectangle spanned by $c'(s)$ and $c''(s)$. This area is given by $\det(c'(s), c''(s))$ which, moreover,

clearly has the same sign as $\kappa(s)$. So

$$\kappa(s) = \det \begin{pmatrix} c_1'(s) & c_1''(s) \\ c_2'(s) & c_2''(s) \end{pmatrix} = [c_1'c_2'' - c_2'c_1''](s).$$

Until now we have been working exclusively with curves parameterized by arclength. Theoretically this is sufficient, since we consider only curves which can be reparameterized by arclength. In practice, however, it is usually very inconvenient to actually perform this reparameterization, which involves the inverse of a function defined as an integral. Moreover, since our formula involves only derivatives, only the integrand of this integral should play any crucial role. Consider any (immersed) curve $c : [a, b] \rightarrow \mathbb{R}^2$. Letting $s : [a, b] \rightarrow [0, L]$ be arclength, and defining $\gamma = c \circ s^{-1}$, we have

$$\begin{aligned} c &= \gamma \circ s \\ \frac{dc}{dt} &= \gamma'(s) \frac{ds}{dt} \quad \left(\text{i.e., } \frac{dc}{dt}(t) = \gamma'(s(t)) \frac{ds}{dt}(t) \right) \\ \frac{d^2c}{dt^2} &= \gamma''(s) \left(\frac{ds}{dt} \right)^2 + \gamma'(s) \frac{d^2s}{dt^2}. \end{aligned}$$

Thus

$$\begin{aligned} \gamma'(s) &= \frac{dc}{dt} \bigg/ \frac{ds}{dt} \\ \gamma''(s) &= \frac{\frac{d^2c}{dt^2} - \frac{d^2s}{dt^2} \frac{dc}{dt} \bigg/ \frac{ds}{dt}}{\left(\frac{ds}{dt} \right)^2} = \frac{\frac{d^2c}{dt^2} - \alpha \frac{dc}{dt}}{\left(\frac{ds}{dt} \right)^2}, \quad \text{say.} \end{aligned}$$

Denoting dc_i/dt by $\dot{c}_i(t)$, we have for the curvature $\kappa : [a, b] \rightarrow \mathbb{R}^2$ of c ,

$$\begin{aligned} \kappa(t) &= \text{curvature of } \gamma \text{ at } s = s(t) \\ &= \det(\gamma'(s), \gamma''(s)) \\ &= (ds/dt)^{-3} \det(\dot{c}(t), \ddot{c}(t) - \alpha \dot{c}(t)) \\ &= (ds/dt)^{-3} \det(\dot{c}(t), \ddot{c}(t)). \end{aligned}$$

Thus

$$\boxed{\kappa = \frac{\dot{c}_1 \ddot{c}_2 - \dot{c}_2 \ddot{c}_1}{(\dot{c}_1^2 + \dot{c}_2^2)^{3/2}}.}$$

Naturally, this formula becomes meaningless for a non-immersed curve, where $\dot{c}_1(t) = \dot{c}_2(t) = 0$. In such cases, we should not generally expect to

have a meaningful notion of curvature, for there is nothing to stop the curve from “changing its curvature” at this point.

Before examining the significance of the curvature function κ further, we pause for an observation. Since the osculating circle is the limiting position of the circle through $c(s_1), c(s_2), c(s_3)$ *no matter how* $s_1, s_2, s_3 \rightarrow s$, it is clearly also the limiting position as $s' \rightarrow s$ of the circle which is tangent to c at $c(s)$ and which passes through $c(s')$. To see this, we just choose s_1, s_2 much closer

to s than s' is. The center of the osculating circle can thus be described as the limiting position of the point S in the figure below as $s' \rightarrow s$. These descriptions of curvature go back to Huygens, Leibniz, and Newton.

We began our discussion of curvature by considering straight lines and circles, which were our original models of curves which ought to have constant curvature. It is certainly clear that our definitions do assign curvature 0 to a

straight line c , for $c'' = 0$ if c is parameterized by arclength; and absolute curvature $|\kappa| = R$ to a circle of radius R , since the circle is its own osculating circle. A really satisfactory measure of curvature ought to assign constant curvature to these curves alone. It is clear that if c , parameterized by arclength, has curvature 0 everywhere, so that $c'' = 0$, then c' is constant, so c is a straight line. The analysis of a curve c with non-zero constant curvature κ (which we might as well assume positive) becomes frustratingly complicated if approached in too straightforward a way. We assume, as usual, that c is parameterized by arclength. Let us introduce the components of the unit tangent vector curve,

$$\mathbf{t}(s) = (\alpha(s), \beta(s)).$$

Then

$$\alpha'^2 + \beta'^2 = \kappa^2,$$

so

$$(1) \quad \alpha' \alpha'' + \beta' \beta'' = 0.$$

Recall also that $\langle \mathbf{t}(s), \mathbf{t}'(s) \rangle = \langle c'(s), c''(s) \rangle = 0$, so

$$(2) \quad \alpha \alpha' + \beta \beta' = 0.$$

Equations (1) and (2) show that (α, β) and (α'', β'') are always perpendicular to (α', β') , so one is a multiple of the other,

$$(3) \quad \begin{aligned} \alpha''(s) &= \mu(s)\alpha(s) \\ \beta''(s) &= \mu(s)\beta(s). \end{aligned}$$

Moreover, differentiating (2) gives

$$\alpha'^2 + \beta'^2 + \alpha \alpha'' + \beta \beta'' = 0$$

or

$$(4) \quad \kappa^2 + \alpha \alpha'' + \beta \beta'' = 0.$$

Substituting from (3), and using $\alpha^2 + \beta^2 = 1$, gives $\mu(s) = -\kappa^2$. Thus,

$$(5) \quad \begin{aligned} \alpha'' + \kappa^2 \alpha &= 0 \\ \beta'' + \kappa^2 \beta &= 0. \end{aligned}$$

The solutions of the differential equation in (5) are $s \mapsto a \sin \kappa s + b \cos \kappa s$, which can also be written as $s \mapsto A \sin(\kappa s + B)$. In order to have $\alpha^2 + \beta^2 = 1$, we clearly need $A = 1$ and

$$\begin{aligned}\alpha(s) &= \sin(\kappa s + B) \\ \beta(s) &= \cos(\kappa s + B).\end{aligned}$$

Thus \mathbf{t} traverses a circle, which implies that c itself is a circle of radius $1/\kappa$.

The complicated calculations in the preceding paragraph conceal a basic principle which is much simpler. Suppose that we are given an arbitrary continuous function $\kappa: [a, b] \rightarrow \mathbb{R}$. We can ask how many arclength parameterized curves $c: [a, b] \rightarrow \mathbb{R}^2$ there are with curvature function equal to κ , without necessarily trying to find a specific formula for these curves. If there is one such curve, then there are automatically others, for translating or rotating a curve will not change its curvature. However, this is the only extent to which the curve is not determined.

2. THEOREM. Let $\kappa: [a, b] \rightarrow \mathbb{R}$ be continuous. Then there is a curve $c: [a, b] \rightarrow \mathbb{R}^2$, parameterized by arclength, whose curvature at s is $\kappa(s)$ for all $s \in [a, b]$. Moreover, if c and \bar{c} are two such curves, then $\bar{c} = A \circ c$ where A is some proper Euclidean motion (a translation followed by a rotation [an element of $\text{SO}(2)$]).

PROOF. Theorem I.5-17 implies that there is a function $\mathbf{t}: [a, b] \rightarrow \mathbb{R}^2$ with

$$(*) \quad \mathbf{t}'(s) = \kappa(s) \cdot (-\mathbf{t}_2(s), \mathbf{t}_1(s)).$$

We can choose $\mathbf{t}(a)$ arbitrarily; choose it to be a unit vector. Now

$$\begin{aligned}(\mathbf{t}_1^2 + \mathbf{t}_2^2)' &= 2\mathbf{t}_1\mathbf{t}_1' + 2\mathbf{t}_2\mathbf{t}_2' \\ &= 2\langle (\mathbf{t}_1, \mathbf{t}_2), (\mathbf{t}_1', \mathbf{t}_2') \rangle \\ &= 2\langle (\mathbf{t}_1, \mathbf{t}_2), \kappa(-\mathbf{t}_2, \mathbf{t}_1) \rangle \\ &= 0.\end{aligned}$$

So $\mathbf{t}(s)$ is a unit vector for all s . There is, again by Theorem I.5-17, a curve $c: [a, b] \rightarrow \mathbb{R}^2$ with $c'(s) = \mathbf{t}(s)$. Since $\mathbf{t}(s)$ is always a unit vector, c is parameterized by arclength. Equation $(*)$ then says that $\mathbf{t}'(s) = \kappa(s) \cdot \mathbf{n}(s)$, so that $\kappa(s)$ is the curvature of c at s .

If c and \bar{c} have the same curvature functions κ , then their unit tangent vectors \mathbf{t} and $\bar{\mathbf{t}}$ both satisfy $(*)$. Now if \mathbf{t} is any solution of $(*)$, clearly $B \circ \mathbf{t}$ is also, for any rotation B . Choosing B so that $B(\mathbf{t}(a)) = \bar{\mathbf{t}}(a)$, and using the uniqueness of solutions of $(*)$ with a given initial condition, we see that $\bar{\mathbf{t}} = B \circ \mathbf{t}$. This implies that \bar{c} differs from $B \circ c$ by a translation. ♦

Notice that this theorem makes the previous calculation unnecessary: Since a circle of radius R has constant curvature $1/R$, any curve with constant curvature $1/R$ differs from this circle by a Euclidean motion, and is consequently another circle of radius $1/R$. More generally, Theorem 2 seems to make further study of curves almost pointless. Although one may still study properties of curvature, there is clearly no point in introducing any similar concept; we would only be interested in concepts that remained the same for c and $A \circ c$, and all of these are already determined by the curvature.

Despite these remarks, we are by no means ready to write off the study of plane curves. Many interesting results remain, of which we will be able to sample only a few. However, these results were all proved many years after the study of curves had been initiated, and are all global results, rather than local ones. To begin, we define certain kinds of curves, with which we will be almost exclusively concerned.

A C^1 curve $c: [a, b] \rightarrow \mathbb{R}^2$ is called **closed** if $c(a) = c(b)$ and $c'(a) = c'(b)$.

One can also regard a closed curve as an immersion of S^1 in \mathbb{R}^2 . A curve is called **simple** if it is one-one. Finally, among the simple closed curves we distinguish a special class of curves called **convex**. These are defined to be the simple closed curves which always lie on one side of their tangent lines.

Although the property enunciated in this definition is precisely the one which is used in all proofs about convex curves, we will nevertheless take time out to equate this definition with a more common one.

Any subset A of \mathbb{R}^2 is called **convex** if the line segment \overline{pq} from p to q is

contained in A whenever $p, q \in A$. Suppose A is convex and p is a point in the boundary of A . A line L through p is called a **support line** of A if A lies completely in one of the closed half-spaces into which L divides \mathbb{R}^2 .

3. PROPOSITION. If A is convex, and p is in the boundary of A , then there is at least one support line L through p .

PROOF. If A has no interior points it lies on a line, and the proof is trivial. If A has an interior point q , let l be the ray from q through p , and let l' be the part starting at p . Clearly l' intersects A only at p , for if a point q' on l' were

in A , then all points between q' and the points in a neighborhood of q would be in A , so p would be an interior point of A .

Choose one side of l' , and consider angles θ such that rays from p making an angle of θ with l' on this side do not intersect A except at p (it may be that $\theta = 0$ is the only possibility). Let θ_1 be the least upper bound of all such θ , and let l_1 be the ray through p making an angle of θ_1 . Let l_2 be the corresponding ray on the other side of l' .

We claim that the angle between l_1 and l_2 is $\geq \pi$, which will surely prove the theorem. To prove the claim, note that there are points of A arbitrarily close to (or perhaps even on) both l_1 and l_2 . If the angle between l_1 and l_2 were $< \pi$,

the triangle containing a suitable pair of such points, and q , would contain p in its interior, which cannot happen, since p is not an interior point of A . ❖

Note (for those who are familiar with Banach spaces). This theorem is essentially the Hahn-Banach Theorem. If A were symmetric about the origin, then \bar{A} would be the unit ball in \mathbb{R}^2 for a Banach space norm $\| \cdot \|$. If $W \subset \mathbb{R}^2$ is the subspace spanned by p , and $\lambda: W \rightarrow \mathbb{R}$ is the linear functional with $\lambda(p) = 1$, then the

desired support line is just a translate of the kernel of an extension $\bar{\lambda}: \mathbb{R}^2 \rightarrow \mathbb{R}$ of λ with $\|\bar{\lambda}\| = 1$. Symmetry of A is really unimportant, for the Hahn-Banach Theorem only requires a norm satisfying $\|av\| = a\|v\|$ for $a > 0$. The proof given here is just a geometrical translation of the main step in the usual proof of the Hahn-Banach Theorem.

We now want to show that a simple closed curve c is convex if and only if the set A consisting of all points on c or inside c is a convex subset of \mathbb{R}^2 . This is going to be pretty hard, since we have never defined the inside of a simple closed curve, and are just assuming that the content of Corollary I.11-15 is intuitively obvious. There is really no need to go through the proof of all this right now; it is only necessary to accept the following fact:

Suppose c is a simple closed curve, and l is a ray from p which intersects c at just one point $q \neq p$. Suppose, moreover, that the tangent line of c at q does *not* lie along l . Then p is inside c .

4. PROPOSITION. Let c be a simple closed curve, and let A be the set of all points on or inside c . Then c is convex (that is, c lies on one side of each of its tangent lines) if and only if A is convex.

PROOF. Suppose first that A is convex. Any point p on c is a boundary point of A , so there is a support line L of A through p . This line is clearly the tangent line of c at p , so c lies on one side of the tangent line through p .

Now suppose c is convex. For each p on c , let H_p be the closed half-plane, bounded by the tangent line through p , in which c lies. Clearly $A \subset \bigcap_p H_p$. Since the intersection $\bigcap_p H_p$ of all H_p is convex (any intersection of convex sets is convex), it suffices to show that we actually have $A = \bigcap_p H_p$. So consider a

point q which is outside A . Let p be the point on c closest to q . Clearly the tangent line L of c at p is perpendicular to the ray l from q through p . It

suffices to show that c lies on the opposite side of L from q , for then $q \notin H_p$. Now if c lay entirely on the same side of L as q , then c could not intersect the ray l at any other point; for it cannot intersect the open segment \overline{pq} , since p is the closest point on c to q , and it certainly could not intersect l at points on the other side of L . By the remark preceding the Proposition, this would mean that q is inside c , a contradiction. ♦

Our first global results about curves depend upon a corresponding global formulation of the curvature function for a curve $c: [a, b] \rightarrow \mathbb{R}^2$. As usual, we assume c is parameterized by arclength, and consider its associated unit tangent vector curve $\mathbf{t}: [a, b] \rightarrow S^1$. Any point in S^1 can be described as $(\cos \theta, \sin \theta)$ for a real number θ . Of course, it is not possible to do this continuously. More precisely, if we define $\mu: \mathbb{R} \rightarrow S^1$ by

$$\mu(\theta) = (\cos \theta, \sin \theta) \in S^1,$$

then there is no continuous function $f: S^1 \rightarrow \mathbb{R}$ with $\mu \circ f = \text{identity}$. On the other hand, for our curve $c: [a, b] \rightarrow \mathbb{R}^2$ there is a continuous function

$f: [a, b] \rightarrow \mathbb{R}$ with

$$\mu(f(s)) = \mathbf{t}(s).$$

More generally,

5. PROPOSITION. Let $\gamma: [a, b] \rightarrow S^1$ be continuous. Then there is a continuous function $f: [a, b] \rightarrow \mathbb{R}$ with $\mu \circ f = \gamma$. Moreover, if f and \tilde{f} are any two such functions, then $f - \tilde{f} = 2\pi k$ for some k .

PROOF. For any $t \in [a, b]$ there is an open connected subset I_t of $[a, b]$ containing t such that $\gamma(I_t)$ is a *proper* connected subset of S^1 . Clearly $\mu^{-1}(\gamma(I_t))$ is then a disjoint union of connected sets and μ restricted to each of them is a homeomorphism onto $\gamma(I_t)$. This shows that if we choose any number v with

$\mu(v) = \gamma(t)$, then f can be defined uniquely on I_t in such a way that it has the value v at t , is continuous, and satisfies $\mu \circ f = \gamma$ on I_t .

We first prove that if there are two continuous functions f and \tilde{f} with $\mu \circ f = \gamma$, then they must differ by $2\pi k$ for some k . It obviously suffices to prove that $f = \tilde{f}$ if $f(a) = \tilde{f}(a)$. Let A be the set of all $t \in [a, b]$ such that $f(t) = \tilde{f}(t)$. Then A is closed, while the previous paragraph shows that A is open. Since $a \in A$ and $[a, b]$ is connected, this shows that $A = [a, b]$.

To prove existence, consider the set B of all $t \in [a, b]$ such that a continuous f can be defined on $[a, t]$, and let t_0 be the least upper bound of B . There is $t_1 \in B$ with $t_1 < t_0$ and $t_1 \in I_{t_0}$. Define a continuous \tilde{f} on I_{t_0} (with any value v at t_0 satisfying $\mu(v) = \gamma(t_0)$). Then $\tilde{f}(t_1) - f(t_1) = 2k\pi$ for some k . Now $\tilde{f} - 2k\pi$ must equal f on $[t_1, t_0]$, by the uniqueness proved previously. So we can extend f to be $\tilde{f} - 2k\pi$ on $[0, t_0]$. This shows that $t_0 \in B$. If $t_0 < b$, then we obtain an immediate contradiction by extending f to $[a, t_0] \cup I_{t_0}$. ♦

If f is the function given by Proposition 5 for the curve $\mathbf{t}: [a, b] \rightarrow S^1$, so that

$$c'(s) = \mathbf{t}(s) = \mu(f(s)) = (\cos f(s), \sin f(s)),$$

then

$$c''(s) = (-f'(s) \sin f(s), f'(s) \cos f(s)).$$

So

$$\begin{aligned} \kappa(s) &= c_1'(s)c_2''(s) - c_2'(s)c_1''(s) \\ &= \cos f(s) \cdot [(f'(s) \cos f(s))] - \sin f(s) \cdot [-f'(s) \sin f(s)]. \end{aligned}$$

We thus have

$$\kappa(s) = f'(s).$$

Notice that this gives us an easy way to reconstruct the curve from its curvature function: We first reconstruct f as $f(s) = \int_0^s \kappa(\theta) d\theta$; this gives us $\mathbf{t}(s) = \mu(f(s))$, so one more integration gives us the curve. Notice also that

$$\begin{aligned} f(b) - f(a) &= \int_a^b f'(s) ds \\ &= \int_a^b \kappa(s) ds; \end{aligned}$$

this quantity is called the **total curvature** of c . If c is a closed curve, the function $\mathbf{t}: [a, b] \rightarrow S^1$ satisfies $\mathbf{t}(a) = \mathbf{t}(b)$, so we may regard it as a map $\mathbf{t}: S^1 \rightarrow S^1$. The total curvature then has a special interpretation.

6. PROPOSITION. The total curvature of a closed curve $c: [a, b] \rightarrow \mathbb{R}^2$ is 2π times the degree of the map $\mathbf{t}: S^1 \rightarrow S^1$. (The degree of a map is defined on pg. I.275.)

PROOF. Since the form “ $d\theta$ ” on S^1 has integral 2π , the degree of \mathbf{t} is

$$\begin{aligned}\frac{1}{2\pi} \int_a^b \mathbf{t}^*(d\theta) &= \frac{1}{2\pi} \int_a^b (\mu \circ f)^*(d\theta) \\ &= \frac{1}{2\pi} \int_a^b f^*(\mu^*(d\theta)).\end{aligned}$$

Now

$$\mu_* \left(\frac{d}{dt} \Big|_t \right) = (-\sin \theta, \cos \theta)_{\mu(\theta)} \in S^1_{\mu(\theta)};$$

this is a unit tangent vector of S^1 , on which $d\theta$ has the value 1. So

$$\mu^*(d\theta) = dt.$$

Thus

$$\begin{aligned}\text{degree of } \mathbf{t} &= \frac{1}{2\pi} \int_a^b f^*(dt) \\ &= \frac{1}{2\pi} \int_a^b f' dt \\ &= \frac{1}{2\pi} [f(b) - f(a)]. \quad \spadesuit\end{aligned}$$

The degree of \mathbf{t} is also called the **rotation index** of c . The left-most figure below illustrates the first of our global theorems.

7. THEOREM (THE HOPF UMLAUFSATZ). The rotation index of a simple closed curve is ± 1 (depending on the direction in which it is traversed).

PROOF. Let $c: [0, L] \rightarrow \mathbb{R}^2$ be the curve, parameterized by arclength, and let $\Delta \subset \mathbb{R}^2$ be

$$\Delta = \{(s_1, s_2) : 0 \leq s_1 \leq s_2 \leq L\}.$$

We define $\phi: \Delta \rightarrow S^1$ by

$$\phi(s_1, s_2) = \frac{c(s_2) - c(s_1)}{|c(s_2) - c(s_1)|} \quad s_1 < s_2 \quad \text{and} \quad (s_1, s_2) \neq (0, L)$$

$$\phi(s, s) = c'(s) = \mathbf{t}(s)$$

$$\phi(0, L) = -c'(0) = -\mathbf{t}(0).$$

It is easy to see that ϕ is continuous. Now the map $s \mapsto \phi(s, s)$ is just $\mathbf{t}: [0, L] \rightarrow S^1$. On the other hand, this map is homotopic to the map γ obtained by applying ϕ to the curve which goes along the other two sides of the triangle, from $(0, 0)$ to (L, L) . So it suffices to compute the degree of γ , which we break

into two pieces γ_1 and γ_2 , defined on $[0, L]$ and $[L, 2L]$, say.

The rotation index of c clearly does not change if we rotate or translate c , so we can assume that c lies in the upper half-plane, with $c(0) = (0, 0)$, and that the tangent line at $c(0)$ is the x -axis, as in the picture at the top of the next page. We assume that c is traversed in such a way that $\mathbf{t}(0) = (1, 0)$. Now, $\gamma_1(s) = \phi(0, s)$ clearly always lies in the semi-circle in the upper half-plane, and $\gamma_1(0) = \mathbf{t}(0)$, while $\gamma_1(L) = -\mathbf{t}(0)$. Consequently, the function f given by Proposition 5 clearly has its image in $[0, \pi]$, with $f(0) = 0$ and $f(L) = \pi$. Similarly, γ_2 lies in the lower half-plane, so the f for γ_2 satisfies $f(L) = \pi$ and $f(2L) = 2\pi$. Thus the degree of \mathbf{t} is $1/2\pi \cdot [2\pi - 0] = 1$. ♦

Using Theorem 7, we can now relate convexity and curvature.

8. THEOREM. A simple closed curve c is convex if and only if its curvature κ satisfies $\kappa \geq 0$ or $\kappa \leq 0$ (depending on the direction in which c is traversed).

PROOF. Let $c: [0, L] \rightarrow \mathbb{R}^2$ be parameterized by arclength, and choose a continuous $f: [0, L] \rightarrow \mathbb{R}$ with $\mu \circ f = \mathbf{t}$.

If $\kappa \geq 0$, then $f' \geq 0$, so f is non-decreasing. Suppose that c were not convex, so that c lies on both sides of the tangent line l through some point p . There are points q_1, q_2 on c which are furthest away from l on both sides of l .

The tangent lines at q_1 and q_2 are clearly parallel to l , so of the three unit tangents at these points, at least two are identical, say $\mathbf{t}(s_1) = \mathbf{t}(s_2)$ for $s_1 < s_2$, with $(s_1, s_2) \neq (0, L)$. Thus $f(s_2) - f(s_1)$ is a multiple of 2π . But f is non-decreasing, and $f(L) = f(0) + 2\pi$, by Theorem 7. So either $f(s_2) = f(s_1)$ or $f(s_2) = f(s_1) + 2\pi$. In the first case it follows that f is constant on $[s_1, s_2]$, so \mathbf{t} is

constant on $[s_1, s_2]$. This implies that c is a straight line on $[s_1, s_2]$, contradicting the fact that none of the points p, q_1, q_2 lies on the tangent lines through the others. If $f(s_2) = f(s_1) + 2\pi$, the other arc of c must similarly be a straight line, which is again a contradiction. Thus c must be convex.

Now suppose c is convex. If there is $s_1 < s_2$ with $f(s_1) = f(s_2)$, so that $\mathbf{t}(s_1) = \mathbf{t}(s_2)$, then there is also s with $\mathbf{t}(s) = -\mathbf{t}(s_1)$, since \mathbf{t} has degree 1, and

is consequently onto S^1 . The tangent lines through two of the three points $c(s), c(s_1), c(s_2)$ must coincide (otherwise c would cross one of them). Thus c is tangent to the same line l at two points, $c(t_1)$ and $c(t_2)$, say. These two points divide c into two arcs, α and β . If l' is perpendicular to l , and intersects l

between $c(t_1)$ and $c(t_2)$, then α and β must intersect l' ; using convexity of c , it is easy to see that α and β intersect l' exactly once. Clearly one arc, say α , always intersects l' at a point further away from l than the other, β . We claim that β lies along l . If not, consider the tangent line through the point P of β furthest from l . This tangent line is parallel to l , and c would lie on both sides of it, a contradiction.

Now, since β lies along l , we have $\mathbf{t}(t_1) = \mathbf{t}(t_2)$. Thus $t_1 = s_1$ and $t_2 = s_2$. Since the curve lies along a line on $[s_1, s_2]$, we have $f(s) = f(s_1)$ for all $s \in [s_1, s_2]$. Thus, f is non-decreasing. ♦

Our final global result about curves in the plane involves another local concept. A **vertex** of a curve c is a point where $\kappa'(s) = 0$. It is easily seen that an ellipse which is not a circle has exactly four vertices, at the ends of the major and minor axes; these are the points where κ has a local maximum or minimum (though a vertex need not generally be of this type). Before proceeding with the next theorem we need a preliminary observation. The curvature κ is defined by

$$\mathbf{t}'(s) = \kappa(s) \cdot \mathbf{n}(s);$$

the existence of such a number $\kappa(s)$ follows from the equation $\langle \mathbf{t}, \mathbf{t} \rangle = 1$, by differentiation. Similarly, from $\langle \mathbf{n}, \mathbf{n} \rangle = 1$ we obtain

$$\langle \mathbf{n}'(s), \mathbf{n} \rangle = 0,$$

which implies that $\mathbf{n}'(s)$ is a multiple of $\mathbf{t}(s)$, say $\mathbf{n}'(s) = \alpha \cdot \mathbf{t}(s)$. On the other hand, from $\langle \mathbf{t}, \mathbf{n} \rangle = 0$ we obtain

$$\langle \mathbf{t}'(s), \mathbf{n}(s) \rangle + \langle \mathbf{t}(s), \mathbf{n}'(s) \rangle = 0,$$

or

$$\kappa(s) + \alpha = 0;$$

hence,

$$(*) \quad \mathbf{n}'(s) = -\kappa(s) \cdot \mathbf{t}.$$

9. THEOREM (THE FOUR VERTEX THEOREM). Every simple closed convex curve has at least four vertices.

PROOF. If $c: [0, L] \rightarrow \mathbb{R}^2$ is the simple closed curve, parameterized by arc-length, then c has at least two vertices—namely, the maximum and minimum points for the curvature. Choose the coordinate system so that the x -axis passes through these two points. Now integration by parts gives the following equation,

in which we are taking integrals of \mathbb{R}^2 -valued functions by integrating each component separately:

$$\begin{aligned}\int_0^L \kappa'(s) \cdot c(s) &= - \int_0^L \kappa(s) \cdot \mathbf{t}(s) ds \\ &= \int_0^L \mathbf{n}'(s) ds \quad \text{by } (*) \\ &= \mathbf{n}(L) - \mathbf{n}(0) = 0.\end{aligned}$$

Consequently, we certainly have

$$(**) \quad \int_0^L \kappa'(s) \langle c(s), e_2 \rangle ds = 0.$$

If there are no other vertices, then $\kappa' > 0$ on one half of c and $\kappa' < 0$ on the other. So $\kappa'(s) \langle c(s), e_2 \rangle$ has the same sign on both halves, contradicting (**). Thus c must have at least one more vertex.

The argument just given actually shows that c cannot be formed of two arcs with $\kappa' > 0$ on one and $\kappa' < 0$ on the other; the same conclusion clearly holds even if $\kappa' \geq 0$ on one and $\kappa' \leq 0$ on the other, since $\kappa' \neq 0$ somewhere. This shows that c must have a fourth vertex; if it had only three, then some pair would divide c into two arcs with $\kappa \geq 0$ on one and $\kappa' \leq 0$ on the other. ♦

We now turn our attention to curves in space, and ask, once again, how to measure the curvature of $c: [a, b] \rightarrow \mathbb{R}^3$. We can still look for the limiting position of circles through $c(s_1), c(s_2), c(s_3)$ as $s_1, s_2, s_3 \rightarrow s$. If this limiting circle exists, its center C must satisfy

$$\begin{aligned}\langle c'(s), c(s) - C \rangle &= 0 \\ \langle c''(s), c(s) - C \rangle &= -\langle c'(s), c'(s) \rangle;\end{aligned}$$

the derivation of this necessary condition still works. However, for space curves these equations do not even determine C ; the first equation merely restricts C to lie on a certain plane, not on a certain line. We must first see whether the *planes* through the points $c(s_i)$ approach a limiting position.

10. PROPOSITION. Let $c: [a, b] \rightarrow \mathbb{R}^3$ be a C^2 curve parameterized by arc-length, with $c''(s) \neq 0$. For s_1, s_2, s_3 sufficiently close to s , the points $c(s_1), c(s_2), c(s_3)$ do not lie on a line. As $s_i \rightarrow s$, the unique plane through the points $c(s_i)$ approaches the plane P spanned by $c'(s)$ and $c''(s)$.

Remark: The plane P should really be described as the plane through $c(s)$ which is parallel to the plane spanned by $c'(s)$ and $c''(s)$, but we will allow ourselves the elliptical terminology suggested by the picture.

PROOF. Assuming for the moment that the points $c(s_i)$ do not lie on a straight line, let $P(s_1, s_2, s_3)$ be the plane spanned by these points, and let $a(s_1, s_2, s_3)$ be a unit vector perpendicular to $P(s_1, s_2, s_3)$. Then the function

$$(*) \quad s \mapsto \langle c(s), a(s_1, s_2, s_3) \rangle$$

is 0 for $s = s_i$. So we have

$$(1) \quad \langle c'(\xi_i), a(s_1, s_2, s_3) \rangle = 0 \quad \xi_i \in (s_i, s_{i+1}), \quad i = 1, 2.$$

It follows that

$$(2) \quad \langle c''(\eta), a(s_1, s_2, s_3) \rangle = 0 \quad \eta \in (\xi_1, \xi_2).$$

Equations (1) and (2), together with continuity of c' and c'' , clearly show that $a(s_1, s_2, s_3)$ approaches a unit vector perpendicular to $c'(s)$ and $c''(s)$, so that $P(s_1, s_2, s_3)$ approaches P .

If the points $c(s_i)$ do lie on a straight line, then we can choose a whole circle of unit vectors $a(s_1, s_2, s_3)$ for which the function $(*)$ vanishes at $s = s_i$. If this were true for s_i arbitrarily close to s , the remaining part of the argument would imply that all of these vectors are nearly perpendicular to P , which is absurd. ♦

The plane described in Proposition 10 is called the **osculating plane** of the curve at s . Notice that, unlike the osculating circle, the osculating plane may exist even if $c''(s) = 0$. For example, if c is a plane curve which is not straight, then the osculating plane certainly exists. The exact conditions for the existence of an osculating plane are not very important for us, but we will pause to indicate the actual state of affairs.

The worst possible situation occurs for the curve

$$c(t) = \begin{cases} 0 & t = 0 \\ (t, e^{-1/t^2}, 0) & t > 0 \\ (t, 0, e^{-1/t^2}) & t < 0, \end{cases}$$

which can't make up its mind whether to osculate in the (x, y) -plane or in the (x, z) -plane. For this curve we have $c^{(k)}(0) = 0$ for all $k \geq 2$, which suggests that we consider only curves with $c^{(k)}(s) \neq 0$ for some $k \geq 2$. Notice that for curves parameterized by arclength, $\langle c'(s), c''(s) \rangle = 0$ implies

$$\langle c'(s), c'''(s) \rangle + \langle c''(s), c''(s) \rangle = 0.$$

So if $c''(s) = 0$, we have $c'''(s)$ perpendicular to $c'(s)$. Similarly, $c'''(s) = 0$ implies that $c^{(4)}(s)$ is perpendicular to $c'(s)$, etc. So the first non-zero higher derivative $c^{(k)}(s)$ is the same as the first derivative which is linearly independent of $c'(s)$. Now suppose P is the plane spanned by $c'(s)$ and this first non-zero $c^{(k)}(s)$. Let s_1, s_2, s_3 be parameter values *on the same side* of s , i.e., $s \leq s_1 < s_2 < s_3$ (or $s_1 < s_2 < s_3 \leq s$). If $a(s_1, s_2, s_3)$ is a unit vector perpendicular to all $c(s_i) - c(s)$, then, as before, we have

$$\begin{aligned} \langle c'(\xi_i), a(s_1, s_2, s_3) \rangle &= 0 \\ \langle c''(\eta), a(s_1, s_2, s_3) \rangle &= 0. \end{aligned}$$

Now $\eta \in (s_1, s_3)$ so $\eta \neq s$. Hence, if $c''(s) = 0$ we have $\theta \in (s, \eta)$ with

$$\langle c'''(\theta), a(s_1, s_2, s_3) \rangle = 0.$$

Continuing in this way, we finally obtain $\lambda \in (s, s_3)$ with

$$\langle c^{(k)}(\lambda), a(s_1, s_2, s_3) \rangle = 0.$$

As before, this shows that the plane through the points $c(s_i)$ approaches P , and that the points $c(s_i)$ cannot lie on a line for s_i arbitrarily close to 0.

If the s_i are allowed to lie on both sides of s , this result is no longer true. For example, consider the curve

$$c(t) = (t, t^4, t^3).$$

We have

$$\begin{aligned}c'(0) &= (1, 0, 0) \\c''(0) &= (0, 0, 0) \\c'''(0) &= (0, 0, 6),\end{aligned}$$

so $(0, 1, 0)$ is perpendicular to the plane spanned by $c'(0)$ and $c'''(0)$. On the other hand, for a vector perpendicular to the plane spanned by $c(0), c(t), c(-t)$ we can choose

$$\begin{aligned}\text{normalized } [c(t) - c(0)] \times [c(-t) - c(0)] \\&= \text{normalized } (t, t^4, t^3) \times (-t, t^4, -t^3) \\&= \text{normalized } (-2t^7, 0, 2t^5) \\&\rightarrow (0, 0, 1).\end{aligned}$$

This strange behavior is clarified by a look at the Taylor expansion

$$c(s) = c(0) + sc'(0) + 0 + \frac{s^3}{6}c'''(0) + o(s^3),$$

which shows that

$$\begin{aligned}[c(s) - c(0)] \times [c(t) - c(0)] &= \left[\frac{st^3}{6} - \frac{ts^3}{6} \right] c'(0) \times c'''(0) \\&\quad + \text{higher order terms.}\end{aligned}$$

When s and t have the same sign, the dominant term is the first. But when s and t have opposite signs this is no longer true—this term may even be 0. I suspect, but have not checked, that the parameter values s_i may be picked on both sides of 0 if and only if the first $k \geq 2$ with $c^{(k)}(0) \neq 0$ is even.

For space curves $c: [a, b] \rightarrow \mathbb{R}^3$ with $c''(s) \neq 0$, we now clearly have an osculating circle, the limit as $s_1, s_2, s_3 \rightarrow s$ of the circle through the points $c(s_i)$; it lies in the osculating plane. We define the curvature κ to be the reciprocal of the radius of this circle, so that

$$\kappa(s) = |\mathbf{t}'(s)|.$$

This definition, once again, determines a curvature even when $c''(s) = \mathbf{t}'(s) = 0$. Unlike the case of plane curves, we cannot obtain a signed curvature, for there is no natural way to pick a vector orthogonal to $\mathbf{t}(s)$. However, when $\kappa(s) \neq 0$, we can now *define* $\mathbf{n}(s)$ by the equation

$$\mathbf{t}'(s) = \kappa(s)\mathbf{n}(s), \quad \mathbf{n}(s) = \text{normalized } \mathbf{t}'(s).$$

The vector $\mathbf{n}(s)$ is called the **principal normal** of c at s . We also define the **binormal** $\mathbf{b}(s)$ by

$$\mathbf{b}(s) = \mathbf{t}(s) \times \mathbf{n}(s),$$

so that $(\mathbf{t}, \mathbf{n}, \mathbf{b})$ is always a positively oriented orthonormal basis.

Note that $\langle \mathbf{b}, \mathbf{b} \rangle = 1$ implies that $\langle \mathbf{b}', \mathbf{b} \rangle = 0$, so that \mathbf{b}' is a linear combination of \mathbf{t} and \mathbf{n} . We also have $\langle \mathbf{b}, \mathbf{t} \rangle = 0$, which implies that

$$\langle \mathbf{b}', \mathbf{t} \rangle = -\langle \mathbf{b}, \mathbf{t}' \rangle = -\langle \mathbf{b}, \mathbf{n} \rangle = 0.$$

Thus \mathbf{b}' is actually a multiple of \mathbf{n} , and we can define a new function τ , the **torsion**, by

$$\mathbf{b}' = -\tau \mathbf{n}.$$

Of course, we can define τ only at points where \mathbf{n} exists, i.e., where $c'' \neq 0$. This is analogous to the fact that κ can be defined only at points where $c' \neq 0$. The reason for choosing the negative sign in this equation will be explained in a moment; we first interpret the absolute value $|\tau|$. The function $\mathbf{b}: [a, b] \rightarrow S^2$ has an arclength function

$$\begin{aligned} \text{length of } \mathbf{b} \text{ on } [a, s] &= \int_a^s |\mathbf{b}'(u)| du \\ &= \int_a^s |\tau(u)| du. \end{aligned}$$

Consequently, $|\tau(s)|$ is the derivative of this arclength function. Since \mathbf{b} is the perpendicular to the osculating plane, this derivative of the length of \mathbf{b} can be thought of as *the rate at which the osculating plane is changing*. Thus $|\tau|$ measures, in some sense, the rate at which the curve deviates from being a plane curve. Classically, curvature and torsion were also known as *first* and *second curvature*, and space curves were called *curves of double curvature*.

To develop a formula for the torsion, we first recall that the cross product $v \times w$ of v and w is defined by the equation

$$(*) \quad \langle z, v \times w \rangle = \det \begin{pmatrix} z \\ v \\ w \end{pmatrix}.$$

[Since the i^{th} component of $v \times w$ is $\langle e_i, v \times w \rangle$, this shows that $v \times w$ can be obtained by computing the determinant

$$v \times w = \det \begin{pmatrix} e_1 & e_2 & e_3 \\ v_1 & v_2 & v_3 \\ w_1 & w_2 & w_3 \end{pmatrix} = (v_2 w_3 - w_2 v_3) e_1 + \cdots$$

purely formally.] Using the fact that \det is alternating, the left side of $(*)$, classically known as the “scalar triple product” (v, w, z) , is seen to satisfy

$$(**) \quad \langle z, v \times w \rangle = -\langle w, v \times z \rangle = \langle w, z \times v \rangle.$$

Now for the torsion τ of a curve c parameterized by arclength we clearly have

$$\begin{aligned} \tau &= \langle -\mathbf{n}, \mathbf{b}' \rangle = \langle -\mathbf{n}, (\mathbf{t} \times \mathbf{n})' \rangle \\ &= \langle -\mathbf{n}, \mathbf{t} \times \mathbf{n}' \rangle + \langle -\mathbf{n}, \mathbf{t}' \times \mathbf{n} \rangle, \quad \text{where } \mathbf{t}' \times \mathbf{n} = 0 \\ &= \left\langle -\frac{c''}{\kappa}, c' \times \left(\frac{c''}{\kappa} \right)' \right\rangle \\ &= \left\langle -\frac{c''}{\kappa}, c' \times \left(\frac{\kappa c''' - \kappa' c''}{\kappa^2} \right) \right\rangle \\ &= -\frac{1}{\kappa^2} \langle c'', c' \times c''' \rangle, \end{aligned}$$

or

$$\tau = \frac{1}{\kappa^2} \langle c' \times c'', c''' \rangle.$$

This shows that $\tau > 0$ when $\mathbf{t}, \mathbf{n}, c'''$ form a positively oriented basis for \mathbb{R}^3 , which is the same as saying that c''' is on the same side of the osculating plane as \mathbf{b} . Now in Taylor's formula,

$$c(s+h) = c(s) + hc'(s) + \frac{h^2}{2}c''(s) + \frac{h^3}{6}c'''(s) + o(h^3),$$

the term $c(s) + hc'(s) + h^2c''(s)/2$ is in the osculating plane at s , so

$$c(s+h) - \left[c(s) + hc'(s) + \frac{h^2}{2}c''(s) \right] = \frac{h^3}{6}c'''(s) + o(h^3)$$

points from the osculating plane to $c(s+h)$. Consequently, if $c'''(s) \neq 0$, then the curve pierces the osculating plane at s , and the points $c(s+h)$ for small

$h > 0$ are on the same side as $c'''(s)$, while points $c(s + h)$ for $h < 0$ are on the other side. Together with our previous remarks, this shows that

if $\tau(s) > 0$, then points $c(s + h)$ for small $h > 0$ lie on the same side of the osculating plane as $\mathbf{b}(s)$, while points $c(s + h)$ for small $h < 0$ lie on the opposite side.

Our formula for τ shows that the torsion for the curve $\bar{c} = s \mapsto c(-s)$ has the same sign as that of c . This is because reversing directions also reverses the binormal. For a curve with an arbitrary parameterization we obtain, proceeding just as in the case of curvature, the formula

$$\tau = \frac{\langle \dot{c} \times \ddot{c}, \ddot{\ddot{c}} \rangle}{\langle \dot{c} \times \ddot{c}, \dot{c} \times \ddot{c} \rangle}.$$

A standard and possibly illuminating way of examining the geometrical significance of κ and τ is to examine the projections of c on the planes spanned by any two of \mathbf{t} , \mathbf{n} , \mathbf{b} . The plane spanned by \mathbf{t} and \mathbf{n} is just the osculating plane.

The plane spanned by the principal normal \mathbf{n} and binormal \mathbf{b} is called, naturally enough, the **normal plane**, and the plane spanned by \mathbf{t} and \mathbf{b} is called the **rectifying plane** (this terminology is explained in Volume III, pg. 186). We can choose a coordinate system for \mathbb{R}^3 so that $c(0) = 0$ and so that the osculating plane of c at 0 is the (x, y) -plane. Further choosing $c'(0) = (1, 0, 0)$ we obtain

$$\begin{aligned} c(0) &= (0, 0, 0) \\ c'(0) &= (1, 0, 0) \\ c''(0) &= (0, \kappa, 0) \\ c'''(0) &= (_, _, \kappa\tau), \end{aligned}$$

the last equation following from the fact that $\tau\kappa^2 = \langle c' \times c'', c''' \rangle$, as shown above. The three components of the Taylor expansion

$$c(s) = c(0) + sc'(0) + \frac{s^2}{2}c''(0) + \frac{s^3}{6}c'''(0) + \cdots$$

give

$$c_1(s) = s + \text{terms of order 3 or more}$$

$$c_2(s) = \frac{\kappa}{2}s^2 + \text{terms of order 3 or more}$$

$$c_3(s) = \frac{\kappa\tau}{6}s^3 + \text{terms of order 4 or more.}$$

So the projections look like

$$y = \frac{\kappa}{2}x^2 \text{ up to order 2 on the osculating plane}$$

$$z = \frac{\kappa\tau}{6}x^3 \text{ up to order 3 on the rectifying plane}$$

$$z^2 = \frac{2\tau^2}{9\kappa}y^3 \text{ up to order 3 on the normal plane.}$$

The figure below shows these projections for the curve on page 30.

osculating plane

normal plane

rectifying plane

Just as in the case of plane curves, we now ask to what extent the curvature and torsion determine a curve.

We note first that a curve c (parameterized by arclength) with $\kappa = 0$ everywhere is a straight line—the proof is the same as before.

Moreover, a curve with $\tau = 0$ everywhere is a plane curve. To prove this, we note that $\tau = 0$ means $\mathbf{b}' = 0$ so that $\mathbf{b}(s) = \mathbf{b}_0$, a constant vector. This implies that $\langle \mathbf{t}, \mathbf{b}_0 \rangle = 0$. But this means that

$$\frac{d}{ds} \langle c(s), \mathbf{b}_0 \rangle = 0,$$

so $\langle c(s), \mathbf{b}_0 \rangle = a$ where a is a constant. Thus c lies in the plane

$$\{p \in \mathbb{R}^3 : \langle p, \mathbf{b}_0 \rangle = a\}.$$

Unlike the case of plane curves, we should not expect a curve with constant curvature to be a circle, unless the torsion is 0. To get some idea of the variety of possibilities, we will examine only one special class of curves, the **helices**, given by the formula

$$c(u) = (a \cos u, a \sin u, bu).$$

We have

$$c'(u) = (-a \sin u, a \cos u, bu),$$

so

$$|c'(u)| = \sqrt{a^2 + b^2} = D,$$

and the reparameterization γ by arclength is given by

$$\gamma(s) = c(s/D),$$

with

$$\begin{aligned} \gamma'(s) &= \left(-\frac{a}{D} \sin \frac{s}{D}, \frac{a}{D} \cos \frac{s}{D}, \frac{b}{D} \right) \\ \gamma''(s) &= \left(-\frac{a}{D^2} \cos \frac{s}{D}, -\frac{a}{D^2} \sin \frac{s}{D}, 0 \right). \end{aligned}$$

Thus

$$\kappa(s) = |\gamma''(s)| = \frac{|a|}{D^2},$$

$$\tau = \frac{\langle \gamma' \times \gamma'', \gamma''' \rangle}{\kappa^2} = \frac{b}{D^2}.$$

Notice that neither κ nor τ depend on the sign of a . Changing a to $-a$ merely rotates the helix through an angle of π around its axis, which is the same as moving it a certain distance in the direction of this axis. However, changing from b to $-b$ changes the helix from “right handed” to “left handed” or vice-versa, and accordingly changes the sign of τ .

By choosing suitable a and b , we can make $|a|/D^2$ and b/D^2 equal to any desired pair (κ, τ) with $\kappa > 0$. So helices give examples of curves with any desired constant curvature (> 0) and constant torsion. Are they the only such curves? Rather than imitating the calculations for the simpler question answered previously, we will immediately ask the more general question, whether κ and τ determine c up to a proper Euclidean motion.

We begin with a recapitulation of the definitions:

$$\mathbf{t}' = \kappa \mathbf{n}$$

$$\mathbf{b}' = -\tau \mathbf{n}.$$

Notice that we have expressed the derivatives of \mathbf{t} and \mathbf{b} in terms of the original vectors $\mathbf{t}, \mathbf{n}, \mathbf{b}$. We can do the same for \mathbf{n} . First, since $\langle \mathbf{n}, \mathbf{n} \rangle = 1$, we obtain $\langle \mathbf{n}', \mathbf{n} \rangle = 0$, so \mathbf{n}' is some linear combination of \mathbf{t} and \mathbf{b} . Now, from $\langle \mathbf{n}, \mathbf{t} \rangle = 0$ we obtain

$$\langle \mathbf{n}', \mathbf{t} \rangle = -\langle \mathbf{n}, \mathbf{t}' \rangle = -\langle \mathbf{n}, \kappa \mathbf{n} \rangle = -\kappa,$$

(we already obtained this equation for the case of plane curves); and from $\langle \mathbf{n}, \mathbf{b} \rangle = 0$ we obtain

$$\langle \mathbf{n}', \mathbf{b} \rangle = -\langle \mathbf{n}, \mathbf{b}' \rangle = -\langle \mathbf{n}, -\tau \mathbf{n} \rangle = \tau.$$

Thus we have, altogether,

$$\begin{array}{rcl} \mathbf{t}' & = & \kappa \mathbf{n} \\ \mathbf{n}' & = & -\kappa \mathbf{t} + \tau \mathbf{b} \\ \mathbf{b}' & = & -\tau \mathbf{n} \end{array}$$

These are called the **Serret-Frenet formulas**. They were obtained independently by Serret in 1851, and by Frenet, in his thesis of 1847, an abstract of which appeared in 1852. Before Serret and Frenet, many geometric properties of curves were investigated with great laboriousness, but afterwards many of these investigations became routine, because, as our next theorem shows, everything about space curves is contained in these formulas.

11. THEOREM. Let $\kappa, \tau: [a, b] \rightarrow \mathbb{R}$ be continuous, with $\kappa > 0$ on $[a, b]$. Then there is a curve $c: [a, b] \rightarrow \mathbb{R}^3$, parameterized by arclength, whose curvature and torsion functions are κ and τ . Any two such curves differ by a proper Euclidean motion (a translation followed by a rotation [an element of $\text{SO}(3)$]).

PROOF. Let us adopt the more systematic notation $\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3$ for $\mathbf{t}, \mathbf{n}, \mathbf{b}$, and define a matrix

$$a_{ij}(s) = \begin{pmatrix} 0 & -\kappa(s) & 0 \\ \kappa(s) & 0 & -\tau(s) \\ 0 & \tau(s) & 0 \end{pmatrix},$$

so that the Serret-Frenet equations become

$$(*) \quad \mathbf{v}_i' = \sum_{j=1}^3 a_{ji} \mathbf{v}_j.$$

Now Theorem I.5-17 implies that there is a function $s \mapsto (\mathbf{v}_1(s), \mathbf{v}_2(s), \mathbf{v}_3(s))$ on $[a, b]$ satisfying (*). We can choose $\mathbf{v}_i(a)$ arbitrarily; choose them to be orthonormal and positively oriented. We claim that $\mathbf{v}_i(s)$ are orthonormal for all $s \in [a, b]$. This is the only significant point in the proof; the rest of the proof is exactly like the proof of Theorem 2.

To prove that the \mathbf{v}_i are always orthonormal, we note that

$$\langle \mathbf{v}_i, \mathbf{v}_j \rangle' = \sum_{k=1}^3 a_{ki} \langle \mathbf{v}_j, \mathbf{v}_k \rangle + a_{kj} \langle \mathbf{v}_i, \mathbf{v}_k \rangle.$$

This shows that the functions $\beta_{ij} = \langle \mathbf{v}_i, \mathbf{v}_j \rangle$ satisfy the differential equation

$$(**) \quad \beta_{ij}' = \sum_{k=1}^3 a_{ki} \beta_{jk} + a_{kj} \beta_{ik},$$

together with the initial conditions $\beta_{ij}(a) = \delta_{ij}$. Since the solutions of (**) are determined by their initial conditions, we can prove \mathbf{v}_i everywhere orthonormal by showing that the functions $\beta_{ij}(s) = \delta_{ij}$ do satisfy (**). In other words, we want to show that

$$\begin{aligned} 0 = \delta_{ij}' &= \sum_{k=1}^3 a_{ki} \delta_{jk} + a_{kj} \delta_{ik} \\ &= a_{ji} + a_{ij}. \end{aligned}$$

But this is true—the matrix (a_{ij}) is skew-symmetric. ♦

The skew-symmetry of (a_{ij}) gives an easy way to remember the Serret-Frenet formulas: the formulas for \mathbf{t}' and \mathbf{b}' are by definition, and the formula for \mathbf{n}' is the one that makes the matrix skew-symmetric. If we think of $\mathbf{t}, \mathbf{n}, \mathbf{b}$ as column vectors, so that $(\mathbf{t}, \mathbf{n}, \mathbf{b})$ denotes a 3×3 matrix, then the Serret-Frenet equations read

$$(\mathbf{t}, \mathbf{n}, \mathbf{b})' = \begin{pmatrix} \mathbf{t}_1' & \mathbf{n}_1' & \mathbf{b}_1' \\ \mathbf{t}_2' & \mathbf{n}_2' & \mathbf{b}_2' \\ \mathbf{t}_3' & \mathbf{n}_3' & \mathbf{b}_3' \end{pmatrix} = \begin{pmatrix} \mathbf{t}_1 & \mathbf{n}_1 & \mathbf{b}_1 \\ \mathbf{t}_2 & \mathbf{n}_2 & \mathbf{b}_2 \\ \mathbf{t}_3 & \mathbf{n}_3 & \mathbf{b}_3 \end{pmatrix} \cdot \begin{pmatrix} 0 & -\kappa & 0 \\ \kappa & 0 & -\tau \\ 0 & \tau & 0 \end{pmatrix}.$$

Since $\mathbf{t}, \mathbf{n}, \mathbf{b}$ are orthonormal and positively oriented, the curve $\alpha(s) = (\mathbf{t}(s), \mathbf{n}(s), \mathbf{b}(s))$ is a curve in $\text{SO}(3)$, the identity component of the orthogonal group $\text{O}(3)$. Recall that the tangent space $\text{SO}(n)_I = \text{O}(n)_I = \mathfrak{o}(n)$ of $\text{SO}(n)$ at I is the set of skew-symmetric matrices. For $A \in \text{SO}(n)$, the tangent space $\text{SO}(n)_A$ is just $L_{A*}(\mathfrak{o}(n))$, which equals $L_A \cdot \mathfrak{o}(n)$, since L_A is a linear function. Thus $\text{SO}(n)_A$ consists of all matrices $A \cdot M$ for $M \in \mathfrak{o}(n)$. Clearly, $A \cdot M = L_{A*}(M)$ is just $\tilde{M}(A)$, where \tilde{M} denotes the left invariant vector field with value M at I . Now the curve $\alpha: [a, b] \rightarrow \text{SO}(3)$ must have its tangent vector $\alpha'(s)$ in $\text{SO}(3)_{\alpha(s)}$, so we must have

$$\alpha'(s) = \alpha(s) \cdot (\text{skew-symmetric matrix}).$$

As we have just seen, this skew-symmetric matrix is just

$$\begin{pmatrix} 0 & -\kappa(s) & 0 \\ \kappa(s) & 0 & -\tau(s) \\ 0 & \tau(s) & 0 \end{pmatrix}.$$

Moreover, this argument shows that skew-symmetry of this matrix is a necessary consequence of the fact that $\mathbf{t}, \mathbf{n}, \mathbf{b}$ are orthonormal. By the same token, we can now present a more illuminating proof that the equations

$$(*) \quad \mathbf{v}_i' = \sum_{j=1}^3 a_{ji} \mathbf{v}_j$$

in the proof of Theorem 11 have an everywhere orthonormal solution. The equation (*) for $\alpha(s) = (\mathbf{v}_1(s), \mathbf{v}_2(s), \mathbf{v}_3(s))$ says that

$$\alpha'(s) = \alpha(s) \cdot a(s).$$

This may simply be regarded as a differential equation *on the manifold* $\text{SO}(3)$, of the type considered in the Addendum to Chapter 5, so its solution is a curve in $\text{SO}(3)$.

The Lie group $\text{SO}(3)$ is playing yet another, hitherto unmentioned, role in Theorem 11. The fact that κ and τ determine c up to a proper Euclidean motion is equivalent to the fact that κ and τ determine $\alpha = (\mathbf{t}, \mathbf{n}, \mathbf{b})$ up to an element of $\text{SO}(3)$, since c is determined up to a translation by \mathbf{t} . In other words, if \bar{c} is another curve with corresponding $\bar{\alpha} = (\bar{\mathbf{t}}, \bar{\mathbf{n}}, \bar{\mathbf{b}})$, and $\bar{\kappa} = \kappa$, $\bar{\tau} = \tau$, then for some $A \in \text{SO}(3)$ we have

$$(\bar{\mathbf{t}}, \bar{\mathbf{n}}, \bar{\mathbf{b}}) = L_A \circ (\mathbf{t}, \mathbf{n}, \mathbf{b}), \quad \text{i.e.,} \quad \bar{\alpha} = L_A \circ \alpha.$$

Now we already have a theorem telling us when the relation $\bar{\alpha} = L_A \circ \alpha$ holds between two maps $\alpha, \bar{\alpha}: [a, b] \rightarrow \text{SO}(3)$. According to Theorem I.10-18, this is the case if and only if $\alpha^*(\omega) = \bar{\alpha}^*(\omega)$ for every left invariant 1-form ω on $\text{SO}(3)$. So κ and τ must have something to do with these left invariant 1-forms on $\text{SO}(3)$. In order to see what is going on here, we begin with a review of some facts about Lie groups.

In Chapter I.10 we defined the natural \mathfrak{g} -valued 1-form ω on a Lie group G by $\omega(a)(\tilde{X}(a)) = X$, where \tilde{X} is the left invariant vector field with $\tilde{X}(e) = X$. Thus ω is the unique left invariant \mathfrak{g} -valued 1-form such that $\omega(e): G_e \rightarrow \mathfrak{g} = G_e$ is the identity. If X_1, \dots, X_n is a basis of \mathfrak{g} , then we can write

$$\omega = \sum_{i=1}^n \omega^i \cdot X_i$$

for certain ordinary left invariant 1-forms ω^i . This equation means that for any tangent vector $Y_a \in G_a$ we have

$$\omega(a)(Y_a) = \sum_{i=1}^n \omega^i(Y_a) \cdot X_i \in \mathfrak{g},$$

the dot denoting multiplication of $X_i \in \mathfrak{g}$ by the real number $\omega^i(a)(Y_a)$. Clearly the ω^i are a basis for the left invariant 1-forms; in fact, the $\omega^i(e)$ are the dual basis to X_1, \dots, X_n . So the natural \mathfrak{g} -valued 1-form ω has all the left invariant 1-forms built into it.

Now for Lie groups G which are subgroups of some $GL(n, \mathbb{R})$ we have an explicit way of finding ω , and hence a basis of left invariant 1-forms. Let P (for “point”) denote the inclusion map of $G \subset GL(n, \mathbb{R}) \subset \mathbb{R}^{n^2}$ into \mathbb{R}^{n^2} . Then $P: G \rightarrow \mathbb{R}^{n^2}$ is an \mathbb{R}^{n^2} -valued function on G . Hence dP is an \mathbb{R}^{n^2} -valued 1-form on G . We can also think of dP as a matrix of ordinary 1-forms on G . This matrix is just

$$dP = (dx^{ij}),$$

except that dx^{ij} here denotes the differential of $x^{ij}|_G$. Notice that dP takes a tangent vector in G_I , i.e., an $n \times n$ matrix M , into itself, so dP corresponds to the identity map of G_I into itself. For any $A \in G$, the map $P \circ L_A: G \rightarrow \mathbb{R}^{n^2}$ is

$$P \circ L_A(B) = A \cdot B,$$

from which it is easy to see that

$$(1) \quad d(P \circ L_A) = A \cdot dP.$$

On G we also have the C^∞ function $B \mapsto B^{-1}$, which we will denote (somewhat confusingly, perhaps) by P^{-1} . For $A \in G$ the map $P^{-1} \circ L_A: G \rightarrow \mathbb{R}^{n^2}$ is

$$(2) \quad P^{-1} \circ L_A(B) = (A \cdot B)^{-1} = B^{-1} \cdot A^{-1} = (P^{-1} \cdot A^{-1})(B).$$

Finally, $P^{-1} \cdot dP$ is a matrix of 1-forms (or an \mathbb{R}^{n^2} -valued 1-form). From (1) and (2) we have

$$\begin{aligned} L_A^*(P^{-1} \cdot dP) &= (P^{-1} \circ L_A) \cdot L_A^*(dP) \\ &= (P^{-1} \circ L_A) \cdot d(L_A^*P) \\ &= (P^{-1} \circ L_A) \cdot d(P \circ L_A) \\ &= (P^{-1} \cdot A^{-1}) \cdot A \cdot dP \\ &= P^{-1} \cdot dP, \end{aligned}$$

so $P^{-1} \cdot dP$ is left invariant. Moreover, for any $M \in G_I$ we have

$$P^{-1} \cdot dP(I)(M) = I^{-1} \cdot dP(I)(M) = M.$$

Hence $P^{-1} \cdot dP$ is the natural \mathfrak{g} -valued 1-form ω on G .

These considerations allow us to determine ω , but it must be remembered that, unless $G = \text{GL}(n, \mathbb{R})$, the forms dx^{ij} are not linearly independent on G . Problem I.10-24 determines ω for $G = \text{GL}(n, \mathbb{R})$, and I.10-23 determines ω for the group $G \subset \text{GL}(2, \mathbb{R})$ consisting of all matrices

$$\begin{pmatrix} a & b \\ 0 & 1 \end{pmatrix} \quad a \neq 0;$$

for this group, x^{11} and x^{12} can be taken as a coordinate system, and ω can be expressed in terms of x^{11} and x^{12} . The more general situation is illustrated by Problem I.10-25, which we shall repeat here. The **special linear group** $\text{SL}(n, \mathbb{R}) \subset \text{GL}(n, \mathbb{R})$ is the set of all matrices of determinant 1. Its Lie algebra, $\mathfrak{sl}(n, \mathbb{R})$, consists of all matrices with trace 0. We can prove this from the fact that

$$\det \exp M = e^{\text{trace } M},$$

in the same way that we found $\mathfrak{o}(n)$; the formula just given is proved in Problem I.10-15. Now we see that, if $x^{11}, x^{12}, x^{21}, x^{22}$ are denoted by x, y, u, v , then for $\text{SL}(2, \mathbb{R})$ we have

$$P^{-1} \cdot dP = \begin{pmatrix} v & -y \\ -u & x \end{pmatrix} \cdot \begin{pmatrix} dx & dy \\ du & dv \end{pmatrix} = \begin{pmatrix} v dx - y du & v dy - y dv \\ -u dx + x du & -u dy + x dv \end{pmatrix}.$$

Remember that x, y, u, v are *not* linearly independent, for the dimension of $\mathfrak{sl}(2, \mathbb{R})$, and hence of $\text{SL}(2, \mathbb{R})$, is clearly 3. In fact, we know that $xv - yu = 1$ on $\text{SL}(2, \mathbb{R})$, which shows that

$$0 = d(xv - yu) = x dv + v dx - y du - u dy$$

on $\text{SL}(2, \mathbb{R})$, i.e., the right side gives 0 when applied to a matrix $M \in \text{SL}(2, \mathbb{R})_A$ for any $A \in \text{SL}(2, \mathbb{R})$. Looking at the formula for $P^{-1} \cdot dP$, this shows that $P^{-1} \cdot dP$ takes such a matrix M to a matrix of trace 0, as it must.

We will now use this circle of ideas to rederive our results about curves, in a more systematic, if less geometric, way. In order to clarify the general nature of the results, we begin once again with curves in the plane, but we now seek the answer to a different classification problem. We already know that if A is a proper Euclidean motion, and $c: [a, b] \rightarrow \mathbb{R}^2$ is any curve, then

- (a) $A \circ c$ is parameterized by arclength whenever c is; we express this fact by saying that arclength is a “natural parameter for curves under the group of proper Euclidean motions”.

- (b) For curves c parameterized by arclength, the curvature function is invariant under proper Euclidean motions, i.e., the function κ for $A \circ c$ equals the function κ for c , whenever A is a proper Euclidean motion. Moreover, the curvature is “a complete set of invariants for curves parameterized by arclength”: if $\bar{\kappa}$ for \bar{c} equals κ for c , then $\bar{c} = A \circ c$ for some proper Euclidean motion A .

We now ask for similar results when A is allowed to be any “special affine motion” [a translation followed by any member of $\text{SL}(2, \mathbb{R})$].

Consider a curve $c: [a, b] \rightarrow \mathbb{R}^2$ for which c' and c'' are always linearly independent. Then $\det(c', c'') \neq 0$ at all points. For simplicity we will assume that $\det(c', c'') > 0$, to avoid writing absolute value signs in various formulas. Our first task is to determine a curve $\alpha_c: [a, b] \rightarrow \text{SL}(2, \mathbb{R})$ analogous to the curve $(\mathbf{t}, \mathbf{n}): [a, b] \rightarrow \text{SO}(2)$. Remember that \mathbf{t} is just c' when c is parameterized by arclength, while \mathbf{n} is basically just chosen so that we will have $(\mathbf{t}, \mathbf{n}) \in \text{SO}(2)$.

For the case of the larger group $\text{SL}(2, \mathbb{R})$ the choice of α_c should be easier. In fact, the choice

$$\alpha_c(t) = (c'(t), c''(t))$$

will work if $\det(c'(t), c''(t)) = 1$. So we ask if there is a reparameterization of c with this property. In other words, is there a function

$$\sigma: [a, b] \rightarrow [0, \ell]$$

such that the reparameterization $\gamma = c \circ \sigma^{-1}$ satisfies

$$\det(\gamma', \gamma'') = 1.$$

Since

$$\begin{aligned} c &= \gamma \circ \sigma \\ c' &= \sigma' \cdot (\gamma' \circ \sigma) \\ c'' &= (\sigma')^2 \cdot (\gamma'' \circ \sigma) + \sigma'' \cdot (\gamma' \circ \sigma), \end{aligned}$$

and thus

$$\begin{aligned} \det(c', c'') &= \det(\sigma' \cdot (\gamma' \circ \sigma), (\sigma')^2 \cdot (\gamma'' \circ \sigma) + \sigma'' \cdot (\gamma' \circ \sigma)) \\ &= (\sigma')^3 \det(\gamma' \circ \sigma, \gamma'' \circ \sigma), \end{aligned}$$

we want

$$\det(c', c'') = (\sigma')^3.$$

We can thus define σ , the “special affine arclength” by

$$\sigma(t) = \int_a^t \sqrt[3]{\det(c'(u), c''(u))} \, du.$$

When c satisfies $\det(c', c'') = 1$, we say that c is “parameterized by special affine arclength”, and the special affine arclength is a natural parameter for curves under the group of special affine motions.

Now consider two curves c, \bar{c} parameterized by special affine arclength. We will have $\bar{c} = A \circ c$ for some special affine motion $A = B \circ \tau$, where $B \in \text{SL}(2, \mathbb{R})$ and τ is a translation, precisely when

$$\alpha_{\bar{c}}(t) = B \cdot \alpha_c(t), \quad \alpha_{\bar{c}} = L_B \circ \alpha_c.$$

By Theorem I.10-18, this is equivalent to the condition

$$\alpha_{\bar{c}}^*(\omega^i) = \alpha_c^*(\omega^i)$$

for every left invariant 1-form ω^i on $\text{SL}(2, \mathbb{R})$, and thus to the condition

$$\alpha_{\bar{c}}^*(\omega) = \alpha_c^*(\omega)$$

for the natural $\mathfrak{sl}(2, \mathbb{R})$ -valued form $\omega = P^{-1} \cdot dP$ on $\text{SL}(2, \mathbb{R})$.

We are thus interested in calculating $\alpha_c^*(P^{-1} \cdot dP)$, which will be a matrix of 1-forms on $[a, b]$

$$\begin{pmatrix} \text{---} dt & \text{---} dt \\ \text{---} dt & \text{---} dt \end{pmatrix};$$

for simplicity we will write all the dt 's after the matrix.

To calculate $\alpha_c^*(P^{-1} \cdot dP)$ we can either use our formula for $P^{-1} \cdot dP$ and write

$$\begin{aligned} \alpha_c^*(P^{-1} \cdot dP) &= \alpha_c^* \begin{pmatrix} v dx - y du & v dy - y dv \\ -u dx + x du & -u dy + x dv \end{pmatrix} \\ &= \begin{pmatrix} v \circ \alpha_c d(x \circ \alpha_c) - \cdots & \cdots \\ \cdots & \cdots \end{pmatrix} \end{aligned}$$

or, what amounts to the same thing, calculate

$$\alpha_c^*(P^{-1} \cdot dP) = \alpha_c^{-1} \cdot d\alpha_c,$$

the entries of which are dt times

$$[\alpha_c(t)]^{-1} \cdot \alpha_c'(t).$$

We have

$$\alpha_c' = \begin{pmatrix} c_1'' & c_1''' \\ c_2'' & c_2''' \end{pmatrix},$$

and using Kramer's rule, together with the fact that $1 = \det \alpha_c = \det(c', c'')$, we find that

$$\alpha_c^{-1} = \begin{pmatrix} c_2'' & -c_1'' \\ -c_2' & c_1' \end{pmatrix}.$$

So

$$\alpha_c^{-1} \cdot \alpha_c' = \begin{pmatrix} c_2'' & -c_1'' \\ -c_2' & c_1' \end{pmatrix} \cdot \begin{pmatrix} c_1'' & c_1''' \\ c_2'' & c_2''' \end{pmatrix}.$$

Since

$$1 = \det(c', c'') = c_1' c_2'' - c_2' c_1'',$$

and thus also

$$0 = c_1' c_2''' - c_2' c_1''',$$

we obtain finally

$$\alpha_c^{-1} \cdot \alpha_c' = \begin{pmatrix} 0 & c_2'' c_1''' - c_1'' c_2''' \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & -\det(c'', c''') \\ 1 & 0 \end{pmatrix}.$$

Thus, curves parameterized by special affine arclength are determined, up to a special affine motion, by one function, the “special affine curvature”

$$\kappa = \det(c'', c''').$$

It is also possible to give a geometric interpretation of the curvature κ , which we only briefly indicate. We first note that a curve c , parameterized by σ , with constant curvature κ satisfies

$$\begin{aligned} [\alpha_c(\sigma)]^{-1} \cdot \alpha_c'(\sigma) &= \begin{pmatrix} 0 & -\kappa \\ 1 & 0 \end{pmatrix} \\ \alpha_c'(\sigma) &= \alpha_c(\sigma) \cdot \begin{pmatrix} 0 & -\kappa \\ 1 & 0 \end{pmatrix}. \end{aligned}$$

One solution of this matrix differential equation is

$$\alpha_c(\sigma) = \exp \left\{ \sigma \cdot \begin{pmatrix} 0 & -\kappa \\ 1 & 0 \end{pmatrix} \right\},$$

that is,

$$\begin{aligned}\alpha_c(\sigma) &= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \sigma \begin{pmatrix} 0 & -\kappa \\ 1 & 0 \end{pmatrix} + \frac{\sigma^2}{2!} \begin{pmatrix} -\kappa & 0 \\ 0 & -\kappa \end{pmatrix} + \frac{\sigma^3}{3!} \begin{pmatrix} 0 & -\kappa^2 \\ \kappa & 0 \end{pmatrix} \\ &\quad + \frac{\sigma^4}{4!} \begin{pmatrix} \kappa^2 & 0 \\ 0 & \kappa^2 \end{pmatrix} + \cdots \\ &= \begin{pmatrix} \cos \sqrt{\kappa} \sigma & -\sqrt{\kappa} \sin \sqrt{\kappa} \sigma \\ \sqrt{\kappa} \sin \sqrt{\kappa} \sigma & \cos \sqrt{\kappa} \sigma \end{pmatrix}\end{aligned}$$

for $\kappa > 0$, with a similar result involving hyperbolic trigonometric functions for $\kappa < 0$. For $\kappa = 0$ we simply have

$$\alpha_c(\sigma) = \begin{pmatrix} 1 & 0 \\ \sigma & 1 \end{pmatrix}.$$

The first column of these solutions give

$\kappa = 0$:

$$c'(\sigma) = (1, \sigma)$$

$$c(\sigma) = \text{constant} + (\sigma, \sigma^2/2), \text{ a parabola}$$

$\kappa > 0$:

$$c'(\sigma) = (\cos \sqrt{\kappa} \sigma, \sqrt{\kappa} \sin \sqrt{\kappa} \sigma)$$

$$c(\sigma) = \text{constant} + (1/\sqrt{\kappa} \sin \sqrt{\kappa} \sigma, -1/\kappa \cos \sqrt{\kappa} \sigma), \text{ an ellipse}$$

$\kappa < 0$:

$c(\sigma) = \text{constant} + (\sqrt{|\kappa|} \cosh \sqrt{|\kappa|}\sigma, 1/|\kappa| \sinh \sqrt{|\kappa|}\sigma)$, a hyperbola

All other solutions $\alpha_c: \mathbb{R} \rightarrow \text{SL}(2, \mathbb{R})$ are special linear transformations times these, and hence are still conic sections.

Now it turns out that as $\sigma_1, \sigma_2, \sigma_3 \rightarrow \sigma$, the parabola through $c(\sigma_1), c(\sigma_2), c(\sigma_3)$ approaches a given parabola, the **osculating parabola**, whose axis lies in the direction of $c''(s)$. And as $\sigma_1, \sigma_2, \sigma_3, \sigma_4 \rightarrow \sigma$, the conic through the four points $c(\sigma_i)$ approaches a given conic, the **hyperosculating conic**, whose curvature κ is that of c at s . However, we will not prove these facts.

We can now return to curves in space, and apply these ideas to classify curves under the group of proper Euclidean motions. With each curve $c: [a, b] \rightarrow \mathbb{R}^3$ we want to associate a curve $\alpha_c: [a, b] \rightarrow \text{SO}(3)$. Assuming $\det(c', c'', c''') > 0$, the obvious choice is to let $\alpha_c(t)$ be the result of applying the Gram-Schmidt orthonormalization process to these three vectors. Introducing the parameterization by (ordinary) arclength, this means that

$$\alpha_c(s) = \left(c'(s), \frac{c''(s)}{|c''(s)|}, c'(s) \times \frac{c''(s)}{|c''(s)|} \right).$$

We now have

$$\alpha_c'(s) = \alpha_c(s) \cdot \begin{pmatrix} 0 & -k(s) & 0 \\ k(s) & 0 & -t(s) \\ 0 & t(s) & 0 \end{pmatrix};$$

the 0 in position (3, 1) comes about because we chose $c', c''/|c''|$ as the first two columns of α_c , while all other features of the matrix are accounted for by the fact that $\alpha_c^{-1} \cdot \alpha_c' = \alpha_c^*(P^{-1} \cdot dP)$ is skew-symmetric, since $\alpha_c: [a, b] \rightarrow \text{SO}(3)$.

Clearly, curves parameterized by arclength are determined up to proper Euclidean motions by k and t , and these functions are obviously just our old κ and τ . If we had bothered to compute $\alpha_c^{-1} \cdot \alpha_{c'}$ for the original curve, not parameterized by arclength, then the entries in positions (2, 1) and (3, 2) would have given us the formulas for κ and τ , derived earlier, for curves with an arbitrary parameterization.

We can classify curves $c: [a, b] \rightarrow \mathbb{R}^n$ under the group of proper Euclidean motions in a similar way. We assume first of all that $\det(c', \dots, c^{(n)}) > 0$. To obtain a curve $\alpha_c: [a, b] \rightarrow \text{SO}(n)$, we first introduce the parameterization by arclength. The first two columns $\mathbf{v}_1, \mathbf{v}_2$ of α_c will be $c', c''/|c''|$. So the first column of $\alpha_c^{-1} \cdot \alpha_{c'}$, which expresses \mathbf{v}_1' in terms of the \mathbf{v}_j , will be

$$\begin{pmatrix} 0 \\ k_1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}$$

for $k_1 = 1/|c''|$. Using skew-symmetry, $\alpha_c^{-1} \cdot \alpha_{c'}$ looks like

$$\alpha_c^{-1} \cdot \alpha_{c'} = \begin{pmatrix} 0 & -k_1 & 0 & \dots & 0 \\ k_1 & 0 & & \times & \\ 0 & & 0 & \times & \\ \vdots & \times & & \ddots & \\ 0 & \times & & & 0 \end{pmatrix}.$$

Since \mathbf{v}_3 , the third column of α_c , is obtained by applying the Gram-Schmidt orthonormalization process to $\mathbf{v}_1, \mathbf{v}_2, c'''$, it is clear that \mathbf{v}_2' will be a linear combination of \mathbf{v}_1 and \mathbf{v}_3 . So the second column of $\alpha_c^{-1} \cdot \alpha_{c'}$ will be

$$\begin{pmatrix} -k_1 \\ 0 \\ k_2 \\ 0 \\ \vdots \\ 0 \end{pmatrix},$$

for some function k_2 . Thus $\alpha_c^{-1} \cdot \alpha_c'$ looks like

$$\alpha_c^{-1} \cdot \alpha_c' = \begin{pmatrix} 0 & -k_1 & 0 & \dots & 0 \\ k_1 & 0 & -k_2 & \dots & 0 \\ 0 & k_2 & 0 & & \times \\ \vdots & & \times & \ddots & \times \\ 0 & & & & 0 \end{pmatrix}.$$

Continuing in this way, we find that

$$\alpha_c^{-1} \cdot \alpha_c' = \begin{pmatrix} 0 & -k_1 & & 0 \\ k_1 & 0 & -k_2 & \\ & k_2 & 0 & \\ & 0 & & \ddots & -k_{n-1} \\ & 0 & & k_{n-1} & 0 \end{pmatrix}$$

for $n - 1$ different “curvature functions” k_1, \dots, k_{n-1} . These $n - 1$ functions classify c up to proper Euclidean motion.

For this classification of curves in \mathbb{R}^n we have had to restrict our attention to curves with $c', \dots, c^{(n)}$ everywhere linearly independent. If we have a curve c such that $c^{(k)}$ is linearly dependent on $c', \dots, c^{(k-1)}$ along a whole interval $[a, b]$, then it is easy to see that on this interval c lies in some $(k - 1)$ -dimensional subspace of \mathbb{R}^n , so that we actually have an easier classification problem on this interval.

The difficulties arise when we try to piece together the information we obtain for the separate intervals, or if $c^{(k)}$ is linearly dependent on $c', \dots, c^{(k-1)}$ at only isolated points (or at some sequence of points, etc.). For example, how can we hope to distinguish between the curve

$$c(t) = \begin{cases} 0 & t = 0 \\ (t, e^{-1/t^2}, 0) & t > 0 \\ (t, 0, e^{-1/t^2}) & t < 0 \end{cases}$$

and the curve

$$c(t) = \begin{cases} 0 & t = 0 \\ (t, 0, e^{-1/t^2}) & t \neq 0 \end{cases}$$

using functions like curvature and torsion? Of course, for analytic curves these difficulties cannot arise. If any small portion of one analytic curve differs by a proper Euclidean motion from a small portion of a second, then the two analytic curves themselves differ by this proper Euclidean motion. But for C^∞ curves, our restrictions are natural ones to make.

Finally, we will use these ideas to classify curves $c: [a, b] \rightarrow \mathbb{R}^n$ under the group of special affine motions of \mathbb{R}^n . We claim first that there is always a function $\sigma: [a, b] \rightarrow [0, l]$ such that the reparameterization $\gamma = c \circ \sigma^{-1}$ satisfies

$$\det(\gamma', \gamma'', \dots, \gamma^{(n)}) = 1.$$

In fact, since

$$\begin{aligned} c &= \gamma \circ \sigma \\ c' &= \sigma' \cdot (\gamma' \circ \sigma) \\ c'' &= (\sigma')^2 \cdot (\gamma'' \circ \sigma) + () \cdot \gamma' \circ \sigma \\ c''' &= (\sigma')^3 \cdot (\gamma''' \circ \sigma) + () \cdot \gamma'' \circ \sigma + () \cdot \gamma' \circ \sigma \\ &\vdots \end{aligned}$$

we clearly need

$$\det(c', \dots, c^{(n)}) = \sigma' \cdot (\sigma')^2 \cdots (\sigma')^n = (\sigma')^{n(n+1)/2},$$

so we define the “special affine arclength” σ in \mathbb{R}^n by

$$\sigma(t) = \int_a^t \sqrt[n(n+1)/2]{\det(c', \dots, c^{(n)})}.$$

Now if we consider only curves $c: [a, b] \rightarrow \mathbb{R}^n$ with $\det(c', \dots, c^{(n)}) = 1$, then we can define $\alpha_c: [a, b] \rightarrow \text{SL}(n, \mathbb{R})$ by

$$\alpha_c = (c', \dots, c^{(n)}),$$

where each $c^{(i)}$ is considered as a column vector. Solving the equation

$$\alpha_c' = \alpha_c \cdot a,$$

we see that the first column of a must be

$$\begin{pmatrix} 0 \\ 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix},$$

the second must be

$$\begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix},$$

and so forth. The last column is arbitrary, except that the matrix a must have trace 0, so $\alpha_c^{-1} \cdot \alpha_c'$ must be of the form

$$\alpha_c^{-1} \cdot \alpha_c' = \begin{pmatrix} 0 & 0 & \dots & -\kappa_1 \\ 1 & 0 & & -\kappa_2 \\ 0 & 1 & & \vdots \\ \vdots & \vdots & & -\kappa_{n-1} \\ 0 & 0 & \dots & 1 & 0 \end{pmatrix}$$

for $n - 1$ “special affine curvature functions” $\kappa_1, \dots, \kappa_{n-1}$; they determine a curve, parameterized by affine arclength, up to special linear affine maps of \mathbb{R}^n .

The special affine arclength σ in \mathbb{R}^n can be introduced only when

$$\det(c', \dots, c^{(n)}) \neq 0.$$

If along some interval the k vectors $c', \dots, c^{(k)}$ are linearly independent, while the vectors $c', \dots, c^{(k)}, c^{(k+1)}$ are linearly *dependent*, then it is easy to see that along this interval the curve c actually lies in some k -dimensional plane in \mathbb{R}^n , and we can therefore introduce the special affine arclength for \mathbb{R}^k along this interval.

The theory runs into troubles when there are isolated points at which

$$\det(c', \dots, c^{(n)}) = 0.$$

In this respect it is similar to the ordinary theory of curves, but the situation is still different, because in the special affine case the function σ which we choose as the special affine arclength will actually depend on the number k for which $c', \dots, c^{(k)}$ are linearly independent—for curves in higher dimensional Euclidean spaces the special affine arclength involves more derivatives. The special affine curvature functions $\kappa_1, \kappa_2, \kappa_3, \dots$ also involve higher derivatives than the corresponding curvature functions $\kappa_1, \kappa_2, \kappa_3, \dots$. This is just what we ought to expect—since the group $\mathrm{SL}(n, \mathbb{R})$ is bigger than $\mathrm{SO}(n)$, we have to build more complicated things from our curve c before we can find something which is invariant under $\mathrm{SL}(n, \mathbb{R})$.

CHAPTER 2

WHAT THEY KNEW ABOUT SURFACES BEFORE GAUSS

Having traversed nearly the whole history of the study of curves, in one chapter, we now turn back to the beginnings of surface theory, and start the long journey toward the modern theory of higher dimensional manifolds. Even though the study of surfaces had begun long before the Serret-Frenet formulas appeared in 1847, the theory of plane curves, at least, was well understood.

The initial study of surfaces in \mathbb{R}^3 began in a way that seems natural enough. Since we have a theory of curves in the plane, we may hope to describe surfaces by investigating the curves in which the surface intersects various planes. Indeed it turns out that we can describe the curvature of such curves in a surprisingly nice and precise way.

The first results along this line, due to Euler, date from 1760. Through a point p on a surface $M \subset \mathbb{R}^3$ we construct the line l which is perpendicular to M_p . For each unit vector $X \in M_p$ we can then consider the plane through p

which contains both X and l . The intersection of this plane and M is the image of a curve c_X with $c_X(0) = p$; we will also suppose c parameterized by arclength, so that $c_X'(0) = X$. We orient all these planes through l by choosing a vector v_p perpendicular to M_p and orienting the plane through X and l so that X, v_p is positively oriented. Then c_X has a signed curvature at 0, which will be denoted by κ_X .

When we replace X by $-X$, the curve c_{-X} is just c_X traversed in the opposite direction. Since the plane through X and v_p now receives the opposite orientation, the curvature κ_{-X} equals the curvature κ_X . Thus, $X \mapsto \kappa_X$ may be thought of as a function of directions in M_p . Euler discovered a striking fact about the curvatures in these different directions:

1. THEOREM (EULER). If the κ_X are not all equal, then there is precisely one direction, represented by a unit vector X_1 , say, in which κ_X has a minimum value $k_1 = \kappa_{X_1}$, and one in which it has a maximum value $k_2 = \kappa_{X_2}$. These two directions are *perpendicular*, and if X makes an angle of θ with X_1 , then

$$\kappa_X = k_1 \cos^2 \theta + k_2 \sin^2 \theta.$$

(Notice that we can just as well write $\kappa_X = k_2 \cos^2 \phi + k_1 \sin^2 \phi$, where ϕ is the angle which X makes with X_2 , since $\phi = \pi/2 - \theta$, and consequently $\cos^2 \theta = \sin^2 \phi$ and $\sin^2 \theta = \cos^2 \phi$. There is also a certain ambiguity in the statement of Euler's theorem which does not affect the final result: If we change the vector v_p so that it points in the opposite direction, then *all* curvatures κ_X are changed to their negatives.)

I do not know Euler's proof of his theorem, and for reasons that will appear later, I am sure that the proof to be presented here is much simpler than the original. Nevertheless, it is sufficiently classical in spirit to serve as an historical substitute for Euler's.

PROOF. We begin by choosing our coordinate system so that $p = (0, 0, 0)$ and so that the tangent plane at p is the (x, y) -plane, which means that in a neighborhood of p the surface M is $\{(x, y, z) : z = f(x, y)\}$, where

$$f(0, 0) = 0$$

$$\frac{\partial f}{\partial x}(0, 0) = 0$$

$$\frac{\partial f}{\partial y}(0, 0) = 0.$$

We now maintain that by rotating the (x, y) -plane we can arrange to have

$$\frac{\partial^2 f}{\partial x \partial y}(0, 0) = 0.$$

To see this, we first recall that rotation through an angle of θ radians is the linear transformation R_θ with matrix $\begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}$. If we rotate the (x, y) -plane by an angle of θ , then M becomes the graph of

$$\begin{aligned} f_\theta &= f \circ R_{-\theta}, \\ f_\theta(x, y) &= f(x \cos \theta - y \sin \theta, x \sin \theta + y \cos \theta). \end{aligned}$$

So

$$\frac{\partial f_\theta}{\partial y}(x, y) = D_1 f(x, y)(-\sin \theta) + D_2 f(x, y)(\cos \theta)$$

$$\begin{aligned} \frac{\partial^2 f_\theta}{\partial x \partial y}(x, y) &= D_{11} f(x, y)(-\sin \theta \cos \theta) + D_{12} f(x, y)[-\sin^2 \theta + \cos^2 \theta] \\ &\quad + D_{22} f(x, y)(\sin \theta \cos \theta) \end{aligned}$$

$$\frac{\partial^2 f_\theta}{\partial x \partial y}(0, 0) = (\cos 2\theta) D_{12} f(0, 0) + \frac{D_{22} f(0, 0) - D_{11} f(0, 0)}{2} \sin 2\theta.$$

In order to have $\partial^2 f_\theta / \partial x \partial y(0, 0) = 0$, we just choose θ so that

$$\begin{aligned} \tan 2\theta &= \frac{2D_{12} f(0, 0)}{D_{11} f(0, 0) - D_{22} f(0, 0)} && \text{if } D_{11} f(0, 0) \neq D_{22} f(0, 0) \\ \theta &= \pi/4 && \text{if } D_{11} f(0, 0) = D_{22} f(0, 0). \end{aligned}$$

Having made this choice of coordinates, we now look at the various planes containing l , i.e., containing the z -axis. First, the (x, z) -plane intersects the surface in the curve

$$c(t) = (t, f(t, 0)).$$

Its curvature at 0 is therefore

$$k_1 = \frac{\dot{c}_1 \ddot{c}_2 - \dot{c}_2 \ddot{c}_1}{(\dot{c}_1^2 + \dot{c}_2^2)^{3/2}} = \frac{\partial^2 f}{\partial x^2}(0, 0).$$

This result holds when we give the (x, z) -plane its usual orientation, which is the same as the orientation making $(e_1)_p, v_p$ positively oriented when we choose v_p to be $(e_3)_p$. Similarly, the (y, z) -plane intersects the surface in the curve $c(t) = (0, t, f(0, t))$ with curvature

$$k_2 = \frac{\partial^2 f}{\partial y^2}(0, 0).$$

Finally, the plane through the z -axis which makes an angle of θ with the x -axis intersects the surface in the curve

$$c(t) = (t, f(t \cos \theta, t \sin \theta)),$$

with curvature

$$\begin{aligned}\kappa &= \frac{d^2}{dt^2} f(t \cos \theta, t \sin \theta) = \cos^2 \theta \frac{\partial^2 f}{\partial x^2}(0, 0) + \sin^2 \theta \frac{\partial^2 f}{\partial y^2}(0, 0) \\ &= k_1 \cos^2 \theta + k_2 \sin^2 \theta.\end{aligned}$$

This formula shows that κ always lies between k_1 and k_2 , the curvatures in two perpendicular directions, and thus proves the whole theorem. ♦

Notice that if $\partial^2 f / \partial x^2, \partial^2 f / \partial y^2 > 0$, so that the surface lies above the (x, y) -plane near p , then our choice of v_p makes $k_1, k_2 > 0$. In general, if a surface locally lies on one side of its tangent plane through p , then the choice of v_p as a vector pointing toward this side makes $k_1, k_2 > 0$. If our surface is the boundary of a convex set in \mathbb{R}^3 , we must therefore choose the *inward* pointing normal to obtain positive curvatures. If k_1 and k_2 are of different signs, there

is generally no such way to distinguish a direction for v_p .

The other main result about curves on surfaces, due to Meusnier, came shortly afterwards, in 1776. Meusnier completed Euler's investigations by finding the curvatures of the curves obtained by intersecting the surface M with *any* plane through $p \in M$. If P is the plane through p which contains l and a unit vector $X \in M_p$, then any other plane P_ϕ which contains X can be described by giving the angle ϕ which it makes with P . Let c be the intersection of P and M , with

$c(0) = p$ and c parameterized by arclength, so that $c'(0) = X$, and let c_ϕ be the corresponding intersection of P_ϕ and M . Meusnier's theorem describes the curvature κ_ϕ of c_ϕ at 0 in terms of the curvature κ_X of c at 0:

$$\kappa_\phi \cdot \cos \phi = \kappa_X.$$

For the case of the unit sphere, pictured above, the curve c is a great circle, of radius 1, while c_ϕ is a circle of radius $\cos \phi$, so that $\kappa_\phi = 1/\cos \phi$. Naturally, in Meusnier's theorem we must restrict ϕ to be less than $\pi/2$. At this angle, the plane P_ϕ is just the tangent plane, and does not generally intersect M in a curve at all; for ϕ close to $\pi/2$, the plane P_ϕ intersects M in a curve of very large curvature (if $\kappa_X \neq 0$).

For Meusnier's theorem we supply a proof which is decidedly non-classical in spirit, but which will be useful to have later on. We first define a function v in a neighborhood $U \subset M$ of p such that $v(q) \in \mathbb{R}^3$ is a unit vector and $v(q)_q \in \mathbb{R}^3_q$ is perpendicular to M_q for all $q \in U$. There are two choices for each $v(q)$; in order to obtain a continuous function $v: U \rightarrow M$, we orient U , and then pick $v(q)$ so that $v(q), v, w$ is positively oriented for v_q, w_q positively oriented in M_q .

For any curve c in M with $c(0) = p$ we have

$$\langle c'(s), v(c(s)) \rangle = 0 \quad \text{for all } s.$$

Differentiating this equation, we have

$$\langle c''(0), v(p) \rangle = - \left\langle c'(0), \frac{dv(c(s))}{ds} \Big|_{s=0} \right\rangle.$$

Now the vector $dv(c(s))/ds|_{s=0}$, with components $dv^i(c(s))/ds|_{s=0}$, depends only on $c'(0) = X$; in fact, it equals $(X(v^1), X(v^2), X(v^3))$. To see this, just remember that to operate on a function $f: M \rightarrow \mathbb{R}$ with a tangent vector $X_p \in M_p$, we can take any curve c with $c'(0) = X_p$ and then $X_p(f) = df(c(t))/dt|_{t=0}$. We can thus write

$$(*) \quad \langle c''(0), v(p) \rangle = a(X) \quad X = c'(0).$$

Meusnier's theorem follows directly from this equation:

2. THEOREM (MEUSNIER). Let P be the plane through $\nu(p)$ and $X \in M_p$, and let κ_ϕ be the curvature of the curve on M cut out by a plane P_ϕ containing X and making an angle of ϕ with the plane P . Then

$$\kappa_\phi \cdot \cos \phi = \kappa_X.$$

PROOF. First apply (*) to the curve c cut out by P . The second derivative $c''(0)$ of this curve is in P , and is also perpendicular to $c'(0) = X$. Consequently, it is a multiple of $\nu(p)$. Since P has been oriented so that $X, \nu(p)$ is positively oriented, it follows that $c''(0) = \kappa_X \cdot \nu(p)$, so

$$a(X) = \langle c''(0), \nu(p) \rangle = \kappa_X.$$

On the other hand, since $c_\phi'(0) = c'(0) = X$, equation (*) also gives

$$(1) \quad \kappa_X = a(X) = \langle c_\phi''(0), \nu(p) \rangle.$$

We can write $c_\phi''(0) = \kappa_\phi \cdot \nu_\phi$ where ν_ϕ is a unit vector which lies in P_ϕ and is perpendicular to X . Then ν_ϕ makes an angle of ϕ with $\nu(p)$, which means that

$$(2) \quad \langle \nu_\phi, \nu(p) \rangle = \cos \phi.$$

Combining equations (1) and (2), we obtain

$$\begin{aligned} \kappa_X &= \langle c_\phi''(0), \nu(p) \rangle \\ &= \langle \kappa_\phi \cdot \nu_\phi, \nu(p) \rangle \\ &= \kappa_\phi \cdot \cos \phi. \quad \blacklozenge \end{aligned}$$

Despite the appealing simplicity of these results, there is something dissatisfying about this whole approach of dissecting a surface into curves; we never seem to really get our hands on the surface itself. To do this, we must move forward 50 years in time.

CHAPTER 3

THE CURVATURE OF SURFACES IN SPACE

A. HOW TO READ GAUSS

The single most important work in the history of differential geometry is Karl Friedrich Gauss' paper, in Latin, of 1827: *Disquisitiones generales circa superficies curvas*. The following translation of (part of) this paper is basically the one published* by The Princeton University Library, 1902, except that it adheres even more closely to the notation and typographic disposition of the original.

In addition, it has been supplemented with remarks designed to make this first confrontation with classical differential geometry much less painful. The translation of Gauss' paper appears to the right—on odd-numbered pages—while corresponding remarks appear to the left.

Although Part B of this chapter is an exposition of Gauss' results, in modern notation, a preliminary reading of Gauss' great work is heartily recommended; and since many of the difficulties will be clarified in Part B, as a general rule it is a good idea to read on, even if a particular section makes very little sense!

*A reprinting was produced in 1965 by Raven Press, but this is also out of print.

REMARKS ON GAUSS' PAPER

§1. Notice that (1), (2), (3) are used as the names of certain points [(1) = (1, 0, 0), etc.], a circumstance that is easy to forget later on.

§2. This section gives a complicated proof, using spherical trigonometry, that the volume of the pyramid shown below is

$$\frac{1}{6} \left| \det \begin{pmatrix} x & y & z \\ x' & y' & z' \\ x'' & y'' & z'' \end{pmatrix} \right|,$$

and also includes remarks about the significance of the sign of the determinant. This result is equivalent to the well-known fact that $|\det A|$ is the volume of the parallelepiped spanned by the rows of A .

Almost all of this section can simply be skipped, except for noting that the

GENERAL INVESTIGATIONS
OF
CURVED SURFACES

1.

Investigations, in which the directions of various straight lines in space are to be considered, attain a high degree of clearness and simplicity if we employ, as an auxiliary, a sphere of radius = 1 described about an arbitrary center, and suppose the different points of the sphere to represent the directions of straight lines parallel to the radii ending at these points. As the position of every point in space is determined by three coordinates, that is to say, the distances of the point from three mutually perpendicular fixed planes, it is necessary to consider, first of all, the directions of the axes perpendicular to these planes. The points on the sphere, which represent these directions, we shall denote by (1), (2), (3). The distance of any one of these points from either of the other two will be a quadrant; and we shall suppose that the directions of the axes are those in which the corresponding coordinates increase.

2.

It will be advantageous to bring together here some propositions which are frequently used in questions of this kind.

I. The angle between two intersecting straight lines is measured by the arc between the points on the sphere which correspond to the directions of the lines.

II. The orientation of any plane whatever can be represented by the great circle on the sphere, the plane of which is parallel to the given plane.

III. The angle between two planes is equal to the spherical angle between the great circles representing them, and, consequently, is also measured by the arc intercepted between the poles of these great circles. And, in like manner, the angle of inclination of a straight line to a plane is measured by the arc drawn from the point which corresponds to the direction of the line, perpendicular to the great circle which represents the orientation of the plane.

IV. Letting $x, y, z; x', y', z'$ denote the coordinates of two points, r the distance between them, and L the point on the sphere which represents the

expression $\cos (1)L$, which will also appear later on, means the cosine of the angle θ between the ray from $(0,0,0)$ through the point $L = (a,b,c)$ on the

sphere and the ray from $(0,0,0)$ through $(1) = (1,0,0)$. Thus, for the usual inner product $\langle \ , \ \rangle$ on \mathbb{R}^3 we have

$$a = \langle L, (1) \rangle = 1 \cdot 1 \cdot \cos \theta,$$

so $\cos (1)L$ is the first component of L , and similarly for $\cos (2)L$ and $\cos (3)L$. [The original contains $\cos (1)L^2$ instead of $\cos^2 (1)L$, etc., and multiplication is always indicated with a low dot \cdot rather than a centered dot.]

direction of the line drawn from the first point to the second, we shall have

$$x' = x + r \cos (1)L, \quad y' = y + r \cos (2)L, \quad z' = z + r \cos (3)L$$

V. From this it follows at once that, generally,

$$\cos^2 (1)L + \cos^2 (2)L + \cos^2 (3)L = 1$$

and also, if L' denote any other point on the sphere,

$$\cos (1)L \cdot \cos (1)L' + \cos (2)L \cdot \cos (2)L' + \cos (3)L \cdot \cos (3)L' = \cos LL'$$

VI. THEOREM. If L, L', L'', L''' denote four points on the sphere, and A the angle which the arcs $LL', L''L'''$ make at their point of intersection, then we shall have

$$\cos LL'' \cdot \cos L'L''' - \cos LL''' \cdot \cos L'L'' = \sin LL' \cdot \sin L''L''' \cdot \cos A$$

Demonstration. Let A denote also the point of intersection itself, and set

$$AL = t, \quad AL' = t', \quad AL'' = t'', \quad AL''' = t'''$$

Then we shall have

$$\begin{aligned} \cos LL'' &= \cos t \cos t'' + \sin t \sin t'' \cos A \\ \cos L'L''' &= \cos t' \cos t''' + \sin t' \sin t''' \cos A \\ \cos LL''' &= \cos t \cos t''' + \sin t \sin t''' \cos A \\ \cos L'L'' &= \cos t' \cos t'' + \sin t' \sin t'' \cos A \end{aligned}$$

and consequently,

$$\begin{aligned} &\cos LL'' \cdot \cos L'L''' - \cos LL''' \cdot \cos L'L'' \\ &= \cos A (\cos t \cos t'' \sin t' \sin t''' + \cos t' \cos t''' \sin t \sin t'' \\ &\quad - \cos t \cos t''' \sin t' \sin t'' - \cos t' \cos t'' \sin t \sin t''') \\ &= \cos A (\cos t \sin t' - \sin t \cos t') (\cos t'' \sin t''' - \sin t'' \cos t''') \\ &= \cos A \cdot \sin (t' - t) \cdot \sin (t''' - t'') \\ &= \cos A \cdot \sin LL' \cdot \sin L''L''' \end{aligned}$$

But as there are for each great circle two branches going out from the point A , these two branches form at this point two angles whose sum is 180° . But our analysis shows that those branches are to be taken whose directions are in the

sense from the point L to L' , and from the point L'' to L''' ; and since great circles intersect in two points, it is clear that either of the two points can be chosen arbitrarily. Also, instead of the angle A , we can take the arc between the poles of the great circles of which the arcs LL' , $L''L'''$ are parts. But it is evident that those poles are to be chosen which are similarly placed with respect to these arcs; that is to say, when we go from L to L' and from L'' to L''' , both of the two poles are to be on the right, or both on the left.

VII. Let L, L', L'' be three points on the sphere and set, for brevity,

$$\begin{aligned}\cos(1)L &= x, & \cos(2)L &= y, & \cos(3)L &= z \\ \cos(1)L' &= x', & \cos(2)L' &= y', & \cos(3)L' &= z' \\ \cos(1)L'' &= x'', & \cos(2)L'' &= y'', & \cos(3)L'' &= z''\end{aligned}$$

and also

$$xy'z'' + x'y''z + x''yz' - xy''z' - x'y'z'' - x''y'z = \Delta$$

Let λ denote the pole of the great circle of which LL' is a part, this pole being the one that is placed in the same position with respect to this arc as the point (1) is with respect to the arc (2)(3). Then we shall have, by the preceding theorem, $yz' - y'z = \cos(1)\lambda \cdot \sin(2)(3) \cdot \sin LL'$, or, because $(2)(3) = 90^\circ$,

$$\begin{aligned}yz' - y'z &= \cos(1)\lambda \cdot \sin LL', & \text{and similarly} \\ zx' - z'x &= \cos(2)\lambda \cdot \sin LL' \\ xy' - x'y &= \cos(3)\lambda \cdot \sin LL'\end{aligned}$$

Multiplying these equations by x'', y'', z'' respectively, and adding, we obtain, by means of the second of the theorems deduced in V,

$$\Delta = \cos \lambda L'' \cdot \sin LL'$$

Now there are three cases to be distinguished. *First*, when L'' lies on the great circle of which the arc LL' is a part, we shall have $\lambda L'' = 90^\circ$, and consequently, $\Delta = 0$. If L'' does not lie on that great circle, the *second* case will be when L'' is on the same side as λ ; the *third* case when they are on opposite sides. In the last two cases the points L, L', L'' will form a spherical triangle, and in the second case these points will lie in the same order as the points (1), (2), (3), and in the opposite order in the third case. Denoting the angles of this triangle simply by L, L', L'' and the perpendicular drawn on the sphere from the point L'' to the side LL' by p , we shall have

$$\sin p = \sin L \cdot \sin LL'' = \sin L' \cdot \sin L'L'', \quad \text{and} \quad \lambda L'' = 90^\circ \mp p$$

§3. This section merely defines (or tries to define) a differentiable surface, and its tangent plane at a point.

§4. At a point $A = (x, y, z)$ in the surface we have a unit normal vector v_A , and $v \in S^2 \subset \mathbb{R}^3$ is what Gauss calls L . The expression $\cos(1)L$ means the cosine of

the angle between the rays from $(0, 0, 0)$ through L and through $(1) = (1, 0, 0)$ (c.f. page 58). So X, Y, Z are just the components of L . Thus X, Y, Z can be considered as functions on the surface [$X(A) =$ first component of v , for v_A a unit normal at A , etc.].

Gauss now nonchalantly introduces infinitely small quantities. The goal of his

the upper sign being taken for the second case, the lower for the third. From this it follows that

$$\pm\Delta = \sin L \cdot \sin LL' \cdot \sin LL'' = \sin L' \cdot \sin LL' \cdot \sin L'L'' = \sin L'' \cdot \sin LL'' \cdot \sin L'L''$$

Moreover, it is evident that the first case can be regarded as contained in the second or third, and it is easily seen that the expression $\pm\Delta$ represents six times the volume of the pyramid formed by the points L, L', L'' and the center of the sphere. Whence, finally, it is clear that the expression $\pm\frac{1}{6}\Delta$ expresses generally the volume of any pyramid contained between the origin of coordinates and the three points whose coordinates are $x, y, z; x', y', z'; x'', y'', z''$.

3.

A curved surface is said to possess continuous curvature at one of its points A , if the directions of all the straight lines drawn from A to points of the surface at an infinitely small distance from A are deflected infinitely little from one and the same plane passing through A . This plane is said to *touch* the surface at the point A . If this condition is not satisfied for any point, the continuity of the curvature is here interrupted, as happens, for example, at the vertex of a cone. The following investigations will be restricted to such surfaces, or to such parts of surfaces, as have the continuity of their curvature nowhere interrupted. We shall only observe now that the methods used to determine the position of the tangent plane lose their meaning at singular points, in which the continuity of the curvature is interrupted, and must lead to indeterminate solutions.

4.

The orientation of the tangent plane is most conveniently studied by means of the direction of the straight line normal to the plane at the point A , which is also called the normal to the curved surface at the point A . We shall represent the direction of this normal by the point L on the auxiliary sphere, and we shall set

$$\cos(1)L = X, \quad \cos(2)L = Y, \quad \cos(3)L = Z$$

and denote the coordinates of the point A by x, y, z . Also let $x + dx, y + dy, z + dz$ be the coordinates of another point A' on the curved surface; ds its distance from A , which is infinitely small; and finally, let λ be the point on the sphere representing the direction of the element AA' . Then we shall have

$$dx = ds \cdot \cos(1)\lambda, \quad dy = ds \cdot \cos(2)\lambda, \quad dz = ds \cdot \cos(3)\lambda$$

initial manipulations is the equation

$$X dx + Y dy + Z dz = 0.$$

If x, y, z are considered as functions on the surface (that is, as the restriction to the surface of the standard coordinate functions on \mathbb{R}^3), then this equation is literally true, interpreting dx, dy, dz as modern differentials. It should be easy to see this (remember how X, Y, Z are defined). Also try to follow Gauss' argument.

The rest of section 4 gives formulas for X, Y, Z in terms of different descriptions of the surface; in each case the formulas are paired with their negatives, since there are two different choices for the unit normal vector:

(1) If the surface is $\{p \in \mathbb{R}^3 : W(p) = 0\}$, for $W: \mathbb{R}^3 \rightarrow \mathbb{R}$, then

$$X = \frac{P}{\sqrt{P^2 + Q^2 + R^2}}, \quad \text{where } P = D_1 W, Q = D_2 W, R = D_3 W, \text{ etc.}$$

[The original has $XX + YY + ZZ = 1$, and $PP + QQ + RR$ for $P^2 + Q^2 + R^2$, and so forth, with a superscript ² used only for the square of a term that is not a single letter.]

(2) If the surface is the image of $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ [Gauss writes dx for $d(x \circ f) = df^1$, etc.] and

$$\begin{aligned} a &= D_1 f^1, & a' &= D_2 f^1 \\ b &= D_1 f^2, & b' &= D_2 f^2 \\ c &= D_1 f^3, & c' &= D_2 f^3 \end{aligned}$$

and, since λL must be equal to 90° ,

$$X \cos (1)\lambda + Y \cos (2)\lambda + Z \cos (3)\lambda = 0$$

By combining these equations we obtain

$$X dx + Y dy + Z dz = 0$$

There are two general methods for defining the nature of a curved surface. The *first* uses the equation between the coordinates x, y, z , which we may suppose reduced to the form $W = 0$, where W will be a function of the indeterminants x, y, z . Let the complete differential of the function W be

$$dW = P dx + Q dy + R dz$$

and on the curved surface we shall have

$$P dx + Q dy + R dz = 0$$

and consequently,

$$P \cos (1)\lambda + Q \cos (2)\lambda + R \cos (3)\lambda = 0$$

Since this equation, as well as the one we have established above, must be true for the directions of all elements ds on the curved surface, we easily see that X, Y, Z must be proportional to P, Q, R respectively, and consequently, since

$$X^2 + Y^2 + Z^2 = 1$$

we shall have either

$$X = \frac{P}{\sqrt{(P^2 + Q^2 + R^2)}}, \quad Y = \frac{Q}{\sqrt{(P^2 + Q^2 + R^2)}}, \quad Z = \frac{R}{\sqrt{(P^2 + Q^2 + R^2)}}$$

or

$$X = \frac{-P}{\sqrt{(P^2 + Q^2 + R^2)}}, \quad Y = \frac{-Q}{\sqrt{(P^2 + Q^2 + R^2)}}, \quad Z = \frac{-R}{\sqrt{(P^2 + Q^2 + R^2)}}$$

The *second* method expresses the coordinates in the form of functions of two variables, p, q . Suppose that differentiation of these functions gives

$$dx = a dp + a' dq$$

$$dy = b dp + b' dq$$

$$dz = c dp + c' dq$$

then

$$X = \frac{bc' - cb'}{\Delta}, \text{ etc.}$$

(3) If the surface is $\{(x, y, z) : z = f(x, y)\}$ for $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$, then

$$X = \frac{t}{\sqrt{1 + t^2 + u^2}}, \quad \text{where } t = D_1 f, u = D_2 f, \text{ etc.}$$

It should not be hard to work out these results, using our terminology. Again, it is instructive to follow Gauss' derivations as well.

§5. This section talks about orienting the surface, so that one can choose between the two unit normals.

Substituting these values in the formula given above, we obtain

$$(aX + bY + cZ) dp + (a'X + b'Y + c'Z) dq = 0$$

Since this equation must hold independently of the values of the differentials dp , dq , we evidently shall have

$$aX + bY + cZ = 0, \quad a'X + b'Y + c'Z = 0$$

From this we see that X, Y, Z will be proportional to the quantities

$$bc' - cb', \quad ca' - ac', \quad ab' - ba'$$

Hence, on setting, for brevity,

$$\sqrt{((bc' - cb')^2 + (ca' - ac')^2 + (ab' - ba')^2)} = \Delta$$

we shall have either

$$X = \frac{bc' - cb'}{\Delta}, \quad Y = \frac{ca' - ac'}{\Delta}, \quad Z = \frac{ab' - ba'}{\Delta}$$

or

$$X = \frac{cb' - bc'}{\Delta}, \quad Y = \frac{ac' - ca'}{\Delta}, \quad Z = \frac{ba' - ab'}{\Delta}$$

With these two general methods is associated a *third*, in which one of the coordinates, z , say, is expressed in the form of a function of the other two, x, y . This method is evidently only a particular case either of the first method, or of the second. If we set

$$dz = t dx + u dy$$

we shall have either

$$X = \frac{-t}{\sqrt{(1+t^2+u^2)}}, \quad Y = \frac{-u}{\sqrt{(1+t^2+u^2)}}, \quad Z = \frac{1}{\sqrt{(1+t^2+u^2)}}$$

or

$$X = \frac{t}{\sqrt{(1+t^2+u^2)}}, \quad Y = \frac{u}{\sqrt{(1+t^2+u^2)}}, \quad Z = \frac{-1}{\sqrt{(1+t^2+u^2)}}$$

5.

The two solutions found in the preceding article evidently refer to opposite points of the sphere, or to opposite directions, as one would expect, since the

§6. In this section Gauss considers the map ν , from the surface to S^2 , which takes A to the unit vector ν which is normal to the surface at that point. The map ν can be used to take any subset R of the surface to a subset $\nu(R)$ of S^2 . The area of $\nu(R)$ is referred to by Gauss as the *total curvature* of R . Then the

normal may be drawn toward either of the two sides of the curved surface. If we wish to distinguish between the two regions bordering upon the surface, and call one the exterior region and the other the interior region, we can then assign to each of the two normals its appropriate solution by aid of the theorem derived in Art. 2 (VII), and at the same time establish a criterion for distinguishing the one region from the other.

In the first method, such a criterion is to be drawn from the sign of the quantity W . Indeed, generally speaking, the curved surface divides those regions of space in which W keeps a positive value from those in which the value of W becomes negative. In fact, it is easily seen from this theorem that, if W takes a positive value toward the exterior region, and if the normal is supposed to be drawn outwardly, the first solution is to be taken. Moreover, it will be easy to decide in any case whether the same rule for the sign of W is to hold throughout the entire surface, or whether for different parts there will be different rules. As long as the coefficients P, Q, R have finite values and do not all vanish at the same time, the law of continuity will prevent any change.

If we follow the second method, we can imagine two systems of curved lines on the curved surface, one system for which p is variable, q constant; the other for which q is variable, p constant. The respective positions of these lines with reference to the exterior region will decide which of the two solutions must be taken. In fact, whenever the three lines, namely, the branch of the line of the former system going out from the point A as p increases, the branch of the line of the latter system going out from the point A as q increases, and the normal drawn toward the exterior region, are *similarly* placed as the x, y, z axes respectively from the origin of abscissas (e.g., if, both for the former three lines and for the latter three, we can conceive the first directed to the left, the second to the right, and the third upward), the first solution is to be taken. But whenever the relative position of the three lines is opposite to the relative position of the x, y, z axes, the second solution will hold.

In the third method, it is to be seen whether, when z receives a positive increment, x and y remaining constant, the point crosses toward the exterior or the interior region. In the former case, for the normal drawn outward, the first solution holds; in the latter case, the second.

6.

Just as each definite point on the curved surface is made to correspond to a definite point on the sphere, by the direction of the normal to the curved surface which is transferred to the surface of the sphere, so also any line whatever, or any figure whatever, on the latter will be represented by a corresponding line

curvature at a point A in the surface is defined as

$$\frac{\text{total curvature of } R}{\text{area of } R}$$

where R is the “surface element” at A , which is supposed to have infinitely small area. As a first approximation to what Gauss is trying to say, we might define the curvature as

$$\lim \frac{\text{total curvature of } R}{\text{area of } R}$$

where the limit is taken as R approaches the point A . It is not *a priori* so clear whether this limit exists, or if it depends on the way in which R “approaches” A .

Gauss also gives considerable discussion to the sign of the curvature.

or figure on the former. In the comparison of two figures corresponding to one another in this way, one of which will be as the map of the other, two important points are to be considered, one when quantity alone is considered, the other when, disregarding quantitative relations, position alone is considered.

The first of these important points will be the basis of some ideas which it seems judicious to introduce into the theory of curved surfaces. Thus, to each part of a curved surface inclosed within definite limits we assign a *total* or *integral curvature*, which is represented by the area of the figure on the sphere corresponding to it. From this integral curvature must be distinguished the somewhat more specific curvature which we shall call the *measure of curvature*. The latter refers to a *point* of the surface, and shall denote the quotient obtained when the integral curvature of the surface element about a point is divided by the area of the element itself; and hence it denotes the ratio of the infinitely small areas which correspond to one another on the curved surface and on the sphere. The use of these innovations will be abundantly justified, as we hope, by what we shall explain below. As for the terminology, we have thought it especially desirable that all ambiguity be avoided. For this reason we have not thought it advantageous to follow strictly the analogy of the terminology commonly adopted (though not approved by all) in the theory of plane curves, according to which the measure of curvature should be called simply curvature, but the total curvature, the amplitude. But why not be free in the choice of words, provided they are not meaningless and not liable to a misleading interpretation?

The position of a figure on the sphere can be either similar to the position of the corresponding figure on the curved surface, or opposite (inverse). The former is the case when two lines going out on the curved surface from the same point in different, but not opposite directions, are represented on the sphere by lines similarly placed, that is, when the map of the line to the right is also to the right; the latter is the case when the contrary holds. We shall distinguish these two cases by the positive or negative *sign* of the measure of curvature. But evidently this distinction can hold only when on each surface we choose a definite face on which we suppose the figure to lie. On the auxiliary sphere we shall use always the exterior face, that is, that turned away from the center; on the curved surface also there may be taken for the exterior face the one already considered, or rather that face from which the normal is supposed to be drawn. For, evidently, there is no change in regard to the similitude of the figures, if on the curved surface both the figure and the normal be transferred to the opposite side, so long as the image itself is represented on the same side of the sphere.

The positive or negative sign, which we assign to the *measure* of curvature according to the position of the infinitely small figure, we extend also to the

§7. In this section Gauss finds a formula for the curvature k at A . His answer, at the top of page 77, is given for a surface which is the graph of $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$. In this case, the functions X and Y can be thought of as functions on \mathbb{R}^2 (that is, we consider $X \circ f$ and $Y \circ f$), and Gauss' answer is

$$k = \frac{\partial X}{\partial x} \frac{\partial Y}{\partial y} - \frac{\partial X}{\partial y} \frac{\partial Y}{\partial x} \quad [= D_1(X \circ f)D_2(Y \circ f) - D_2(X \circ f)D_1(Y \circ f)].$$

[The notation $\frac{dX}{dx}$, etc., in the original has been preserved. Similarly, a few

integral curvature of a finite figure on the curved surface. However, if we wish to discuss the general case, some explanations will be necessary, which we can only touch here briefly. So long as the figure on the curved surface is such that to *distinct* points on itself there correspond distinct points on the sphere, the definition needs no further explanation. But whenever this condition is not satisfied, it will be necessary to take into account twice or several times certain parts of the figure on the sphere. Whence for a similar, or inverse position, may arise an accumulation of areas, or the areas may partially or wholly destroy each other. In such a case, the simplest way is to suppose the curved surface divided into parts, such that each part, considered separately, satisfies the above condition; to assign to each of the parts its integral curvature, determining this magnitude by the area of the corresponding figure on the sphere, and the sign by the position of this figure; and, finally, to assign to the total figure the integral curvature arising from the addition of the integral curvatures which correspond to the single parts. So, generally, the integral curvature of a figure is equal to $\int k d\sigma$, $d\sigma$ denoting the element of area of the figure, and k the measure of curvature at any point. The principal points concerning the geometric representation of this integral reduce to the following. To the perimeter of the figure on the curved surface (under the restriction of Art. 3) will correspond always a closed line on the sphere. If the latter nowhere intersect itself, it will divide the whole surface of the sphere into two parts, one of which will correspond to the figure on the curved surface; and its area (taken as positive or negative according as, with respect to its perimeter, its position is similar, or inverse, to the position of the figure on the curved surface) will represent the integral curvature of the figure on the curved surface. But whenever this line intersects itself once or several times, it will give a complicated figure, to which, however, it is possible to assign a definite area as legitimately as in the case of a figure without nodes; and this area, properly interpreted, will give always an exact value for the integral curvature. However, we must reserve for another occasion the more extended exposition of the theory of these figures viewed from this very general standpoint.

7.

We shall now find a formula which will express the measure of curvature for any point of a curved surface. Let $d\sigma$ denote the area of an element of this surface; then $Z d\sigma$ will be the area of the projection of this element on the plane of the coordinates x, y ; and consequently, if $d\Sigma$ is the area of the corresponding element on the sphere, $Z d\Sigma$ will be the area of its projection on the same plane. The positive or negative sign of Z will, in fact, indicate that the position of the projection is similar or inverse to that of the projected element. Evidently these

lines later the expressions $\frac{ddz}{dx^2}$ and $\frac{ddz}{dx \cdot dy}$ stand for $\frac{\partial^2 z}{\partial x^2}$ and $\frac{\partial^2 z}{\partial x \partial y}$, etc.]

Gauss obtains this answer by considering an infinitesimal triangle “ $d\sigma$ ” with one vertex at $(x, y, f(x, y))$, one vertex at $(x + dx, y + dy, f(x + dx, y + dy))$, and one at $(x + \delta x, y + \delta y, f(x + \delta x, y + \delta y))$. It is a challenge both to follow Gauss’ reasoning, and to put it in modern terms. Either way, one needs Gauss’ preliminary observation that

$$\frac{\text{area } v(d\sigma)}{\text{area } d\sigma} = \frac{\text{area of projection on } (x, y)\text{-plane of } v(d\sigma)}{\text{area of projection on } (x, y)\text{-plane of } d\sigma}.$$

This mysterious equation really says that the tangent plane of M at A is parallel to the tangent plane of S^2 at $v(A)$. If this hint does not help, simply accept the formula for k , which will be derived later, using modern terminology.

The remainder of section 7 evaluates k in terms of partial derivatives of f (which Gauss denotes by z).

projections have the same ratio as to quantity and the same relation as to position as the elements themselves. Let us consider now a triangular element on the curved surface, and let us suppose that the coordinates of the three points which form its projection are

$$\begin{array}{ll} x, & y \\ x + dx, & y + dy \\ x + \delta x, & y + \delta y \end{array}$$

The double area of this triangle will be expressed by the formula

$$dx \cdot \delta y - dy \cdot \delta x$$

and this will be in a positive or negative form according as the position of the side from the first point to the third, with respect to the side from the first point to the second, is similar or opposite to the position of the y -axis of coordinates with respect to the x -axis of coordinates.

In like manner, if the coordinates of the three points which form the projection of the corresponding element on the sphere, from the center of the sphere as origin, are

$$\begin{array}{ll} X, & Y \\ X + dX, & Y + dY \\ X + \delta X, & Y + \delta Y \end{array}$$

the double area of this projection will be expressed by

$$dX \cdot \delta Y - dY \cdot \delta X$$

and the sign of this expression is determined in the same manner as above. Wherefore the measure of curvature at this point of the curved surface will be

$$k = \frac{dX \cdot \delta Y - dY \cdot \delta X}{dx \cdot \delta y - dy \cdot \delta x}$$

If now we suppose the nature of the curved surface to be defined according to the third method considered in Art. 4, X and Y will be in the form of functions of the quantities x, y . We shall have, therefore,

$$\begin{aligned} dX &= \left(\frac{dX}{dx}\right) dx + \left(\frac{dX}{dy}\right) dy \\ \delta X &= \left(\frac{dX}{dx}\right) \delta x + \left(\frac{dX}{dy}\right) \delta y \\ dY &= \left(\frac{dY}{dx}\right) dx + \left(\frac{dY}{dy}\right) dy \\ \delta Y &= \left(\frac{dY}{dx}\right) \delta x + \left(\frac{dY}{dy}\right) \delta y \end{aligned}$$

When these values have been substituted, the above expression becomes

$$k = \left(\frac{dX}{dx}\right)\left(\frac{dY}{dy}\right) - \left(\frac{dX}{dy}\right)\left(\frac{dY}{dx}\right)$$

Setting, as above,

$$\frac{dz}{dx} = t, \quad \frac{dz}{dy} = u$$

and also

$$\frac{ddz}{dx^2} = T, \quad \frac{ddz}{dx \cdot dy} = U, \quad \frac{ddz}{dy^2} = V$$

or

$$dt = T dx + U dy, \quad du = U dx + V dy$$

we have from the formulæ given above

$$X = -tZ, \quad Y = -uZ, \quad (1 + t^2 + u^2)Z^2 = 1$$

and hence

$$dX = -Z dt - t dZ$$

$$dY = -Z du - u dZ$$

$$(1 + t^2 + u^2) dZ + Z(t dt + u du) = 0$$

or

$$dZ = -Z^3(t dt + u du)$$

$$dX = -Z^3(1 + u^2) dt + Z^3 t u du$$

$$dY = +Z^3 t u dt - Z^3(1 + t^2) du$$

and so

$$\frac{dX}{dx} = Z^3(- (1 + u^2)T + t u U)$$

$$\frac{dX}{dy} = Z^3(- (1 + u^2)U + t u V)$$

$$\frac{dY}{dx} = Z^3(t u T - (1 + t^2)U)$$

$$\frac{dY}{dy} = Z^3(t u U - (1 + t^2)V)$$

Substituting these values in the above expression, it becomes

$$k = Z^6(TV - U^2)(1 + t^2 + u^2) = Z^4(TV - U^2) = \frac{TV - U^2}{(1 + t^2 + u^2)^2}$$

§8. This section, except for the last theorem, was already done in Chapter 2.

8.

By a suitable choice of origin and axes of coordinates, we can easily make the values of the quantities t , u , U vanish for a definite point A . Indeed, the first two conditions will be fulfilled at once if the tangent plane at this point be taken for the xy -plane. If, further, the origin is placed at the point A itself, the expression for the coordinate z evidently takes the form

$$z = \frac{1}{2}T^0x^2 + U^0xy + \frac{1}{2}V^0y^2 + \Omega$$

where Ω will be of higher degree than the second. Turning now the axes of x and y through an angle M such that

$$\tan 2M = \frac{2U^0}{T^0 - V^0}$$

it is easily seen that there must result an equation of the form

$$z = \frac{1}{2}Tx^2 + \frac{1}{2}Vy^2 + \Omega$$

In this way the third condition is also satisfied. When this has been done, it is evident that

I. If the curved surface be cut by a plane passing through the normal itself and through the x -axis, a plane curve will be obtained, the radius of curvature of which at the point A will be $= \frac{1}{T}$, the positive or negative sign indicating that the curve is concave or convex toward that region toward which the coordinates z are positive.

II. In like manner $\frac{1}{V}$ will be the radius of curvature at the point A of the plane curve which is the intersection of the surface and the plane through the y -axis and the z -axis.

III. Setting $x = r \cos \varphi$, $y = r \sin \varphi$, the equation becomes

$$z = \frac{1}{2}(T \cos^2 \varphi + V \sin^2 \varphi)r^2 + \Omega$$

from which we see that if the section is made by a plane through the normal at A and making an angle φ with the x -axis, we shall have a plane curve whose radius of curvature at the point A will

$$= \frac{1}{T \cos^2 \varphi + V \sin^2 \varphi}$$

IV. Therefore, whenever we have $T = V$, the radii of curvature in *all* the normal planes will be equal. But if T and V are not equal, it is evident that, since

§§9, 10, 11. These sections are essentially calculations, involving no new ideas. Every once in a while Gauss calculates a differential instead of some partial derivatives, but this should cause no difficulties.

The goal is the very last, four-line-long, equation at the end of section 11.

for any value whatever of the angle φ , $T \cos^2 \varphi + V \sin^2 \varphi$ falls between T and V , the radii of curvature in the principal sections considered in I and II refer to the extreme curvatures; that is to say, the one to the maximum curvature, the other to the minimum, if T and V have the same sign. On the other hand, one has the greatest convex curvature, the other the greatest concave curvature, if T and V have opposite signs. These conclusions contain almost all that the illustrious EULER was the first to prove on the curvature of curved surfaces.

V. The measure of curvature at the point A on the curved surface takes the very simple form $k = TV$, whence we have the

THEOREM. *The measure of curvature at any point whatever of the surface is equal to a fraction whose numerator is unity, and whose denominator is the product of the two extreme radii of curvature of the sections by normal planes.*

At the same time it is clear that the measure of curvature is positive for concavo-concave or convexo-convex surfaces (which distinction is not essential), but negative for concavo-convex surfaces. If the surface consists of parts of each kind, then on the lines separating the two kinds the measure of curvature ought to vanish. Later we shall make a detailed study of the nature of curved surfaces for which the measure of curvature everywhere vanishes.

9.

The general formula for the measure of curvature given at the end of Art. 7 is the most simple of all, since it involves only five elements. We shall arrive at a more complicated formula, indeed, one involving nine elements, if we wish to use the first method of representing a curved surface. Keeping the notation of Art. 4, let us set also

$$\begin{aligned} \frac{ddW}{dx^2} &= P', & \frac{ddW}{dy^2} &= Q', & \frac{ddW}{dx^2} &= R' \\ \frac{ddW}{dy \cdot dz} &= P'', & \frac{ddW}{dx \cdot dz} &= Q'', & \frac{ddW}{dx \cdot dy} &= R'' \end{aligned}$$

so that

$$\begin{aligned} dP &= P' dx + R'' dy + Q'' dz \\ dQ &= R'' dx + Q' dy + P'' dz \\ dR &= Q'' dx + P'' dy + R' dz \end{aligned}$$

Now since $t = -\frac{P}{R}$, we find through differentiation

$$R^2 dt = -R dP + P dR = (PQ'' - RP') dx + (PP'' - RR'') dy + (PR' - RQ'') dz$$

[As you can probably figure out for yourself, \mathfrak{c} is an alternate form of β .]

or, eliminating dz by means of the equation $P dx + Q dy + R dz = 0$,

$$R^3 dt = (-R^2 P' + 2PRQ'' - P^2 R') dx + (PRP'' + QRQ'' - PQR' - R^2 R'') dy$$

In like manner we obtain

$$R^3 du = (PRP'' + QRQ'' - PQR' - R^2 R'') dx + (-R^2 Q' + 2QRP'' - Q^2 R') dy$$

From this we conclude that

$$\begin{aligned} R^3 T &= -R^2 P' + 2PRQ'' - P^2 R' \\ R^3 U &= PRP'' + QRQ'' - PQR' - R^2 R'' \\ R^3 V &= -R^2 Q' + 2QRP'' - Q^2 R' \end{aligned}$$

Substituting these values in the formula of Art. 7, we obtain for the measure of curvature k the following symmetric expression:

$$\begin{aligned} (P^2 + Q^2 + R^2)^2 k &= P^2(Q'R' - P''^2) + Q^2(P'R' - Q''^2) + R^2(P'Q' - R''^2) \\ &\quad + 2QR(Q''R'' - P'P'') + 2PR(P''R'' - Q'Q'') + 2PQ(P''Q'' - R'R'') \end{aligned}$$

10.

We obtain a still more complicated formula, indeed, one involving fifteen elements, if we follow the second general method of defining the nature of a curved surface. It is, however, very important that we develop this formula also. Retaining the notations of Art. 4, let us put also

$$\begin{aligned} \frac{ddx}{dp^2} &= \alpha, & \frac{ddx}{dp \cdot dq} &= \alpha', & \frac{ddx}{dq^2} &= \alpha'' \\ \frac{ddy}{dp^2} &= \beta, & \frac{ddy}{dp \cdot dq} &= \beta', & \frac{ddy}{dq^2} &= \beta'' \\ \frac{ddz}{dp^2} &= \gamma, & \frac{ddz}{dp \cdot dq} &= \gamma', & \frac{ddz}{dq^2} &= \gamma'' \end{aligned}$$

and let us put, for brevity,

$$\begin{aligned} bc' - cb' &= A \\ ca' - ac' &= B \\ ab' - ba' &= C \end{aligned}$$

First we see that $A \, dx + B \, dy + C \, dz = 0$, or $dz = -\frac{A}{C} \, dx - \frac{B}{C} \, dy$; thus, inasmuch as z may be regarded as a function of x, y , we have

$$\begin{aligned}\frac{dz}{dx} &= t = -\frac{A}{C} \\ \frac{dz}{dy} &= u = -\frac{B}{C}\end{aligned}$$

Then from the formulæ $dx = a \, dp + a' \, dq$, $dy = b \, dp + b' \, dq$, we have

$$\begin{aligned}C \, dp &= b' \, dx - a' \, dy \\ C \, dq &= -b \, dx + a \, dy\end{aligned}$$

Thence we obtain for the total differentials of t, u

$$\begin{aligned}C^3 \, dt &= (A \frac{dC}{dp} - C \frac{dA}{dp})(b' \, dx - a' \, dy) + (C \frac{dA}{dq} - A \frac{dC}{dq})(b \, dx - a \, dy) \\ C^3 \, du &= (B \frac{dC}{dp} - C \frac{dB}{dp})(b' \, dx - a' \, dy) + (C \frac{dB}{dq} - B \frac{dC}{dq})(b \, dx - a \, dy)\end{aligned}$$

If now we substitute in these formulæ

$$\begin{aligned}\frac{dA}{dp} &= c' \epsilon + b \gamma' - c \epsilon' - b' \gamma \\ \frac{dA}{dq} &= c' \epsilon' + b \gamma'' - c \epsilon'' - b' \gamma' \\ \frac{dB}{dp} &= a' \gamma + c \alpha' - a \gamma' - c' \alpha \\ \frac{dB}{dq} &= a' \gamma' + c \alpha'' - a \gamma'' - c' \alpha' \\ \frac{dC}{dp} &= b' \alpha + a \epsilon' - b \alpha' - a' \epsilon \\ \frac{dC}{dq} &= b' \alpha' + a \epsilon'' - b \alpha'' - a' \epsilon'\end{aligned}$$

and if we note that the values of the differentials dt, du thus obtained must be equal, independently of the differentials dx, dy , to the quantities $T \, dx + U \, dy$, $U \, dx + V \, dy$ respectively, we shall find, after some sufficiently obvious

transformations,

$$\begin{aligned}
 C^3T &= \alpha Ab'^2 + 6Bb'^2 + \gamma Cb'^2 \\
 &\quad - 2\alpha' Abb' - 26'Bbb' - 2\gamma' Cbb' \\
 &\quad + \alpha'' Ab^2 + 6''Bb^2 + \gamma'' Cb^2 \\
 C^3U &= -\alpha Aa'b' - 6Ba'b' - \gamma Ca'b' \\
 &\quad + \alpha' A(ab' + ba') + 6'B(ab' + ba') + \gamma' C(ab' + ba') \\
 &\quad - \alpha'' Aab - 6''Bab - \gamma'' Cab \\
 C^3V &= \alpha Aa'^2 + 6Ba'^2 + \gamma Ca'^2 \\
 &\quad - 2\alpha' Aaa' - 26'Baa' - 2\gamma' Caa' \\
 &\quad + \alpha'' Aa^2 + 6''Ba^2 + \gamma'' Ca^2
 \end{aligned}$$

Hence, if we put, for the sake of brevity,

$$A\alpha + B6 + C\gamma = D \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$A\alpha' + B6' + C\gamma' = D' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$A\alpha'' + B6'' + C\gamma'' = D'' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

we shall have

$$\begin{aligned}
 C^3T &= Db'^2 - 2D'bb' + D''b^2 \\
 C^3U &= -Da'b' + D'(ab' + ba') - D''ab \\
 C^3V &= Da'^2 - 2D'aa' + D''a^2
 \end{aligned}$$

From this we find, after the reckoning has been carried out,

$$C^6(TV - U^2) = (DD'' - D'^2)(ab' - ba')^2 = (DD'' - D'^2)C^2$$

and therefore the formula for the measure of curvature

$$k = \frac{DD'' - D'^2}{(A^2 + B^2 + C^2)^2}$$

By means of the formula just found we are going to establish another, which may be counted among the most productive theorems in the theory of curved

surfaces. Let us introduce the following notation:

$$\begin{aligned} a^2 + b^2 + c^2 &= E \\ aa' + bb' + cc' &= F \\ a'^2 + b'^2 + c'^2 &= G \\ a\alpha + b\beta + c\gamma &= m \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4) \end{aligned}$$

$$a\alpha' + b\beta' + c\gamma' = m' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

$$a\alpha'' + b\beta'' + c\gamma'' = m'' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

$$a'\alpha + b'\epsilon + c'\gamma = n \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

$$a'\alpha' + b'\beta' + c'\gamma' = n' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

$$a'\alpha'' + b'\beta'' + c'\gamma'' = n'' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

$$A^2 + B^2 + C^2 = EG - F^2 = \Delta$$

Let us eliminate from the equations 1, 4, 7 the quantities δ, γ , which is done by multiplying them by $bc' - cb'$, $b'C - c'B$, $cB - bC$ respectively and adding: in this way we obtain

$$\begin{aligned} & (A(bc' - cb') + a(b'C - c'B) + a'(cB - bC))\alpha \\ & = D(bc' - cb') + m(b'C - c'B) + n(cB - bC) \end{aligned}$$

an equation which is easily transformed into

$$AD = \alpha\Delta + a(nF - mG) + a'(mF - nE)$$

Likewise the elimination of α , γ or α , δ from the same equations gives

$$BD = 6\Delta + b(nF - mG) + b'(mF - nE)$$

$$CD = \gamma\Delta + c(nF - mG) + c'(mF - nE)$$

Multiplying these three equations by α'' , β'' , γ'' respectively and adding, we obtain

$$DD'' = (\alpha\alpha'' + \ell\ell'' + \gamma\gamma'')\Delta + m''(nF - mG) + n''(mF - nE) . \quad (10)$$

If we treat the equations 2, 5, 8 in the same way, we obtain

$$AD' = \alpha' \Delta + a(n'F - m'G) + a'(m'F - n'E)$$

$$BD' = \epsilon' \Delta + b(n'F - m'G) + b'(m'F - n'E)$$

$$CD' = \gamma' \Delta + c(n'F - m'G) + c'(m'F - n'E)$$

§12. If $M, N \subset \mathbb{R}^3$ are surfaces, then a *development* of M on N is simply a map $f: M \rightarrow N$ which is an isometry (with respect to the induced Riemannian metrics).

and after these equations are multiplied by α' , β' , γ' respectively, addition gives

$$D'^2 = (\alpha'^2 + \beta'^2 + \gamma'^2)\Delta + m'(n'F - m'G) + n'(m'F - n'E)$$

A combination of this equation with equation (10) gives

$$\begin{aligned} DD'' - D'^2 &= (\alpha\alpha'' + \beta\beta'' + \gamma\gamma'' - \alpha'^2 - \beta'^2 - \gamma'^2)\Delta \\ &\quad + E(n'^2 - nn'') + F(nm'' - 2m'n' + mn'') + G(m'^2 - mm'') \end{aligned}$$

It is clear that we have

$$\frac{dE}{dp} = 2m, \quad \frac{dE}{dq} = 2m', \quad \frac{dF}{dp} = m' + n, \quad \frac{dF}{dq} = m'' + n', \quad \frac{dG}{dp} = 2n', \quad \frac{dG}{dq} = 2n''$$

or

$$\begin{aligned} m &= \frac{1}{2} \frac{dE}{dp}, & m' &= \frac{1}{2} \frac{dE}{dq}, & m'' &= \frac{dF}{dq} - \frac{1}{2} \frac{dG}{dp} \\ n &= \frac{dF}{dp} - \frac{1}{2} \frac{dE}{dq}, & n' &= \frac{1}{2} \frac{dG}{dp}, & n'' &= \frac{1}{2} \frac{dG}{dq} \end{aligned}$$

Moreover, it is easily shown that we shall have

$$\begin{aligned} \alpha\alpha'' + \beta\beta'' + \gamma\gamma'' - \alpha'^2 - \beta'^2 - \gamma'^2 &= \frac{dn}{dq} - \frac{dn'}{dp} = \frac{dm''}{dp} - \frac{dm'}{dq} \\ &= -\frac{1}{2} \cdot \frac{ddE}{dq^2} + \frac{ddF}{dp \cdot dq} - \frac{1}{2} \cdot \frac{ddG}{dp^2} \end{aligned}$$

If we substitute these different expressions in the formula for the measure of curvature derived at the end of the preceding article, we obtain the following formula, which involves only the quantities E , F , G and their differential quotients of the first and second orders:

$$\begin{aligned} 4(EG - F^2)^2 k &= E \left(\frac{dE}{dq} \cdot \frac{dG}{dq} - 2 \frac{dF}{dp} \cdot \frac{dG}{dq} + \left(\frac{dG}{dp} \right)^2 \right) \\ &\quad + F \left(\frac{dE}{dp} \cdot \frac{dG}{dq} - \frac{dE}{dq} \cdot \frac{dG}{dp} - 2 \frac{dE}{dq} \cdot \frac{dF}{dq} + 4 \frac{dF}{dp} \cdot \frac{dF}{dq} - 2 \frac{dF}{dp} \cdot \frac{dG}{dp} \right) \\ &\quad + G \left(\frac{dE}{dp} \cdot \frac{dG}{dp} - 2 \frac{dE}{dp} \cdot \frac{dF}{dq} + \left(\frac{dE}{dq} \right)^2 \right) \\ &\quad - 2(EG - F^2) \left(\frac{ddE}{dq^2} - 2 \frac{ddF}{dp \cdot dq} + \frac{ddG}{dp^2} \right) \end{aligned}$$

12.

Since we always have

$$dx^2 + dy^2 + dz^2 = E dp^2 + 2F dp \cdot dq + G dq^2$$

it is clear that $\sqrt{(E dp^2 + 2F dp \cdot dq + G dq^2)}$ is the general expression for the linear element on the curved surface. The analysis developed in the preceding article thus shows us that for finding the measure of curvature there is no need of finite formulæ, which express the coordinates x, y, z as functions of the indeterminants p, q ; but that the general expression for the magnitude of any linear element is sufficient. Let us proceed to some applications of this very important theorem.

Suppose that our surface can be developed upon another surface, curved or plane, so that to each point of the former surface, determined by the coordinates x, y, z , will correspond a definite point of the latter surface, whose coordinates are x', y', z' . Evidently x', y', z' can also be regarded as functions of the indeterminants p, q , and therefore for the element $\sqrt{(dx'^2 + dy'^2 + dz'^2)}$ we shall have an expression of the form

$$\sqrt{(E' dp^2 + 2F' dp \cdot dq + G' dq^2)}$$

where E', F', G' also denote functions of p, q . But from the very notion of the *development* of one surface upon another it is clear that the elements corresponding to one another on the two surfaces are necessarily equal. Therefore we shall have identically

$$E = E', \quad F = F', \quad G = G'$$

Thus the formula of the preceding article leads of itself to the remarkable

THEOREM. *If a curved surface is developed upon any other surface whatever, the measure of curvature in each point remains unchanged.*

Also it is evident that *any finite part whatever of the curved surface will retain the same integral curvature after development upon another surface.*

Surfaces developable upon a plane constitute the particular case to which geometers have heretofore restricted their attention. Our theory shows at once that the measure of curvature at every point of such surfaces is equal to zero. Consequently, if the nature of these surfaces is defined according to the third method, we shall have at every point

$$\frac{ddz}{dx^2} \cdot \frac{ddz}{dy^2} - \left(\frac{ddz}{dx \cdot dy} \right)^2 = 0$$

a criterion which, though indeed known a short time ago, has not, at least to our knowledge, commonly been demonstrated with as much rigor as is desirable.

What we have explained in the preceding article is connected with a particular method of studying surfaces, a very worthy method which may be thoroughly

§14. Throughout this section Gauss uses x, y, z to denote $x \circ c, y \circ c, z \circ c$, for the curve c under consideration. The integral in the second display, involving both d and δ , is what we would write as

$$\begin{aligned} \left. \frac{dL(\bar{\alpha}(u))}{du} \right|_{u=0} &= \left. \frac{d}{du} \right|_{u=0} \int_a^b \sqrt{\left(\frac{\partial \alpha^1(u, t)}{\partial t} \right)^2 + \dots} dt \\ &= \int_a^b \frac{\frac{\partial \alpha^1(0, t)}{\partial u} \frac{\partial^2 \alpha^1(0, t)}{\partial u \partial t} + \dots}{\sqrt{\left(\frac{\partial \alpha^1(0, t)}{\partial u} \right)^2 + \dots}} dt = \int_a^b \frac{\frac{dc^1}{dt} \frac{\partial^2 \alpha^1(0, t)}{\partial u \partial t} + \dots}{\sqrt{\left(\frac{\partial \alpha^1(0, t)}{\partial u} \right)^2 + \dots}} dt. \end{aligned}$$

Thus, $\frac{dc^1}{dt}$ is $\frac{dx}{[dt]}$ and $\frac{\partial^2 \alpha^1(0, t)}{\partial u \partial t} = \frac{\partial^2 \alpha^1(0, t)}{\partial t \partial u}$ is $\frac{d\delta x}{[\partial t \partial u]}$. The next two lines show what this becomes after integration by parts. The integral is

$$- \int_a^b \frac{\partial \alpha^1}{\partial u}(0, t) \frac{d}{dt} \left(\frac{dc^1/dt}{\sqrt{\dots}} \right) + \dots dt;$$

here $\frac{\partial \alpha^1}{\partial u}(0, t)$ is $\frac{\delta x}{[\partial u]}$.

developed by geometers. When a surface is regarded, not as the boundary of a solid, but as a flexible, though not extensible solid, one dimension of which is supposed to vanish, then the properties of the surface depend in part upon the form to which we can suppose it reduced, and in part are absolute and remain invariable, whatever may be the form into which the surface is bent. To these latter properties, the study of which opens to geometry a new and fertile field, belong the measure of curvature and the integral curvature, in the sense which we have given to these expressions. To these belong also the theory of shortest lines, and a great part of what we reserve to be treated later. From this point of view, a plane surface and a surface developable on a plane, e.g., cylindrical surfaces, conical surfaces, etc., are to be regarded as essentially identical; and the generic method of defining in a general manner the nature of the surfaces thus considered is always based upon the formula $\sqrt{(E dp^2 + 2F dp \cdot dq + G dq^2)}$, which connects the linear element with the two indeterminants p, q . But before following this study further, we must introduce the principles of the theory of shortest lines on a given curved surface.

14.

The nature of a curved line in space is generally given in such a way that the coordinates x, y, z corresponding to the different points of it are given in the form of functions of a single variable, which we shall call w . The length of such a line from an arbitrary initial point to the point whose coordinates are x, y, z , is expressed by the integral

$$\int dw \cdot \sqrt{\left(\frac{dx}{dw}\right)^2 + \left(\frac{dy}{dw}\right)^2 + \left(\frac{dz}{dw}\right)^2}$$

If we suppose that the position of the line undergoes an infinitely small variation, so that the coordinates of the different points receive the variations $\delta x, \delta y, \delta z$, the variation of the whole length becomes

$$= \int \frac{dx \cdot d\delta x + dy \cdot d\delta y + dz \cdot d\delta z}{\sqrt{(dx^2 + dy^2 + dz^2)}}$$

which expression we can change into the form

$$\frac{dx \cdot \delta x + dy \cdot \delta y + dz \cdot \delta z}{\sqrt{(dx^2 + dy^2 + dz^2)}} - \int \left(\delta x \cdot d \frac{dx}{\sqrt{(dx^2 + dy^2 + dz^2)}} + \delta y \cdot d \frac{dy}{\sqrt{(dx^2 + dy^2 + dz^2)}} + \delta z \cdot d \frac{dz}{\sqrt{(dx^2 + dy^2 + dz^2)}} \right)$$

We know that, in case the line is to be the shortest between its end points, all that stands under the integral sign must vanish. Since the line must lie on the given

Notice that Gauss has given $dL(\bar{\alpha}(u))/du|_{u=0}$ for an arbitrary variation in 3-space, not just a variation through curves in the surface. His $x = x \circ c$ is a coordinate function of c in 3-space, *not* a coordinate function with respect to some coordinate system on the surface. If the surface is $\{p : W(p) = 0\}$ for some $W: \mathbb{R}^3 \rightarrow \mathbb{R}$, so that on the surface we have

$$0 = dW = P dx + Q dy + R dz \quad P = D_1 W, \quad Q = D_2 W, \quad R = D_3 W,$$

then for variations α through curves on the surface we will have

$$dW(\delta x, \delta y, \delta z) = dW \left(\frac{\partial \alpha^1}{\partial u}(0, t), \frac{\partial \alpha^2}{\partial u}(0, t), \frac{\partial \alpha^3}{\partial u}(0, t) \right) = 0,$$

and any set of $\partial \alpha^i / \partial u(0, t)$ with this property comes from some variation on the surface. Using this, Gauss deduces a necessary and sufficient condition for a curve γ , parameterized by arclength, to be a geodesic on the surface. Unlike our equations for geodesics, this condition [the next-to-last displayed formula in this section] is expressed in terms of quantities which make sense only in \mathbb{R}^3 :

$$\frac{\gamma^{1''}(t)}{X(\gamma(t))} = \frac{\gamma^{2''}(t)}{Y(\gamma(t))} = \frac{\gamma^{3''}(t)}{Z(\gamma(t))},$$

i.e., $\gamma''(t)$ is a multiple of the normal vector at $\gamma(t)$. It takes a little detective work to see that Gauss is really considering a curve parameterized by arclength. Try to prove Gauss' result by modifying our proof of Euler's equations.

§15. The proof in this section is essentially our (first) proof of Gauss' Lemma (I.9-12). There are two main differences. First, Gauss uses the condition of section 14 rather than our equations. Second, for a surface it is unnecessary to choose a curve $v: \mathbb{R} \rightarrow M_q$ and manufacture the variation α that occurs in the proof of Lemma I.9-12. Instead, we just use

$\alpha(r, \phi) = \text{point with "polar coordinates" } (r, \phi).$

surface, whose nature is defined by the equation $P dx + Q dy + R dz = 0$, the variations $\delta x, \delta y, \delta z$ also must satisfy the equation $P \delta x + Q \delta y + R \delta z = 0$, and from this it follows at once, according to well-known rules, that the differentials

$$d \frac{dx}{\sqrt{(dx^2 + dy^2 + dz^2)}}, \quad d \frac{dy}{\sqrt{(dx^2 + dy^2 + dz^2)}}, \quad d \frac{dz}{\sqrt{(dx^2 + dy^2 + dz^2)}}$$

must be proportional to the quantities P, Q, R respectively. Let dr be the element of the curved line; λ the point on the sphere representing the direction of this element; L the point on the sphere representing the direction of the normal to the curved surface; finally, let ξ, η, ζ be the coordinates of the point λ , and X, Y, Z be those of the point L with reference to the center of the sphere. We shall then have

$$dx = \xi dr, \quad dy = \eta dr, \quad dz = \zeta dr$$

from which we see that the above differentials become $d\xi, d\eta, d\zeta$. And since the quantities P, Q, R are proportional to X, Y, Z , the character of shortest lines is expressed by the equations

$$\frac{d\xi}{X} = \frac{d\eta}{Y} = \frac{d\zeta}{Z}$$

Moreover, it is easily seen that $\sqrt{(d\xi^2 + d\eta^2 + d\zeta^2)}$ is equal to the small arc on the sphere which measures the angle between the directions of the tangents at the beginning and at the end of the element dr , and is thus $= \frac{dr}{\rho}$, if ρ denotes the radius of curvature of the shortest line at this point; thus we shall have

$$\rho d\xi = X dr, \quad \rho d\eta = Y dr, \quad \rho d\zeta = Z dr$$

15.

Suppose that an infinite number of shortest lines go out from a given point A on the curved surface, and suppose that we distinguish these lines from one another by the angle that the first element of each of them makes with the first element of one of them which we take for the first. Let φ be that angle, or, more generally, a function of that angle, and r the length of such a shortest line from the point A to the point whose coordinates are x, y, z . Since to definite values of the variables r, φ there correspond definite points of the surface, the coordinates x, y, z can be regarded as function of r, φ . We shall retain for the notation $\lambda, L, \xi, \eta, \zeta, X, Y, Z$ the same meaning as in the preceding article, this notation referring to any point whatever on any one of the shortest lines.

All the shortest lines that are of the same length r will end on another line whose length, measured from an arbitrary initial point, we shall denote by v . Thus v can be regarded as a function of the indeterminants r, φ , and if λ' denotes the point on the sphere corresponding to the direction of the element dv , and also ξ', η', ζ' denote the coordinates of this point with reference to the center of the sphere, we shall have

$$\frac{dx}{d\varphi} = \xi' \cdot \frac{dv}{d\varphi}, \quad \frac{dy}{d\varphi} = \eta' \cdot \frac{dv}{d\varphi}, \quad \frac{dz}{d\varphi} = \zeta' \cdot \frac{dv}{d\varphi}$$

From these equations and from the equations

$$\frac{dx}{dr} = \xi, \quad \frac{dy}{dr} = \eta, \quad \frac{dz}{dr} = \zeta$$

we have

$$\frac{dx}{dr} \cdot \frac{dx}{d\varphi} + \frac{dy}{dr} \cdot \frac{dy}{d\varphi} + \frac{dz}{dr} \cdot \frac{dz}{d\varphi} = (\xi\xi' + \eta\eta' + \zeta\zeta') \cdot \frac{dv}{d\varphi} = \cos \lambda\lambda' \cdot \frac{dv}{d\varphi}$$

Let S denote the first member of this equation, which will also be a function of r, φ . Differentiation of S with respect to r gives

$$\begin{aligned} \frac{dS}{dr} &= \frac{d^2x}{dr^2} \cdot \frac{dx}{d\varphi} + \frac{d^2y}{dr^2} \cdot \frac{dy}{d\varphi} + \frac{d^2z}{dr^2} \cdot \frac{dz}{d\varphi} + \frac{1}{2} \cdot \frac{d\left(\left(\frac{dx}{dr}\right)^2 + \left(\frac{dy}{dr}\right)^2 + \left(\frac{dz}{dr}\right)^2\right)}{d\varphi} \\ &= \frac{d\xi}{dr} \cdot \frac{dx}{d\varphi} + \frac{d\eta}{dr} \cdot \frac{dy}{d\varphi} + \frac{d\zeta}{dr} \cdot \frac{dz}{d\varphi} + \frac{1}{2} \cdot \frac{d(\xi^2 + \eta^2 + \zeta^2)}{d\varphi} \end{aligned}$$

But $\xi^2 + \eta^2 + \zeta^2 = 1$, and therefore its differential = 0; and by the preceding article we have, if ρ denotes the radius of curvature of the line r ,

$$\frac{d\xi}{dr} = \frac{X}{\rho}, \quad \frac{d\eta}{dr} = \frac{Y}{\rho}, \quad \frac{d\zeta}{dr} = \frac{Z}{\rho}$$

Thus we have

$$\frac{dS}{dr} = \frac{1}{\rho} \cdot (X\xi' + Y\eta' + Z\zeta') \cdot \frac{dv}{d\varphi} = \frac{1}{\rho} \cdot \cos L\lambda' \cdot \frac{dv}{d\varphi} = 0$$

since λ' evidently lies on the great circle whose pole is L . From this we see that S is independent of r , and is, therefore, a function of φ alone. But for $r = 0$ we evidently have $v = 0$, consequently $\frac{dv}{d\varphi} = 0$, and $S = 0$ independently of φ . Thus, in general, we have necessarily $S = 0$, and so $\cos \lambda\lambda' = 0$, i.e., $\lambda\lambda' = 90^\circ$. From this follows the

Gauss also gives a “geometric” proof of the lemma, using infinitesimal triangles. Perhaps the easiest way to make this rigorous would be to use our second proof of Gauss’ Lemma.

§16. This section states a generalization of Gauss’ Lemma, which has also been given in Problem I.9-28.

§17. In terms of a coordinate system (p, q) on a surface, the Riemannian metric that it acquires as a subset of \mathbb{R}^3 has the expression

$$\langle \cdot, \cdot \rangle = E dp \otimes dp + F dp \otimes dq + F dq \otimes dp + G dq \otimes dq,$$

so that

$$\| \cdot \| = \sqrt{E dp \cdot dp + 2F dp \cdot dq + G dq \cdot dq}.$$

THEOREM. *If on a curved surface an infinite number of shortest lines of equal length be drawn from the same initial point, the lines joining their extremities will be normal to each of the lines.*

We have thought it worth while to deduce this theorem from the fundamental property of shortest lines; but the truth of the theorem can be made apparent without any calculation by means of the following reasoning. Let AB , AB' be two shortest lines of the same length including at A an infinitely small angle, and let us suppose that one of the angles made by the element BB' with the lines BA , $B'A$ differs from a right angle by a finite quantity. Then, by the law of continuity, one will be greater and the other less than a right angle. Suppose the angle at B is equal to $90^\circ - \omega$, and take on the line AB a point C , such that $BC = BB' \cdot \operatorname{cosec} \omega$. Then, since the infinitely small triangle $BB'C$ may be regarded as plane, we shall have $CB' = BC \cdot \cos \omega$, and consequently

$$AC + CB' = AC + BC \cdot \cos \omega = AB - BC \cdot (1 - \cos \omega) = AB' - BC \cdot (1 - \cos \omega),$$

i.e., the path from A to B' through the point C is shorter than the shortest line, Q.E.D.

16.

With the theorem of the preceding article we associate another, which we state as follows: *If on a curved surface we imagine any line whatever, from the different points of which are drawn at right angles and toward the same side an infinite number of shortest lines of the same length, the curve which joins their other extremities will cut each of the lines at right angles.* For the demonstration of this theorem no change need be made in the preceding analysis, except that φ must denote the length of the *given* curve measured from an arbitrary point; or rather, a function of this length. Thus all of the reasoning will hold here also, with this modification, that $S = 0$ for $r = 0$ is now implied in the hypothesis itself. Moreover, this theorem is more general than the preceding one, for we can regard it as including the first one if we take for the given line the infinitely small circle described about the center A . Finally, we may say that here also geometric considerations may take the place of the analysis, which, however, we shall not take the time to consider here, since they are sufficiently obvious.

17.

We return to the formula $\sqrt{(E dp^2 + 2F dp \cdot dq + G dq^2)}$, which expresses generally the magnitude of a linear element on the curved surface, and investigate, first of all, the geometric meaning of the coefficients E , F , G . We have

Gauss uses ω to denote the angle between $\partial/\partial p$ and $\partial/\partial q$ (thus, ω is a function on the surface). Gauss' formula for $\cos \omega$ should be clear. Gauss also mentions that

$$dV = \sqrt{EG - F^2} dp \wedge dq,$$

a special case of the formula on pg. I.311.

To interpret the last two formulas in this section, we must divide ds , dp , and dq by dt in all places; it is to be understood that $dp/dt = (p \circ c)'(t)$, etc., where c is the curve we are considering. It is simplest to assume that c is parameterized by arclength, so that the terms ds/dt are 1. If

$$\theta(s) = \text{angle between } c'(s) \text{ and } \left. \frac{\partial}{\partial p} \right|_{c(s)},$$

then

$$\cos \theta = \frac{\left\langle c', \frac{\partial}{\partial p} \right\rangle}{\left\| \frac{\partial}{\partial p} \right\|} = \frac{E \frac{dp(c(s))}{ds} + F \frac{dq(c(s))}{ds}}{\sqrt{E}},$$

since

$$c' = \frac{dp(c(s))}{ds} \frac{\partial}{\partial p} + \frac{dq(c(s))}{ds} \frac{\partial}{\partial q}.$$

Moreover, the area of the parallelogram spanned by c' and $\partial/\partial p$ is

$$\sin \theta \cdot \left\| \frac{\partial}{\partial p} \right\|, \quad \text{and also} \quad dV \left(\frac{\partial}{\partial p}, c' \right),$$

from which we obtain

$$\sin \theta = \frac{\sqrt{EG - F^2} \frac{dq(c(s))}{ds}}{\sqrt{E}}.$$

§18. In this section Gauss deduces the conditions for a curve γ (having the component functions $\gamma^1 = p \circ \gamma$, $\gamma^2 = q \circ \gamma$) to be a critical point for the length function.

Unlike the condition in section 14, the result is expressed totally in terms of the Riemannian metric $\langle \cdot, \cdot \rangle$ on the surface, and is essentially the condition for a geodesic that we obtained in Chapter I.9. However, the derivation is different, because the geodesic is assumed to satisfy $q(\gamma(t)) = \gamma^2(t) = t$ ["we regard p as a function of q "].

It is not necessary to actually follow the derivation. The really important point is simply the equation that constitutes the first line that appears in the

already said in Art. 5 that two systems of lines may be supposed to lie on the curved surface, p being variable, q constant along each of the lines of the one system; and q variable, p constant along each of the lines of the other system. Any point whatever on the surface can be regarded as the intersection of a line of the first system with a line of the second; and then the element of the first line adjacent to this point and corresponding to a variation dp will be $= \sqrt{E} \cdot dp$, and the element of the second line corresponding to the variation dq will be $= \sqrt{G} \cdot dq$. Finally, denoting by ω the angle between these elements, it is easily seen that we shall have $\cos \omega = \frac{F}{\sqrt{EG}}$. Furthermore, the area of the surface element in the form of a parallelogram between the two lines of the first system, to which correspond $q, q + dq$, and the two lines of the second system, to which correspond $p, p + dp$, will be $\sqrt{(EG - F^2)} dp \cdot dq$.

Any line whatever on the curved surface belonging to neither of the two systems is determined when p and q are supposed to be functions of a new variable, or one of them is supposed to be a function of the other. Let s be the length of such a curve, measured from an arbitrary initial point, and in either direction chosen as positive. Let θ denote the angle which the element $ds = \sqrt{(E dp^2 + 2F dp \cdot dq + G dq^2)}$ makes with the line of the first system drawn through the initial point of the element, and, in order that no ambiguity may arise, let us suppose that this angle is measured from that branch of the first line on which the values of p increase, and is taken as positive toward that side toward which the values of q increase. These conventions being made, it is easily seen that

$$\begin{aligned}\cos \theta \cdot ds &= \sqrt{E} \cdot dp + \sqrt{G} \cdot \cos \omega \cdot dq = \frac{E dp + F dq}{\sqrt{E}} \\ \sin \theta \cdot ds &= \sqrt{G} \cdot \sin \omega \cdot dq = \frac{\sqrt{(EG - F^2)} \cdot dq}{\sqrt{E}}\end{aligned}$$

18.

We shall now investigate the condition that this line be a shortest line. Since its length s is expressed by the integral

$$s = \int \sqrt{(E dp^2 + 2F dp \cdot dq + G dq^2)}$$

the condition for a minimum requires that the variation of this integral arising from an infinitely small change in the position become $= 0$. The calculation, for our purpose, is more simply made in this case, if we regard p as a function of q .

second large display on page 105 (after the words “Thus we have”). For a curve parameterized by arclength, this equation says that

$$\begin{aligned} \frac{\partial E}{\partial p}(c(s)) \left(\frac{dc^1}{ds} \right)^2 + 2 \frac{\partial F}{\partial p}(c(s)) \frac{dc^1}{ds} \frac{dc^2}{ds} + \frac{\partial G}{\partial p}(c(s)) \left(\frac{dc^2}{ds} \right)^2 \\ = 2 \frac{d}{ds} \left[E(c(s)) \frac{dc^1}{ds} + F(c(s)) \frac{dc^2}{ds} \right]. \end{aligned}$$

It is a very useful exercise to write out the equations on pg. I.329 for the case of a 2-dimensional manifold, with $g_{11} = E$, $g_{12} = F$, $g_{22} = G$, and show that the first of these equations (the equation for $k = 1$) yields the above equation (it will be necessary to perform the differentiation on the right side).

Although Gauss performs various further manipulations, it is only necessary to follow the next step,

$$2 \frac{d}{ds} \left[E \frac{dc^1}{ds} + F \frac{dc^2}{ds} \right] = 2 \frac{d}{ds} \sqrt{E} \cos \theta,$$

where θ is defined in the previous section.

§19. In this section Gauss rewrites formulas from preceding sections for the case of a coordinate system (p, q) which is “orthogonal” ($\langle \partial/\partial p, \partial/\partial q \rangle = F = 0$). The important case for us is the last he considers, in which the coordinates are

When this is done, if the variation is denoted by the characteristic δ , we have

$$\begin{aligned}\delta s &= \int \frac{\left(\frac{dE}{dp} \cdot dp^2 + \frac{2dF}{dp} \cdot dp \cdot dq + \frac{dG}{dp} \cdot dq^2\right) \delta p + (2E dp + 2F dq) d \delta p}{2 ds} \\ &= \frac{E dp + F dq}{ds} \cdot \delta p + \int \delta p \cdot \left\{ \frac{\frac{dE}{dp} \cdot dp^2 + \frac{2dF}{dp} \cdot dp \cdot dq + \frac{dG}{dp} \cdot dq^2}{2 ds} - d \cdot \frac{E dp + F dq}{ds} \right\}\end{aligned}$$

and we know that what is included under the integral sign must vanish independently of δp . Thus we have

$$\begin{aligned}\frac{dE}{dp} \cdot dp^2 + \frac{2dF}{dp} \cdot dp \cdot dq + \frac{dG}{dp} \cdot dq^2 &= 2 ds \cdot d \cdot \frac{E dp + F dq}{ds} \\ &= 2 ds \cdot d \cdot \sqrt{E} \cdot \cos \theta = \frac{ds \cdot dE \cdot \cos \theta}{\sqrt{E}} - 2 ds \cdot d\theta \cdot \sqrt{E} \cdot \sin \theta \\ &= \frac{(E dp + F dq) dE}{E} - 2\sqrt{(EG - F^2)} \cdot dq \cdot d\theta \\ &= \left(\frac{E dp + F dq}{E}\right) \cdot \left(\frac{dE}{dp} \cdot dp + \frac{dE}{dq} \cdot dq\right) - 2\sqrt{(EG - F^2)} \cdot dq \cdot d\theta\end{aligned}$$

This gives the following conditional equation for a shortest line:

$$\sqrt{(EG - F^2)} \cdot d\theta = \frac{1}{2} \cdot \frac{F}{E} \cdot \frac{dE}{dp} \cdot dp + \frac{1}{2} \cdot \frac{F}{E} \cdot \frac{dE}{dq} \cdot dq + \frac{1}{2} \cdot \frac{dE}{dq} \cdot dp - \frac{dF}{dp} \cdot dp - \frac{1}{2} \cdot \frac{dG}{dp} \cdot dq$$

which can also be written

$$\sqrt{(EG - F^2)} \cdot d\theta = \frac{1}{2} \cdot \frac{F}{E} \cdot dE + \frac{1}{2} \cdot \frac{dE}{dq} \cdot dp - \frac{dF}{dp} \cdot dp - \frac{1}{2} \cdot \frac{dG}{dp} \cdot dq$$

From this equation, by means of the equation

$$\cot \theta = \frac{E}{\sqrt{(EG - F^2)}} \cdot \frac{dp}{dq} + \frac{F}{\sqrt{(EG - F^2)}}$$

it is also possible to eliminate the angle θ , and to derive a differential equation of the second order between p and q , which, however, would become more complicated and less useful for applications than the preceding.

The general formulæ, which we have derived in Arts. 11, 18 for the measure of curvature and the variation in the direction of a shortest line, become much simpler if the quantities p, q are so chosen that the lines of the first system cut

the “polar coordinates” (r, ϕ) defined in terms of the geodesics emanating from a point A of the surface. Here Gauss obtains the formula

$$k = -\frac{1}{\sqrt{G}} \frac{\partial^2 \sqrt{G}}{\partial r^2},$$

and

$$\frac{d\theta}{ds} = -\frac{\partial \sqrt{G}}{\partial r} \frac{d\phi(c(s))}{ds},$$

where θ is the angle the geodesic c makes with the lines $\phi = \text{constant}$. Notice that (r, ϕ) is not a coordinate system on a whole neighborhood of A ; we must delete one geodesic ray, including the point A itself. Consequently, \sqrt{G} and $\partial \sqrt{G} / \partial r$ are not even defined at A . Gauss’ final assertions in this section should be interpreted as saying that

$$\begin{aligned} \lim_{B \rightarrow A} \sqrt{G}(B) &= 0 \\ \lim_{B \rightarrow A} \frac{\partial \sqrt{G}}{\partial r}(B) &= 1. \end{aligned}$$

everywhere orthogonally the lines of the second system; i.e., in such a way that we have generally $\omega = 90^\circ$, or $F = 0$. Then the formula for the measure of curvature becomes

$$4E^2G^2k = E \cdot \frac{dE}{dq} \cdot \frac{dG}{dq} + E \left(\frac{dG}{dp} \right)^2 + G \cdot \frac{dE}{dp} \cdot \frac{dG}{dp} + G \left(\frac{dE}{dq} \right)^2 - 2EG \left(\frac{ddE}{dq^2} + \frac{ddG}{dp^2} \right)$$

and for the variation of the angle θ

$$\sqrt{EG} \cdot d\theta = \frac{1}{2} \cdot \frac{dE}{dq} \cdot dp - \frac{1}{2} \cdot \frac{dG}{dp} \cdot dq$$

Among the various cases in which we have this condition of orthogonality, the most important is that in which all the lines of one of the two systems, e.g., the first, are shortest lines. Here for a constant value of q the angle θ becomes $= 0$, and therefore the equation for the variation of θ just given shows that we must have $\frac{dE}{dq} = 0$, or that the coefficient E must be independent of q ; i.e., E must be either a constant or a function of p alone. It will be simplest to take for p the length of each line of the first system, which length, when all the lines of the first system meet in a point, is to be measured from this point, or, if there is no common intersection, from any line whatever of the second system. Having made these conventions, it is evident that p and q denote now the same quantities that were expressed in Arts. 15, 16 by r and φ , and that $E = 1$. Thus the two preceding formulæ become:

$$4G^2k = \left(\frac{dG}{dp} \right)^2 - 2G \frac{ddG}{dp^2}$$

$$\sqrt{G} \cdot d\theta = -\frac{1}{2} \cdot \frac{dG}{dp} \cdot dq$$

or, setting $\sqrt{G} = m$,

$$k = -\frac{1}{m} \cdot \frac{ddm}{dp^2}, \quad d\theta = -\frac{dm}{dp} \cdot dq$$

Generally speaking, m will be a function of p , q , and $m dq$ the expression for the element of any line whatever of the second system. But in the particular case where all the lines p go out from the same point, evidently we must have $m = 0$ for $p = 0$. Furthermore, in the case under discussion we will take for q the angle itself which the first element of any line whatever of the first system makes with the element of any one of the lines chosen arbitrarily. Then, since for an infinitely small value of p the element of a line of the second system (which can be regarded as a circle described with radius p) is $= p dq$, we shall have for

§20. If you have come this far, there should be no problem with this final section. Here is the picture.

an infinitely small value of p , $m = p$, and consequently, for $p = 0$, $m = 0$ at the same time, and $\frac{dm}{dp} = 1$.

20.

We pause to investigate the case in which we suppose that p denotes in a general manner the length of the shortest line drawn from a fixed point A to any other point whatever of the surface, and q the angle that the first element of this line makes with the first element of another given shortest line going out from A . Let B be a definite point in the latter line, for which $q = 0$, and C another definite point of the surface, at which we denote the value of q simply by A . Let us suppose the points B, C joined by a shortest line, the parts of which, measured from B , we denote in a general way, as in Art. 18, by s ; and, as in the same article, let us denote by θ the angle which any element ds makes with the element dp ; finally, let us denote by θ^0, θ' the values of the angle θ at the points B, C . We have thus on the curved surface a triangle formed by shortest lines. The angles of this triangle at B and C we shall denote simply by the same letters, and B will be equal to $180^0 - \theta$, C to θ' itself. But, since it is easily seen from our analysis that all the angles are supposed to be expressed, not in degrees, but by numbers, in such a way that the angle $57^0 17' 45''$, to which corresponds an arc equal to the radius, is taken for the unit, we must set

$$\theta^0 = \pi - B, \quad \theta' = C$$

where 2π denotes the circumference of the sphere. Let us now examine the integral curvature of this triangle, which is $= \int k d\sigma$, $d\sigma$ denoting a surface element of the triangle. Wherefore, since this element is expressed by $m dp \cdot dq$, we must extend the integral $\iint m dp \cdot dq$ over the whole surface of the triangle. Let us begin by integration with respect to p , which, because $k = -\frac{1}{m} \cdot \frac{ddm}{dp^2}$, gives $dq \cdot (\text{Const.} - \frac{dm}{dp})$, for the integral curvature of the area lying between the lines of the first system, to which correspond the values $q, q + dq$ of the second indeterminate. Since this integral curvature must vanish for $p = 0$, the constant introduced by integration must be equal to the value of $\frac{dm}{dq}$ for $p = 0$, i.e., equal to unity. Thus we have $dq(1 - \frac{dm}{dp})$, where for $\frac{dm}{dp}$ must be taken the value corresponding to the end of this area on the line CB . But on this line we have, by the preceding article, $\frac{dm}{dq} \cdot dq = -d\theta$, whence our expression is changed into $dq + d\theta$. Now by a second integration, taken from $q = 0$ to $q = A$, we find that the integral curvature $= A + \theta' - \theta^0 = A + B + C - \pi$.

The integral curvature is equal to the area of that part of the sphere which corresponds to the triangle, taken with the positive or negative sign according as the curved surface on which the triangle lies is concavo-concave or concavo-convex. For unit area will be taken the square whose side is equal to unity (the radius of the sphere), and then the whole surface of the sphere becomes $= 4\pi$. Thus the part of the surface of the sphere corresponding to the triangle is to the whole surface of the sphere as $\pm(A + B + C - \pi)$ is to 4π . This theorem, which, if we mistake not, ought to be counted among the most elegant in the theory of curved surfaces, may also be stated as follows:

The excess over 180^0 of the sum of the angles of a triangle formed by shortest lines on a concavo-concave curved surface, or the deficit from 180^0 of the sum of the angles of a triangle formed by shortest lines on a concavo-convex curved surface, is measured by the area of the part of the sphere which corresponds, through the directions of the normals, to that triangle, if the whole surface of the sphere is set equal to 720 degrees.

More generally, in any polygon whatever of n sides, each formed by a shortest line, the excess of the sum of the angles over $(2n - 4)$ right angles, or the deficit from $(2n - 4)$ right angles (according to the nature of the curved surface), is equal to the area of the corresponding polygon on the sphere, if the whole surface of the sphere is set equal to 720 degrees. This follows at once from the preceding theorem by dividing the polygon into triangles.

B. GAUSS' THEORY OF SURFACES

This part of the chapter presents Gauss' results in modern dressing. It can be read completely independently of the first part, but there are frequent comparisons with Gauss' original paper. Some of Gauss' notation will be changed; in particular, we will use K for Gauss' k .

We consider a 2-dimensional submanifold M of \mathbb{R}^3 , with $i: M \rightarrow \mathbb{R}^3$ the inclusion map. We also assume that M has been oriented. Since all our results will be local ones, we merely need an orientation in a neighborhood of each point, so this assumption does not place any real restriction on M . (However, we must still investigate to what extent our results depend on the choice of the orientation.)

At each point $p \in M$ there is a unique unit vector $v(p) \in \mathbb{R}^3$ such that

- (1) $v(p)_p \in \mathbb{R}^3_p$ is perpendicular to M_p
- (2) $v(p), v, w$ is positively oriented in \mathbb{R}^3 whenever $v_p, w_p \in M_p$ is positively oriented.

We thus have the **normal map** $v: M \rightarrow \mathbb{R}^3$, which actually goes to the unit sphere, $v: M \rightarrow S^2 \subset \mathbb{R}^3$. Notice that in his paper Gauss uses X, Y, Z for

$v^1(p), v^2(p), v^3(p)$. The idea of using this map may have been suggested to Gauss by astronomical practices, as he indicates in an abstract of the paper (also included in the Princeton University Library translation, and the Raven Press reprint). At any rate, the map v turns out to play such a crucial role that it is often called the **Gauss map**.

An explicit formula for $v: M \rightarrow S^2$ can be obtained from various explicit descriptions of M . For example, if $M = \{p \in \mathbb{R}^3 : W(p) = 0\}$ for some function $W: \mathbb{R}^3 \rightarrow \mathbb{R}$, then $dW = 0$ on M , i.e., $dW(v_q) = 0$ for all $v_q \in M_q$. This means that

$$D_1 W(q) \cdot v^1 + D_2 W(q) \cdot v^2 + D_3 W(q) \cdot v^3 = 0$$

$$\frac{\partial W}{\partial x}(q) \cdot v^1 + \frac{\partial W}{\partial y}(q) \cdot v^2 + \frac{\partial W}{\partial z}(q) \cdot v^3 = 0 \quad \text{for all } v_q \in M_q.$$

This equation can be written

$$\left\langle \left(\frac{\partial W}{\partial x}(q), \frac{\partial W}{\partial y}(q), \frac{\partial W}{\partial z}(q) \right), v \right\rangle = 0 \quad \text{for all } v_q \in M_q.$$

Consequently,

$$v(q) = \text{normalized} \left(\frac{\partial W}{\partial x}(q), \frac{\partial W}{\partial y}(q), \frac{\partial W}{\partial z}(q) \right),$$

which is precisely the formula Gauss gives.

We can also find v in terms of a coordinate system χ . To avoid confusion, we will denote the standard coordinate system in \mathbb{R}^2 by (s, t) [Gauss uses (p, q)]

and we will denote the inverse function $\chi^{-1}: \mathbb{R}^2 \rightarrow M \subset \mathbb{R}^3$ by f . It is naturally necessary to consider the component functions of f , considered as a map into \mathbb{R}^3 , in order to obtain a formula for v ; we cannot obtain a formula for v totally in terms of χ , since this coordinate system tells us nothing about the way M is situated in \mathbb{R}^3 . Note that if $q = f(s, t)$, then

$$\begin{aligned} \frac{\partial}{\partial \chi^1} \Big|_q &= \left(\frac{\partial f}{\partial s}(s, t) \right)_q = \left(\frac{\partial f^1}{\partial s}(s, t), \frac{\partial f^2}{\partial s}(s, t), \frac{\partial f^3}{\partial s}(s, t) \right)_q \\ \frac{\partial}{\partial \chi^2} \Big|_q &= \left(\frac{\partial f}{\partial t}(s, t) \right)_q = \left(\frac{\partial f^1}{\partial t}(s, t), \frac{\partial f^2}{\partial t}(s, t), \frac{\partial f^3}{\partial t}(s, t) \right)_q. \end{aligned}$$

Consequently,

$$v(f(s, t)) = \text{normalized cross product} \left(\frac{\partial f^1}{\partial s}, \frac{\partial f^2}{\partial s}, \frac{\partial f^3}{\partial s} \right) \times \left(\frac{\partial f^1}{\partial t}, \frac{\partial f^2}{\partial t}, \frac{\partial f^3}{\partial t} \right).$$

Thus we have

$$\nu(f(s, t)) = \pm \frac{\frac{\partial f^2}{\partial s} \frac{\partial f^3}{\partial t} - \frac{\partial f^2}{\partial t} \frac{\partial f^3}{\partial s}}{\Delta}, \quad \text{---}, \quad \text{---},$$

for

$\Delta = \text{norm of the cross product,}$

exactly as in Gauss.

Finally, if M is the graph of $g: \mathbb{R}^2 \rightarrow \mathbb{R}$, so that

$$M = \{(x, y, g(x, y)) : x, y \in \mathbb{R}^2\},$$

then M is the image of $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ defined by

$$f(s, t) = (s, t, g(s, t)).$$

It follows that

$$\nu(x, y, g(x, y)) = \text{normalized cross product} \left(1, 0, \frac{\partial g}{\partial x}\right) \times \left(0, 1, \frac{\partial g}{\partial y}\right).$$

We are now ready for a preliminary, non-rigorous, definition of the **curvature** $K(p)$ of M at p :

$$K(p) = \lim_{A \rightarrow p} \frac{\text{area } \nu(A)}{\text{area } A},$$

where the limit is taken as the region A around p becomes smaller and smaller. There would be considerable difficulties involved in making this definition rigorous. In the first place, we would have to prove that the limit exists. More crucial, the “area of $\nu(A)$ ” needs some interpretation; in the figure below we want “area of $\nu(A)$ ” to be negative, because ν is orientation reversing near p .

However, even with this non-rigorous definition we can find the curvature of certain surfaces.

Consider first the surface S^2 . The map $v: S^2 \rightarrow S^2$ is just the identity, so at

each point $p \in S^2$ we have

$$K(p) = \lim_{A \rightarrow p} \frac{\text{area } v(A)}{\text{area } A} = \lim_{A \rightarrow p} \frac{\text{area } A}{\text{area } A} = 1.$$

For the case of the sphere $S^2(r)$ of radius r , we have

$$\begin{aligned} K(p) &= \lim_{A \rightarrow p} \frac{\text{area } v(A)}{\text{area } A} \\ &= \frac{1/r^2 \cdot \text{area } A}{\text{area } A} \\ &= \frac{1}{r^2}, \end{aligned}$$

Two diagrams of spheres. The left sphere is labeled $S^2(r)$ and has a shaded region A on its surface. The right sphere is labeled S^2 and has a smaller shaded region $v(A)$ on its surface. Arrows indicate the mapping from A to $v(A)$.

which certainly seems reasonable.

Next we consider a plane P . The function $v: P \rightarrow S^2$ is constant, so

$$K(p) = \lim_{A \rightarrow p} \frac{\text{area } v(A)}{\text{area } A} = \lim_{A \rightarrow p} \frac{0}{\text{area } A} = 0;$$

the plane does not curve.

Finally, we consider a cylinder Z . In this case, the function $v: Z \rightarrow S^2$ is not constant, but the image of v always lies along a certain arc in S^2 , so for all

points $p \in Z$ we have

$$K(p) = \lim_{A \rightarrow p} \frac{\text{area } v(A)}{\text{area } A} = \lim_{A \rightarrow p} \frac{0}{\text{area } A} = 0.$$

The cylinder, too, does not curve! It begins to look as if we have the “wrong” definition of curvature; only later will Gauss explain why this is the “right” definition.

The manner in which we produce a rigorous definition of curvature is really very simple. Since M is a submanifold of \mathbb{R}^3 , which has the usual Riemannian metric $\langle \cdot, \cdot \rangle$, we can give M the induced Riemannian metric $i^*\langle \cdot, \cdot \rangle$. Together with the orientation which we have given M , this metric determines a 2-form “ dV ” on M , namely

$$dV(q)(v_q, w_q) = \text{signed area of the parallelogram spanned by } v \text{ and } w.$$

On the sphere S^2 we also have a volume element, coming from its induced Riemannian metric and its usual orientation. As a glance at pg. I.264 will show, this is just the 2-form which we have denoted by σ' .

We now define the **Gaussian curvature** $K(p)$ of M at p to be

$$K(p) = \frac{v^*(\sigma')(p)}{dV(p)};$$

in this equation, the division of 2-forms makes sense because any 2-form on the 2-dimensional manifold M is a multiple of the non-zero 2-form dV . If the

vectors $v_p, w_p \in M_p$ are orthonormal, then our definition says that

$$\begin{aligned} K(p) &= v^*(\sigma')(p)(v_p, w_p) \\ &= \sigma'(v(p))(v_*v_p, v_*w_p) \quad \text{for orthonormal } v_p, w_p. \end{aligned}$$

This definition of $K(p)$ involves v , and hence the orientation μ which we picked for a neighborhood of p . Choosing the opposite orientation $-\mu$ changes v to $-v = A \circ v$, where $A: S^2 \rightarrow S^2$ is the antipodal map, and consequently changes

$$v^*(\sigma') \quad \text{to} \quad v^*(A^*(\sigma')) = -v^*(\sigma').$$

On the other hand, dV is also changed to $-dV$, so $K(p)$ does not depend on the choice of orientation.

Notice that if v is one-one in a neighborhood of p , then for every region A contained in that neighborhood we have

$$\begin{aligned} \text{area } v(A) &= \int_{v(A)} \sigma' \\ &= \pm \int_A v^*(\sigma') \quad \text{depending on whether } v \text{ is} \\ &\quad \text{orientation preserving or reversing.} \end{aligned}$$

Consequently,

$$\frac{\text{area } v(A)}{\text{area } A} = \frac{\pm \int_A v^*(\sigma')}{\int_A dV}.$$

We thus recover our original “definition”, provided that

$$\lim_{A \rightarrow p} \frac{\pm \int_A v^*(\sigma')}{\int_A dV} = \pm \frac{v^*(\sigma')(p)}{dV(p)} = \pm K(p);$$

although this result seems reasonable, by continuity of $v^*(\sigma')$ and dV , we will not worry about the exact manner in which A must approach p in order for the limit to work out. If v is not one-one in a neighborhood of p , then we must have $v_*(p) = 0$, so the rigorous definition gives $K(p) = 0$, which is more or less what one would expect from the intuitive definition.

Although we will eventually obtain a neater expression for K , we begin by deriving Gauss’ first formula for K , using essentially the same reasoning as

Gauss uses. We first observe that the tangent plane M_p is *parallel* to the tangent plane $S^2_{v(p)}$ of S^2 at $v(p)$. The reason is very simple: the tangent plane $S^2_{v(p)}$

is perpendicular to $v(p)$, and so is M_p , by the very definition of $v(p)$. In the previous two sentences we have used the identification of \mathbb{R}^3_p with \mathbb{R}^3 , the identification of M_p with $i_*M_p \subset \mathbb{R}^3_p$, etc. Without further warning, we shall continue to do so, to avoid cluttering up the page with extra symbolism.

If $v_p, w_p \in M_p$ are linearly independent, then

$$K(p) = \frac{\text{area of parallelogram } P \text{ spanned by } v_*v_p, v_*w_p}{\text{area of parallelogram } Q \text{ spanned by } v_p, w_p}.$$

Since M_p is parallel to $S^2_{v(p)}$, this implies that

$$K(p) = \frac{\text{area of projection of } P \text{ on } (x, y)\text{-plane}}{\text{area of projection of } Q \text{ on } (x, y)\text{-plane}}$$

(provided the denominator is not zero). In particular, suppose M is the graph of $g: \mathbb{R}^2 \rightarrow \mathbb{R}$, and consequently the image of $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ defined by

$$f(s, t) = (s, t, g(s, t)).$$

We choose

$$v = \frac{\partial f}{\partial s} = \left(1, 0, \frac{\partial g}{\partial s}\right)$$

$$w = \frac{\partial f}{\partial t} = \left(0, 1, \frac{\partial g}{\partial t}\right)$$

and consider $v_p, w_p \in M_p$, for $p = f(s, t)$. Then

$$\begin{aligned} & \text{area of projection of } Q \text{ on } (x, y)\text{-plane} \\ &= \text{area of parallelogram spanned by } (1, 0) \text{ and } (0, 1) \\ &= 1. \end{aligned}$$

On the other hand,

$$\begin{aligned} v_*(v_p) &= v_* \left(\left. \frac{\partial f}{\partial s} \right|_p \right) = v_* f_* \left(\frac{\partial}{\partial s} \right) \\ &= (v \circ f)_* \left(\frac{\partial}{\partial s} \right) \\ &= \left(\frac{\partial(v \circ f)}{\partial s} \right)_{v(p)} = \left(\frac{\partial(v^1 \circ f)}{\partial s}, \frac{\partial(v^2 \circ f)}{\partial s}, \frac{\partial(v^3 \circ f)}{\partial s} \right)_{v(p)}. \end{aligned}$$

(Here all partial derivatives are to be evaluated at the point (s, t) .) Similarly,

$$v_*(w_p) = \left(\frac{\partial(v^1 \circ f)}{\partial t}, \frac{\partial(v^2 \circ f)}{\partial t}, \frac{\partial(v^3 \circ f)}{\partial t} \right)_{v(p)}.$$

Consequently,

$$\begin{aligned} K(f(s, t)) &= \text{area of projection of } P \text{ on } (x, y)\text{-plane} \\ &= \text{area of parallelogram spanned by} \\ &\quad \left(\frac{\partial(v^1 \circ f)}{\partial s}, \frac{\partial(v^2 \circ f)}{\partial s} \right) \text{ and } \left(\frac{\partial(v^1 \circ f)}{\partial t}, \frac{\partial(v^2 \circ f)}{\partial t} \right) \\ &= \frac{\partial(v^1 \circ f)}{\partial s} \frac{\partial(v^2 \circ f)}{\partial t} - \frac{\partial(v^1 \circ f)}{\partial t} \frac{\partial(v^2 \circ f)}{\partial s}. \end{aligned}$$

This is precisely the formula Gauss obtains, at the top of page 77. If we use the formula

$$v(x, y, g(x, y)) = \text{normalized cross product } \left(1, 0, \frac{\partial g}{\partial x} \right) \times \left(0, 1, \frac{\partial g}{\partial y} \right),$$

we obtain, after a little calculation,

$$(*) \quad K(x, y, g(x, y)) = \frac{\frac{\partial^2 g}{\partial x^2} \frac{\partial^2 g}{\partial y^2} - \left(\frac{\partial^2 g}{\partial x \partial y} \right)^2}{\left(1 + \left(\frac{\partial g}{\partial x} \right)^2 + \left(\frac{\partial g}{\partial y} \right)^2 \right)^{3/2}}.$$

We can compare this with the results of Chapter 2, in which we picked our coordinate system so that

$$p = (0, 0, 0) = (0, 0, g(0, 0))$$

$$\frac{\partial g}{\partial x}(0, 0) = \frac{\partial g}{\partial y}(0, 0) = 0$$

$$\frac{\partial^2 g}{\partial x \partial y}(0, 0) = 0.$$

In this case, we obtained the result that the minimum k_1 and maximum k_2 of all curvatures cut out by normal planes through p are the minimum and maximum of $\partial^2 g / \partial x^2(0, 0)$ and $\partial^2 g / \partial y^2(0, 0)$. Now for our special choice of coordinates in \mathbb{R}^3 , formula (*) becomes

$$K(p) = \frac{\partial^2 g}{\partial x^2} \frac{\partial^2 g}{\partial y^2} = k_1 \cdot k_2.$$

(Notice that, just as K does not depend on the orientation of M , neither does the *product* $k_1 \cdot k_2$, even though k_1 and k_2 individually do). We thus have the following result:

The Gaussian curvature $K(p)$ at any point $p \in M$ is the product of the extreme curvatures of the curves through p cut out by normal planes.

cylinder of radius a
 $K = k_1 \cdot k_2 = 0$

sphere of radius a
 $K = k_1 \cdot k_2 = \frac{1}{a^2}$

graph of $z = \frac{ax^2}{2} - \frac{ay^2}{2}$
 $K(0, 0, 0) = k_1 \cdot k_2 = -a^2$

To prove this result we have followed Gauss' exposition. In particular, the proof of Euler's Theorem which appeared in Chapter 2 is Gauss'. Undoubtedly, this proof is considerably simpler than Euler's, for Gauss remarks with pride

“These conclusions contain almost all that the illustrious Euler was the first to prove on the curvature of curved surfaces.” Nevertheless, later developments provided a nicer way of obtaining these results, which will consequently now be rederived.

The definition of curvature involves the map $\nu: M \rightarrow S^2 \subset \mathbb{R}^3$, but even more important, it involves the map $\nu_*: M_p \rightarrow S^2_{\nu(p)}$. We can also think of ν as an \mathbb{R}^3 -valued function $\nu: M \rightarrow \mathbb{R}^3$, and we then have a map

$$d\nu: M_p \rightarrow \mathbb{R}^3,$$

namely

$$\begin{aligned} d\nu(v_p) &= (dv^1(v_p), dv^2(v_p), dv^3(v_p)) \\ &= (v_p(v^1), v_p(v^2), v_p(v^3)). \end{aligned}$$

We claim that $d\nu$ is essentially the same as ν_* ; to be precise,

$$\nu_*(v_p) = d\nu(v_p)_{\nu(p)}.$$

Probably the easiest way* to see this is to take a curve c in M with $c'(0) = v_p$. Then

$$\begin{aligned} \nu_*(v_p) &= (\nu \circ c)'(0) \\ &= \left(\frac{d(v^1 \circ c)}{dt} \Big|_{t=0}, \frac{d(v^2 \circ c)}{dt} \Big|_{t=0}, \frac{d(v^3 \circ c)}{dt} \Big|_{t=0} \right)_{\nu(p)} \\ &= (v_p(v^1), v_p(v^2), v_p(v^3))_{\nu(p)}. \end{aligned}$$

*A more formal way is to introduce the inclusion map $j: S^2 \rightarrow \mathbb{R}^3$, and observe that we are really trying to prove that

$$j_*\nu_*(v_p) = d(j \circ \nu)_{\nu(p)}.$$

The result then follows from Problem I.4-3, applied to the component functions of ν .

Taking advantage of the identification of \mathbb{R}^3 with \mathbb{R}^3_p , we can introduce one more confusion, and consider dv as a map

$$dv: M_p \rightarrow \mathbb{R}^3_p.$$

Since $dv(v_p)$ is parallel to $v_*(v_p) \in S^2_{v(p)}$, and since $S^2_{v(p)}$ is parallel to M_p , we see that we actually have a map

Despite the tortuous process used to define this map, the net result can be described very simply: $dv(v_p)$ is just $v_*(v_p)$ moved back up to a parallel vector in M_p .

The map $dv: M_p \rightarrow M_p$ is sometimes called the **Weingarten map**. Using it, we can define a tensor \mathbf{II} on M which is covariant of order 2: for $v_p, w_p \in M_p$ we define

$$\mathbf{II}(p)(v_p, w_p) = -\langle dv(v_p), w_p \rangle.$$

Notice that \mathbf{II} *does* depend on the choice of v , and hence on the orientation picked for M . This tensor \mathbf{II} is called the **second fundamental form** of M . But, as we shall soon see, it is *not* alternating, and hence not a 2-form. We can see the reason for the word “form” in the classical terminology by looking at another tensor that you may be worrying about. The **first fundamental form** \mathbf{I} of M is just the induced Riemannian metric $i^*(\langle \cdot, \cdot \rangle)$ on M (where $\langle \cdot, \cdot \rangle$ is the usual Riemannian metric on \mathbb{R}^3). Thus

$$\mathbf{I}(p)(v_p, w_p) = \langle v_p, w_p \rangle \quad [= \langle v, w \rangle].$$

Classically, one worked not with \mathbf{I} and \mathbf{II} but with the functions $v \mapsto \mathbf{I}(v, v)$ and $v \mapsto \mathbf{II}(v, v)$, which are “quadratic forms” in the components of v (compare pg. I.314).

The second fundamental form provides us with a name for a quantity that appeared in Chapter 2:

0. PROPOSITION. Let c be a curve in M which is parameterized by arc-length. Let $c(0) = p$, and let $X = c'(0) \in M_p$. Then

$$\langle c''(0), \nu(p) \rangle = \Pi(X, X) \quad [\text{i.e., } \Pi(p)(X, X)].$$

Consequently, $\Pi(X, X)$ is the signed curvature κ_X of the curve cut out on M by the normal plane through $\nu(p)$ and X (with $X, \nu(p)$ positively oriented). Moreover, if κ_ϕ is the curvature of the curve c_ϕ cut out by the plane which contains X and makes an angle of ϕ with the normal plane, then

$$\kappa_\phi \cdot \cos \phi = \kappa_X.$$

PROOF. Clearly

$$(1) \quad \left. \frac{d\nu(c(s))}{ds} \right|_{s=0} = d\nu(X).$$

Since

$$\langle c'(s), \nu(c(s)) \rangle = 0 \quad \text{for all } s,$$

differentiation yields, using (1),

$$\begin{aligned} \langle c''(0), \nu(p) \rangle &= -\langle c'(0), d\nu(X) \rangle \\ &= -\langle X, d\nu(X) \rangle \\ &= \Pi(X, X). \end{aligned}$$

This, of course, is precisely the result (proved in precisely the same way) which was derived in Chapter 2. The rest of the theorem is proved just as before. ♦

Unlike Meusnier's Theorem, which involves Π in a trivial way, Euler's Theorem involves a crucial property of Π :

1. THEOREM. The second fundamental form Π of M is symmetric,

$$\Pi(p)(X_p, Y_p) = \Pi(p)(Y_p, X_p) \quad \text{for } X_p, Y_p \in M_p.$$

FIRST PROOF. Near p we can represent M as the image of a function $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$. Let $N = \nu \circ f$, so that N is " ν , considered as a function on \mathbb{R}^2 ". Then

$$d\nu \left(\frac{\partial f}{\partial s} \right) = d\nu \left(f_* \left(\frac{\partial}{\partial s} \right) \right) = f_* \left(\frac{\partial}{\partial s} \right) (\nu) = \frac{\partial}{\partial s} (\nu \circ f) = \frac{\partial N}{\partial s}.$$

Now we clearly have

$$\left\langle N, \frac{\partial f}{\partial t} \right\rangle = 0.$$

Differentiating with respect to s gives

$$\left\langle N, \frac{\partial^2 f}{\partial s \partial t} \right\rangle = - \left\langle \frac{\partial N}{\partial s}, \frac{\partial f}{\partial t} \right\rangle = - \left\langle dv \left(\frac{\partial f}{\partial s} \right), \frac{\partial f}{\partial t} \right\rangle = \Pi \left(\frac{\partial f}{\partial s}, \frac{\partial f}{\partial t} \right).$$

Exactly the same argument gives

$$(a) \quad \left\langle N, \frac{\partial^2 f}{\partial t \partial s} \right\rangle = \Pi \left(\frac{\partial f}{\partial t}, \frac{\partial f}{\partial s} \right).$$

Thus

$$\Pi \left(\frac{\partial f}{\partial s}, \frac{\partial f}{\partial t} \right) = \Pi \left(\frac{\partial f}{\partial t}, \frac{\partial f}{\partial s} \right).$$

Since $\partial f/\partial s, \partial f/\partial t$ are a basis for the tangent space of M at each point, Π is symmetric. For later use we also note that similar arguments lead to the equations

$$(b) \quad \Pi \left(\frac{\partial f}{\partial s}, \frac{\partial f}{\partial s} \right) = \left\langle N, \frac{\partial^2 f}{\partial s^2} \right\rangle$$

$$(c) \quad \Pi \left(\frac{\partial f}{\partial t}, \frac{\partial f}{\partial t} \right) = \left\langle N, \frac{\partial^2 f}{\partial t^2} \right\rangle.$$

Equations (a)–(c) are called the *Weingarten equations*.

SECOND (COORDINATE FREE, FANCY) PROOF. Let Y be a vector field in a neighborhood $U \subset M$ of p whose value at p is Y_p , and such that $Y(q) \in M_q$ for all $q \in U$. Since

$$\langle v, Y \rangle = 0 \quad \text{on } U,$$

we have

$$\begin{aligned} 0 &= X_p(\langle v, Y \rangle) = \langle X_p(v), Y_p \rangle + \langle v(p), X_p(Y) \rangle \\ &= \langle dv(X_p), Y_p \rangle + \langle v(p), X_p(Y) \rangle, \end{aligned}$$

where $X_p(Y)$ denotes the vector whose i^{th} component is $X_p(Y^i)$, for Y^i the i^{th} component of Y . This shows that

$$\Pi(p)(X_p, Y_p) = \langle v(p), X_p(Y) \rangle.$$

If a vector field X is picked similarly, then we have a corresponding equation, and it follows that

$$\Pi(p)(X_p, Y_p) - \Pi(p)(Y_p, X_p) = \langle v(p), X_p(Y) - Y_p(X) \rangle.$$

It is easy to check that in \mathbb{R}^n we have $X_p(Y) - Y_p(X) = [X, Y](p)$, so that

$$\Pi(p)(X_p, Y_p) - \Pi(p)(Y_p, X_p) = \langle v(p), [X, Y](p) \rangle.$$

But the right side is 0, since $[X, Y](p) \in M_p$. ♦

The symmetry of Π states an important property of the map $dv: M_p \rightarrow M_p$; this map is self-adjoint,

$$\langle dv(X), Y \rangle = \langle X, dv(Y) \rangle, \quad X, Y \in M_p.$$

Recall that if V is a vector space with an inner product $\langle \cdot, \cdot \rangle$, then a linear transformation $T: V \rightarrow V$ is called **self-adjoint** (with respect to $\langle \cdot, \cdot \rangle$) if

$$\langle Tv, w \rangle = \langle v, Tw \rangle \quad \text{for all } v, w \in V.$$

This is equivalent to saying that the matrix of T is symmetric with respect to any *orthonormal* basis. It is an elementary fact that eigenvectors v_1 and v_2 of T with distinct eigenvalues must be orthogonal, for if $Tv_i = \lambda_i v_i$ with $\lambda_1 \neq \lambda_2$, then

$$\lambda_1 \langle v_1, v_2 \rangle = \langle Tv_1, v_2 \rangle = \langle v_1, Tv_2 \rangle = \lambda_2 \langle v_1, v_2 \rangle.$$

The main theorem about self-adjoint transformations (the “spectral theorem”) states that a self-adjoint $T: V \rightarrow V$ has a basis of eigenvectors v_1, \dots, v_n . We have seen that eigenvectors with distinct eigenvalues are orthogonal. If two or more eigenvectors have the same eigenvalue, then all vectors in the subspace they span are eigenvectors, so we can select an orthogonal collection spanning the subspace. If we also choose our eigenvectors to be of unit length, we thus obtain an orthonormal basis of eigenvalues. Applying this to $dv: M_p \rightarrow M_p$ we see that there is an orthonormal basis X_1, X_2 of M_p with

$$dv(X_i) = \lambda_i X_i.$$

This fact is what is behind

2. THEOREM (EULER). The curvatures κ_X have a minimum k_1 in one direction and a maximum k_2 in a perpendicular direction. For a direction X making an angle of θ with the first direction we have

$$\kappa_X = k_1 \cos^2 \theta + k_2 \sin^2 \theta.$$

PROOF. Let X_1 and X_2 be unit eigenvectors of Π . Then by Proposition 0

$$\begin{aligned} \kappa_{X_i} &= \Pi(X_i, X_i) = -\langle dv(X_i), X_i \rangle \\ &= -\langle \lambda_i X_i, X_i \rangle \\ &= -\lambda_i. \end{aligned}$$

If we express any other unit vector $X \in M_p$ as

$$X = (\cos \theta)X_1 + (\sin \theta)X_2,$$

then

$$\begin{aligned}\kappa_X &= \Pi(X, X) = -\langle dv(X), X \rangle \\ &= -\langle \lambda_1(\cos \theta)X_1 + \lambda_2(\sin \theta)X_2, (\cos \theta)X_1 + (\sin \theta)X_2 \rangle \\ &= -\lambda_1 \cos^2 \theta - \lambda_2 \sin^2 \theta.\end{aligned}$$

As before, this completes the proof.* ♦

To connect the curvatures k_1, k_2 with K , we first note that K can be expressed very succinctly in terms of dv .

3. PROPOSITION. The Gaussian curvature $K(p)$ at $p \in M$ is

$$K(p) = \text{determinant of } dv: M_p \rightarrow M_p.$$

PROOF. If $Y_1, Y_2 \in M_p$ are linearly independent, then

$$\begin{aligned}K(p) &= \frac{v^*(\sigma')(p)(Y_1, Y_2)}{dV(p)(Y_1, Y_2)} \\ &= \frac{\sigma'(v(p))(v_*Y_1, v_*Y_2)}{dV(p)(Y_1, Y_2)}.\end{aligned}$$

Using the fact that $S^2_{v(p)}$ is parallel to M_p , and remembering that we are considering dv as a map into M_p , this can be written simply

$$K(p) = \frac{dV(p)(dv(Y_1), dv(Y_2))}{dV(p)(Y_1, Y_2)}.$$

Since dV is a 2-form, this ratio is indeed just $\det dv$. ♦

* Notice that we have reduced Euler's Theorem to a fact about the eigenvalues $\lambda_1 \leq \lambda_2$ of a self-adjoint transformation $T: V \rightarrow V$ on a 2-dimensional vector space:

$$\lambda_1 = \min_{\|v\|=1} \langle Tv, v \rangle, \quad \lambda_2 = \max_{\|v\|=1} \langle Tv, v \rangle.$$

For higher dimensions there is a minimax definition of the various eigenvalues. See Courant, *Über die Abhängigkeit ...*, Nachrichten, Königlichen Gesellschaft der Wissenschaften zu Göttingen, Math. Phys. Klasse 1919, pp. 255–264.

4. COROLLARY. Let $Y_1, Y_2 \in M_p$ be orthonormal. Then

$$K(p) = \det(\Pi(Y_i, Y_j)) = \det \begin{pmatrix} \Pi(Y_1, Y_1) & \Pi(Y_1, Y_2) \\ \Pi(Y_2, Y_1) & \Pi(Y_2, Y_2) \end{pmatrix}.$$

PROOF. Since $\Pi(Y_i, Y_j) = \langle -dv(Y_i), Y_j \rangle$, the matrix of dv with respect to Y_1, Y_2 is

$$\begin{pmatrix} -\Pi(Y_1, Y_1) & -\Pi(Y_2, Y_1) \\ -\Pi(Y_1, Y_2) & -\Pi(Y_2, Y_2) \end{pmatrix},$$

which has the same determinant as the matrix $(\Pi(Y_i, Y_j))$. ♦

5. COROLLARY. Let $Y_1, Y_2 \in M_p$ be linearly independent. Then

$$K(p) = \frac{\det(\Pi(Y_i, Y_j))}{\det(\langle Y_i, Y_j \rangle)} = \frac{\det(\Pi(Y_i, Y_j))}{\det(I(Y_i, Y_j))}.$$

PROOF. Corollary 4 proves the formula for orthonormal X_1, X_2 . If $Y_i = \sum_j a_{ij} X_j$, then replacing X_1, X_2 by Y_1, Y_2 multiplies both numerator and denominator by $\det(a_{ij})$. ♦

6. COROLLARY. For any $p \in M$ we have

$$K(p) = k_1 \cdot k_2.$$

PROOF. Apply Corollary 4 when $Y_1, Y_2 \in M_p$ are the orthonormal basis of eigenvectors of dv , with eigenvalues $-k_1, -k_2$. Then

$$K(p) = \det \begin{pmatrix} -k_1 & 0 \\ 0 & -k_2 \end{pmatrix} = k_1 \cdot k_2. \quad \spadesuit$$

Corollary 5 allows us to develop an explicit formula for K , which involves some standard symbolism to be introduced first. If $\chi = (x, y)$ is a coordinate system on M , then we write the first fundamental form I as

$$I = E dx \otimes dx + F dx \otimes dy + F dy \otimes dx + G dy \otimes dy.$$

If $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ is the inverse of χ , so that

$$\begin{aligned} \frac{\partial}{\partial x} &= \frac{\partial f}{\partial s} \\ \frac{\partial}{\partial y} &= \frac{\partial f}{\partial t}, \end{aligned}$$

then

$$\begin{aligned}
 E &= \left\langle \frac{\partial f}{\partial s}, \frac{\partial f}{\partial s} \right\rangle = \sum_{i=1}^3 \left(\frac{\partial f^i}{\partial s} \right)^2 \\
 F &= \sum_{i=1}^3 \frac{\partial f^i}{\partial s} \frac{\partial f^i}{\partial t} \\
 G &= \sum_{i=1}^3 \left(\frac{\partial f^i}{\partial t} \right)^2.
 \end{aligned}
 \tag{*}$$

[Notice that the left sides of these equations really mean $E(f(s, t))$, etc. (the functions E, F, G themselves are defined on M). This is just the form we want. For example, to compute $\partial E / \partial x$ at $q = f(\bar{s}, \bar{t})$ we have

$$\begin{aligned}
 \frac{\partial E}{\partial x}(q) &= D_1(E \circ \chi^{-1})(\chi(q)) \\
 &= D_1(E \circ f)(\chi(q)) \\
 &= \frac{\partial E}{\partial s}(\bar{s}, \bar{t});
 \end{aligned}$$

the E on the last line denotes the same function on \mathbb{R}^2 which appears in the equations (*).

The symbols E, F, G were introduced by Gauss himself (at the beginning of section 11 of his paper), and they have remained standard ever since. There are also standard symbols for the second fundamental form:

$$\Pi = l \, dx \otimes dx + m \, dx \otimes dy + m \, dy \otimes dx + n \, dy \otimes dy.$$

To obtain formulas for l, m, n , we look at the Weingarten equations in the first proof of Theorem 1, and note that

$$\begin{aligned}
 l &= \Pi \left(\frac{\partial f}{\partial s}, \frac{\partial f}{\partial s} \right) = \left\langle N, \frac{\partial^2 f}{\partial s^2} \right\rangle = \sum_{i=1}^3 v^i(f(s, t)) \frac{\partial^2 f^i}{\partial s^2} \\
 m &= \sum_{i=1}^3 v^i(f(s, t)) \frac{\partial^2 f^i}{\partial s \partial t} \\
 n &= \sum_{i=1}^3 v^i(f(s, t)) \frac{\partial^2 f^i}{\partial t^2};
 \end{aligned}
 \tag{**}$$

formulas for $v^i(f(s, t))$ have already been given on pages 113–114. Using Corollary 5, we now have the classical formula

$$K(p) = \frac{ln - m^2}{EG - F^2}(p).$$

The symbols l, m, n do not appear in Gauss, who instead uses the symbols D, D', D'' for certain quantities proportional to them. These symbols are introduced on page 87; it is easy to see that Gauss' formula for K on this page is equivalent to the one we have just derived, although Gauss obtained it in a different way, by beginning with the formula which we derived on page 119.

Our next theorem probably requires an apology in advance. The result looks amazingly unappetizing; it's hard to see why anyone would want it even if he had it, and the proof is merely an involved calculation. Nevertheless, we will justify its existence soon after proving it. The calculation appearing in the proof should be a lot easier to follow than Gauss'.

7. THEOREM. Let (x, y) be a coordinate system on a neighborhood of $p \in M \subset \mathbb{R}^3$, and let

$$I = i^*(\langle \cdot, \cdot \rangle) = E dx \otimes dx + F dx \otimes dy + F dy \otimes dx + G dy \otimes dy.$$

Then

$$\begin{aligned} 4(EG - F^2)^2 K = & E \left(\frac{\partial E}{\partial y} \frac{\partial G}{\partial y} - 2 \frac{\partial F}{\partial x} \frac{\partial G}{\partial y} + \left(\frac{\partial G}{\partial x} \right)^2 \right) \\ & + F \left(\frac{\partial E}{\partial x} \frac{\partial G}{\partial y} - \frac{\partial E}{\partial y} \frac{\partial G}{\partial x} - 2 \frac{\partial E}{\partial y} \frac{\partial F}{\partial y} + 4 \frac{\partial F}{\partial x} \frac{\partial F}{\partial y} - 2 \frac{\partial F}{\partial x} \frac{\partial G}{\partial x} \right) \\ & + G \left(\frac{\partial E}{\partial x} \frac{\partial G}{\partial x} - 2 \frac{\partial E}{\partial x} \frac{\partial F}{\partial y} + \left(\frac{\partial E}{\partial y} \right)^2 \right) \\ & - 2(EG - F^2) \left(\frac{\partial^2 E}{\partial y^2} - 2 \frac{\partial^2 F}{\partial x \partial y} + \frac{\partial^2 G}{\partial x^2} \right). \end{aligned}$$

PROOF. Consider the inverse $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ of the coordinate system (x, y) . To save space we will denote

$$\frac{\partial^2 f}{\partial s \partial t} = D_{12} f \quad \text{simply by } f_{12},$$

and similarly for other partial derivatives. We have

$$K = \frac{ln - m^2}{EG - F^2},$$

where, by (**),

$$\begin{aligned} l &= \langle f_{11}, N \rangle = \left\langle f_{11}, \frac{f_1 \times f_2}{\sqrt{EG - F^2}} \right\rangle \\ m &= \langle f_{12}, N \rangle = \left\langle f_{12}, \frac{f_1 \times f_2}{\sqrt{EG - F^2}} \right\rangle \\ n &= \langle f_{22}, N \rangle = \left\langle f_{22}, \frac{f_1 \times f_2}{\sqrt{EG - F^2}} \right\rangle. \end{aligned}$$

Thus

$$\begin{aligned} K(EG - F^2)^2 &= \langle f_{11}, f_1 \times f_2 \rangle \cdot \langle f_{22}, f_1 \times f_2 \rangle - \langle f_{12}, f_1 \times f_2 \rangle^2 \\ &= \det \begin{pmatrix} f_{11} \\ f_1 \\ f_2 \end{pmatrix} \cdot \det \begin{pmatrix} f_{22} \\ f_1 \\ f_2 \end{pmatrix} - \det \begin{pmatrix} f_{12} \\ f_1 \\ f_2 \end{pmatrix} \cdot \det \begin{pmatrix} f_{12} \\ f_1 \\ f_2 \end{pmatrix}. \end{aligned}$$

In this equation each f_i and f_{ij} is considered as a row of the matrix. If we use f_i^t and f_{ij}^t to denote the columns with the same entries, then we also have

$$\begin{aligned} K(EG - F^2)^2 &= \det \begin{pmatrix} f_{11} \\ f_1 \\ f_2 \end{pmatrix} \cdot \det(f_{22}^t, f_1^t, f_2^t) - \det \begin{pmatrix} f_{12} \\ f_1 \\ f_2 \end{pmatrix} \cdot \det(f_{12}^t, f_1^t, f_2^t) \\ &= \det \left[\begin{pmatrix} f_{11} \\ f_1 \\ f_2 \end{pmatrix} \cdot (f_{22}^t, f_1^t, f_2^t) \right] \\ &\quad - \det \left[\begin{pmatrix} f_{12} \\ f_1 \\ f_2 \end{pmatrix} \cdot (f_{12}^t, f_1^t, f_2^t) \right] \\ &= \det \begin{pmatrix} \langle f_{11}, f_{22} \rangle & \langle f_{11}, f_1 \rangle & \langle f_{11}, f_2 \rangle \\ \langle f_1, f_{22} \rangle & E & F \\ \langle f_2, f_{22} \rangle & F & G \end{pmatrix} \\ &\quad - \det \begin{pmatrix} \langle f_{12}, f_{12} \rangle & \langle f_{12}, f_1 \rangle & \langle f_{12}, f_2 \rangle \\ \langle f_{12}, f_1 \rangle & E & F \\ \langle f_{12}, f_2 \rangle & F & G \end{pmatrix} \end{aligned}$$

$$= \det \begin{pmatrix} \langle f_{11}, f_{22} \rangle - \langle f_{12}, f_{12} \rangle & \langle f_{11}, f_1 \rangle & \langle f_{11}, f_2 \rangle \\ \langle f_1, f_{22} \rangle & E & F \\ \langle f_2, f_{22} \rangle & F & G \end{pmatrix} \\ - \det \begin{pmatrix} 0 & \langle f_{12}, f_1 \rangle & \langle f_{12}, f_2 \rangle \\ \langle f_{12}, f_1 \rangle & E & F \\ \langle f_{12}, f_2 \rangle & F & G \end{pmatrix}.$$

But from the definitions of E, F, G in (*) we have

$$\langle f_{11}, f_1 \rangle = \frac{1}{2} E_1 \quad (E_1 = \partial E / \partial s)$$

$$\langle f_{12}, f_1 \rangle = \frac{1}{2} E_2$$

$$\langle f_{22}, f_2 \rangle = \frac{1}{2} G_2$$

$$\langle f_{12}, f_2 \rangle = \frac{1}{2} G_1$$

$$\langle f_{11}, f_2 \rangle = F_1 - \frac{1}{2} E_2$$

$$\langle f_{22}, f_1 \rangle = F_2 - \frac{1}{2} G_1.$$

Moreover, from the fourth and fifth equations we obtain

$$\frac{1}{2} G_{11} = \frac{\partial}{\partial s} \langle f_{12}, f_2 \rangle = \langle f_{121}, f_2 \rangle + \langle f_{12}, f_{21} \rangle$$

$$F_{12} - \frac{1}{2} E_{22} = \frac{\partial}{\partial t} \langle f_{11}, f_2 \rangle = \langle f_{112}, f_2 \rangle + \langle f_{11}, f_{22} \rangle.$$

Subtracting the first of these from the second, we then obtain

$$\langle f_{11}, f_{22} \rangle - \langle f_{12}, f_{12} \rangle = -\frac{1}{2} G_{11} + F_{12} - \frac{1}{2} E_{22}.$$

So we have, finally,

$$K(EG - F^2)^2 = \det \begin{pmatrix} -\frac{1}{2} G_{11} + F_{12} - \frac{1}{2} E_{22} & \frac{1}{2} E_1 & F_1 - \frac{1}{2} E_2 \\ F_2 - \frac{1}{2} G_1 & E & F \\ \frac{1}{2} G_2 & F & G \end{pmatrix} \\ - \det \begin{pmatrix} 0 & \frac{1}{2} E_2 & \frac{1}{2} G_1 \\ \frac{1}{2} E_2 & E & F \\ \frac{1}{2} G_1 & F & G \end{pmatrix},$$

which gives the formula in the statement of the theorem! ❖

From Theorem 7 we can deduce an immediate Corollary, which appears on page 93 of the translation:

“Thus the formula of the preceding article leads of itself to the remarkable

THEOREM. If a curved surface is developed upon any other surface whatever, the measure of curvature in each point remains unchanged.”

The Latin word for ‘remarkable’ has become part of the traditional name for this result:

8. COROLLARY (THEOREMA EGREGIUM). If $f, g: M \rightarrow \mathbb{R}^3$ are two imbeddings (or even immersions) such that $f^*\langle \cdot, \cdot \rangle = g^*\langle \cdot, \cdot \rangle$, then the Gaussian curvature of $f(M) \subset \mathbb{R}^3$ at $f(p)$ equals the Gaussian curvature of $g(M)$ at $g(p)$.

The Theorema Egregium justifies the close attention which we have given to the Gaussian curvature K of a surface. Although defined in terms of the imbedding of the surface in \mathbb{R}^3 , it turns out to depend only on the Riemannian metric induced by that imbedding. This shows why the Gaussian curvature of a cylinder must be 0—there is a (local) isometry from the plane to the cylinder: If the cylinder $Z \subset \mathbb{R}^3$ is

$$Z = \{(x, y, z) : x^2 + y^2 = a^2\},$$

then a local isometry $f: \mathbb{R}^2 \rightarrow Z$ is given by

$$f(s, t) = \left(a \cos \frac{s}{a}, a \sin \frac{s}{a}, t \right).$$

It is easily checked that f_* is an isometry at any point, but the result should be clear without any calculations whatsoever. To prove that Z is locally isometric to \mathbb{R}^2 , just take a piece of paper, and roll it up into a cylinder. The map which takes a point on the flat piece of paper into the corresponding point on the rolled up piece of paper is an isometry. The isometric properties of this map

are expressed by the everyday experience that paper cannot be stretched, but merely bent.

The Theorema Egregium is often expressed by saying that Gaussian curvature is a “bending invariant”. Anyone who has ever made a paper dunce hat knows (though he may not know that he knows) that the cone is also locally isometric to the plane, and hence has Gaussian curvature 0.

Map makers, and anyone who has had to wrap a spherical object, know that a piece of paper cannot be bent onto even a small portion of a sphere. A mathematical proof follows immediately from the Theorema Egregium, for a sphere has non-zero Gaussian curvature. The situation for surfaces is thus completely different from that for curves. All 1-dimensional Riemannian manifolds are locally isometric to \mathbb{R}^1 , for if we choose an immersed curve c in the manifold, then the arclength function of c is an isometry into \mathbb{R}^1 . So there are no interesting bending invariants of a curve; all the interesting characteristics of a curve are invariants under the group of Euclidean motions. The Gaussian curvature is, of course, an invariant under the group of Euclidean motions, but it is also invariant under the much larger (but still important) group of maps which are merely defined on the surface, and are isometries there. (As a contrast, the **mean curvature** $\frac{1}{2}(k_1 + k_2)$ is invariant under the group of Euclidean motions, but it is *not* a bending invariant; for example, the plane has mean curvature 0, while a cylinder of radius a has mean curvature $a/2$.)

In the previous paragraph we appealed to the Theorema Egregium to prove that a sphere is not locally isometric to the plane. But it is also possible to give a much more elementary proof of this fact, that will convince some one who knows a little geometry. If there were an isometry from a neighborhood of $p \in S^2$ into the plane, then a small triangle ABC around p , with portions

of great circles as sides, would have to be mapped into an ordinary triangle $A'B'C'$ on the plane, since great circles are geodesics on the sphere. The angles at A, B, C would also have to equal the angles A', B', C' . This is impossible, since $\angle A + \angle B + \angle C > \pi$, while $\angle A' + \angle B' + \angle C' = \pi$. This phenomenon turns out to have a generalization to arbitrary surfaces, a result that Gauss felt “ought to be counted among the most elegant in the theory of curved surfaces”. In deriving this result we will essentially follow Gauss, but we will use some of our previous results about geodesics, and suppress some of the additional formulas which Gauss obtains along the way, so that the argument may appear somewhat simpler.

In expounding the theory of geodesics, Gauss derives two conditions, of entirely different natures, for a geodesic on a surface. Although the first of these conditions is not necessary for our final goal, it is an interesting exercise in the calculus of variations, as well as an interesting result in its own right. We consider a curve $c: [a, b] \rightarrow M$ and a variation α keeping endpoints fixed. Looking at the energy function (Gauss looks at length instead), we have

$$\begin{aligned} \frac{dE(\bar{\alpha}(u))}{du} \Big|_{u=0} &= \frac{d}{du} \Big|_{u=0} \frac{1}{2} \int_a^b \left\langle \frac{\partial \alpha}{\partial t}(u, t), \frac{\partial \alpha}{\partial t}(u, t) \right\rangle dt \\ &= \int_a^b \left\langle \gamma'(t), \frac{\partial^2 \alpha}{\partial u \partial t}(0, t) \right\rangle dt \\ &= - \int_a^b \left\langle \gamma''(t), \frac{\partial \alpha}{\partial u}(0, t) \right\rangle dt, \quad \text{using integration by parts.} \end{aligned}$$

This result holds for *any* variation α keeping endpoints fixed. The final integral

must therefore be zero whenever $\partial\alpha/\partial u(0,t) \in M_{\gamma(t)}$ for all t , since there is then a variation α through curves on M with these values of $\partial\alpha/\partial u(0,t)$. In other

words, γ is a geodesic on M if and only if

$$\int_a^b \langle \gamma''(t), \eta(t) \rangle dt = 0 \quad \text{for every } \eta \text{ satisfying } \langle \eta(t), v(\gamma(t)) \rangle = 0.$$

In particular, we can choose

$$\eta(t) = \phi(t)[\gamma''(t) - \langle \gamma''(t), v(\gamma(t)) \rangle v(\gamma(t))]$$

where ϕ is a C^∞ function on $[a, b]$ with $\phi > 0$ on (a, b) and $\phi(a) = \phi(b) = 0$. We then obtain

$$0 = \int_a^b \phi(t) [\langle \gamma''(t), \gamma''(t) \rangle - \langle \gamma''(t), v(\gamma(t)) \rangle^2] dt.$$

Since $v(\gamma(t))$ has length 1, the Schwarz inequality (Theorem I.9-1(2)) shows that the term in brackets is always ≤ 0 . Since $\phi(t) > 0$ on (a, b) , the term in brackets must actually be 0 everywhere. This implies that $\gamma''(t)$ and $v(\gamma(t))$ are everywhere *linearly dependent*. In other words,

The curve γ on M is a geodesic if and only if
 γ'' is always perpendicular to M .

Notice that this condition makes sense only for a surface in \mathbb{R}^3 ; the vector γ'' has no meaning for an abstract Riemannian manifold.

We now pass to the equations for a geodesic on any 2-dimensional Riemannian manifold. However, we will work with a special coordinate system. Consider a neighborhood of $p \in M$ which is $\exp(U)$, where $U \subset M_p$ is a neighborhood of 0 on which \exp is one-one. Identify M_p with \mathbb{R}^2 by choosing an orthonormal basis for M_p . Introducing polar coordinates (ρ, ϕ) on M_p (minus some ray), we obtain a coordinate system $(r, \varphi) = (\rho, \phi) \circ \exp^{-1}$ on $\exp(U)$ (minus some geodesic ray), where ρ is now chosen so that $\rho = 1$ for vectors in M_p with norm 1.

This implies that $\|\partial/\partial r\| = 1$. We also know that $\langle \partial/\partial r, \partial/\partial \varphi \rangle = 0$, by Gauss' Lemma. So we have

$$\langle \cdot, \cdot \rangle = dr \otimes dr + G d\varphi \otimes d\varphi$$

for some function G . The function G is just $G(q) = \langle \partial/\partial \varphi|_q, \partial/\partial \varphi|_q \rangle$. Clearly, G can be considered as defined on $\exp(U) - \{p\}$, even though any particular coordinate system (r, φ) can be defined only on $\exp(U)$ minus some geodesic ray. In terms of the g_{ij} notation we have

$$\begin{aligned} g_{11} &= 1, & g^{11} &= 1 \\ g_{12} &= g_{21} = 0, & g^{12} &= g^{21} = 0 \\ g_{22} &= G, & g^{22} &= \frac{1}{G}. \end{aligned}$$

An easy calculation from the definitions (pp. I.326 and I.328) then gives

$$[12, 2] = [22, 2] = \frac{1}{2} \frac{\partial G}{\partial r}$$

$$[22, 1] = -\frac{1}{2} \frac{\partial G}{\partial r}$$

$$\text{all other } [ij, k] = 0;$$

$$\Gamma_{12}^2 = \Gamma_{21}^2 = \frac{1}{2G} \frac{\partial G}{\partial r}$$

$$\Gamma_{22}^1 = -\frac{1}{2} \frac{\partial G}{\partial r}$$

$$\text{all other } \Gamma_{ij}^k = 0.$$

The equations for a geodesic (pg. I.329) thus give

$$(1) \quad \frac{d^2 \gamma^1}{ds^2} = \frac{1}{2} \frac{\partial G}{\partial r}(\gamma(s)) \left(\frac{d\gamma^2}{ds} \right)^2.$$

Now suppose γ is some curve parameterized by arclength, and let $\theta(s)$ be the angle between $\gamma'(s)$ and $\partial/\partial r|_{\gamma(s)}$. Clearly

$$(2) \quad \begin{aligned} \cos \theta(s) &= \left\langle \gamma'(s), \frac{\partial}{\partial r} \Big|_{\gamma(s)} \right\rangle \\ &= \left\langle \frac{d\gamma^1}{ds} \frac{\partial}{\partial r} \Big|_{\gamma(s)} + \frac{d\gamma^2}{ds} \frac{\partial}{\partial \varphi} \Big|_{\gamma(s)}, \frac{\partial}{\partial r} \Big|_{\gamma(s)} \right\rangle \\ &= \frac{d\gamma^1}{ds}. \end{aligned}$$

For a geodesic γ we obtain from (1) and (2),

$$(3) \quad \begin{aligned} \frac{1}{2} \frac{\partial G}{\partial r}(\gamma(s)) \left(\frac{d\gamma^2}{ds} \right)^2 &= \frac{d \cos \theta(s)}{ds} \\ &= -\sin \theta(s) \frac{d\theta(s)}{ds}. \end{aligned}$$

Finally, note that the area of the parallelogram spanned by the unit vectors $\gamma'(s)$ and $\partial/\partial r|_{\gamma(s)}$ equals

$$(4) \quad \begin{aligned} \sin \theta(s) \quad \text{and also equals} \quad dV \left(\frac{\partial}{\partial r} \Big|_{\gamma(s)}, \gamma'(s) \right) \\ &= \sqrt{G}(\gamma(s)) dr \wedge d\varphi \left(\frac{\partial}{\partial r} \Big|_{\gamma(s)}, \frac{d\gamma^1}{ds} \frac{\partial}{\partial r} \Big|_{\gamma(s)} + \frac{d\gamma^2}{ds} \frac{\partial}{\partial \varphi} \Big|_{\gamma(s)} \right) \\ &= \sqrt{G}(\gamma(s)) \frac{d\gamma^2}{ds}. \end{aligned}$$

So we obtain

$$\frac{1}{2} \frac{\partial G}{\partial r}(\gamma(s)) \left(\frac{d\gamma^2}{ds} \right)^2 = -\sqrt{G}(\gamma(s)) \frac{d\gamma^2}{ds} \frac{d\theta}{ds},$$

$$\frac{d\theta}{ds} = -\frac{1}{2} \frac{\frac{\partial G}{\partial r}}{\sqrt{G}}(\gamma(s)) \frac{d\gamma^2}{ds},$$

and thus

$$(*) \quad \frac{d\theta}{ds} = \frac{\partial \sqrt{G}}{\partial r}(\gamma(s)) \frac{d\gamma^2}{ds}$$

for any geodesic γ . This is the equation Gauss finally obtains, on page 107 of the translation.

Gauss also obtains the expression for K in this special coordinate system. Theorem 7 now takes the much simpler form

$$4G^2 K = \left(\frac{\partial G}{\partial r} \right)^2 - 2G \frac{\partial^2 G}{\partial r^2},$$

which gives

$$(**) \quad K = -\frac{1}{\sqrt{G}} \frac{\partial^2 \sqrt{G}}{\partial r^2}.$$

It will now be necessary to obtain some further information about the function \sqrt{G} , for which Gauss gives very brief arguments. We will find it convenient to express G “as a function of ρ and ϕ ”; that is, we consider

$$g = G \circ \exp \circ P^{-1},$$

where $P: M_p\text{-ray} \rightarrow (0, \delta] \times (0, 2\pi)$ is $P = (\rho, \phi)$, so that $g(\rho_0, \phi_0)$ is $G(\exp v)$, where $v \in M_p$ has polar coordinates (ρ_0, ϕ_0) . At times it will also be convenient to use (ρ, ϕ) to stand for a point in M_p , as well as standing for the coordinate functions themselves.

The function g can be considered as defined on $(0, \delta] \times [0, 2\pi]$ (with the same values at $(\rho, 0)$ as at $(\rho, 2\pi)$). What we want to examine is the behavior

of g near $(0, \phi)$. We do this by comparing distances on M_p with those on M . On the vector space M_p we have an inner product $\langle \cdot, \cdot \rangle_p$; since the tangent space $(M_p)_v$ of M_p at $v \in M_p$ can be identified with M_p , we can use $\langle \cdot, \cdot \rangle_p$ to obtain a Riemannian metric on M_p . To keep things straight, we will use v, w to denote elements of M_p , and X_v, Y_v to denote tangent vectors in the tangent space $(M_p)_v$. For each $X_v \in (M_p)_v$ we thus have a certain norm, which we will denote by $\|X_v\|$. Now recall that $\exp_*: (M_p)_0 \rightarrow M_p$ is the identity map (when we identify $(M_p)_0$ with M_p), so that we certainly have

$$\|X_0\| = \|\exp_*(X_0)\|_p, \quad X_0 \in (M_p)_0.$$

If $\varepsilon > 0$, it follows that for $v \in M_p$ sufficiently close to 0 and $X_v \in (M_p)_v$ of unit norm $\|X_v\| = 1$ we have

$$\left| \|X_v\| - \|\exp_*(X_v)\|_{\exp(v)} \right| < \varepsilon,$$

so that for any $Y_v \in (M_p)_v$ we have

$$\left| \|Y_v\| - \|\exp_*(Y_v)\|_{\exp(v)} \right| < \varepsilon \cdot \|Y_v\|.$$

Noting that $\exp_*(\partial/\partial\phi|_v) = \partial/\partial\phi|_{\exp(v)}$, we have

$$(1) \quad \left| \left\| \frac{\partial}{\partial\phi} \right\|_v - \left\| \frac{\partial}{\partial\phi} \right\|_{\exp(v)} \right| < \varepsilon \cdot \left\| \frac{\partial}{\partial\phi} \right\|_v,$$

for all sufficiently small v , while clearly

$$\left\| \frac{\partial}{\partial\phi} \right\|_v = \|v\|_p = \rho(v).$$

Dividing all terms of (1) by ρ yields

$$\left| 1 - \frac{\sqrt{g}(\rho, \phi)}{\rho} \right| < \varepsilon,$$

for all sufficiently small ρ . Since this is true for all $\varepsilon > 0$, we have thus shown that

$$(2) \quad \sqrt{g}(\rho, \phi) = \rho + o(\rho),$$

where $o(\rho)$ denotes a function on $(0, \delta] \times [0, 2\pi]$ such that

$$\lim_{\rho \rightarrow 0} \frac{o(\rho)}{\rho} = 0 \quad (\text{uniformly in } \phi).$$

Clearly \sqrt{g} remains continuous on $[0, \delta] \times [0, 2\pi]$ if we define

$$(***) \quad \sqrt{g}(0, \phi) = 0.$$

Notice, moreover, that equation (2) now immediately implies that

$$(***) \quad \frac{\partial \sqrt{g}}{\partial \rho}(0, \phi) = 1$$

(where $\partial \sqrt{g} / \partial \rho(0, \phi)$ really denotes a right hand derivative). However, we want to know that $\partial \sqrt{g} / \partial \rho$ is actually continuous on $[0, \delta] \times [0, 2\pi]$; the argument for this will require another step.

From equation (**) we have, on $(0, \delta] \times [0, 2\pi]$,

$$\frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) = -\sqrt{g}(\rho, \phi) \cdot K(\exp(\rho, \phi)) \quad \begin{array}{l} \text{[where } \exp(\rho, \phi) \text{ really means} \\ \exp(v), \text{ where } v \in M_p \text{ has} \\ \text{polar coordinates } (\rho, \phi)\text{]}, \end{array}$$

which shows that $\partial^2 \sqrt{g} / \partial \rho^2(\rho, \phi) \rightarrow 0$ as $\rho \rightarrow 0$. It follows, in particular, that $\partial^2 \sqrt{g} / \partial \rho^2$ is bounded. For $\rho > 0$ we have

$$\frac{\partial \sqrt{g}}{\partial \rho}(\rho, \phi) = \frac{\partial \sqrt{g}}{\partial \rho}(\delta, \phi) - \int_{\rho}^{\delta} \frac{\partial^2 \sqrt{g}}{\partial \rho^2}(t, \phi) dt,$$

which immediately implies that

$$\lim_{\rho \rightarrow 0} \frac{\partial \sqrt{g}}{\partial \rho}(\rho, \phi) \text{ exists.}$$

By a standard theorem of calculus (see e.g., Spivak, *Calculus*, 3rd ed., pg. 200), the limit must be $\partial \sqrt{g} / \partial \rho(0, \phi)$, which equals 1, by (****). It follows, in particular, that

$$\begin{aligned} \text{(*****)} \quad \int_0^{\rho_0} -\frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) d\rho &= \lim_{\varepsilon \rightarrow 0} \int_{\varepsilon}^{\rho_0} -\frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) d\rho \\ &= \lim_{\varepsilon \rightarrow 0} \frac{\partial \sqrt{g}}{\partial \rho}(\varepsilon, \phi) - \frac{\partial \sqrt{g}}{\partial \rho}(\rho_0, \phi) \\ &= 1 - \frac{\partial \sqrt{g}}{\partial \rho}(\rho_0, \phi). \end{aligned}$$

We are ready to prove a theorem.

9. THEOREM. Let A, B, C be three points of $\exp(U)$, where U is a convex neighborhood of $0 \in M_A$, on which \exp is a diffeomorphism, and let α be a geodesic in $\exp(U)$ between B and C . Denote the geodesic segment from A to C by β and the geodesic segment from A to B by γ , and let $\triangle ABC$ be the “geodesic triangle” bounded by α, β, γ . Also let $\angle A$ denote the angle between β and γ , etc. Then

$$\int_{\triangle ABC} K dV = \angle A + \angle B + \angle C - \pi.$$

PROOF. Let $b, c \in M_p$ be the vectors with $\exp(b) = B$ and $\exp(c) = C$. Choose the polar coordinates ρ, ϕ on M_p so that $\phi(b) = 0$. Then $\phi(c)$ is just $\angle A$.

It is easy to see that α cannot intersect the same geodesic ray through A twice, so it must be the image under \exp of a curve in M_A which is the graph $\rho = f(\phi)$ of some function in the polar coordinates ρ, ϕ . Let $\theta(\phi)$ be the angle between $\partial/\partial r|_q$ and $\alpha'(q)$, where q is \exp of the vector with polar coordinates $(f(\phi), \phi)$.

We clearly have

$$\theta(0) = \pi - \angle B, \quad \theta(\angle A) = \angle C.$$

Consequently,

$$\begin{aligned}
 \int_{\Delta ABC} K dV &= \int_{\exp^{-1}(\Delta ABC)} \exp^*(K dV) \\
 &= \int_{\exp^{-1}(\Delta ABC)} -\frac{1}{\sqrt{g}} \frac{\partial^2 \sqrt{g}}{\partial \rho^2} \cdot \sqrt{g} d\rho \wedge d\phi \quad \text{by } (**) \\
 &= \int_0^{\angle A} \left(\int_0^{f(\phi)} -\frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) d\rho \right) d\phi \\
 &= \int_0^{\angle A} \left(1 - \frac{\partial \sqrt{g}}{\partial \rho}(f(\phi), \phi) \right) d\phi \quad \text{by } (****) \\
 &= \int_0^{\angle A} \left(1 + \frac{d\theta}{d\phi}(\phi) \right) d\phi \quad \text{by } (*) \\
 &= \angle A + \theta(\angle A) - \theta(0) \\
 &= \angle A + \angle C + \angle B - \pi. \quad \spadesuit
 \end{aligned}$$

According to Theorem 9, on a surface with everywhere positive curvature the sum of the angles of a triangle with geodesic sides is always $> \pi$, while on a surface with everywhere negative curvature the sum of the angle is always $< \pi$. This certainly looks like the case in pictures, and one can even see that the bigger the triangle, the bigger the difference between $\angle A + \angle B + \angle C$ and π .

Notice that in the proof of Theorem 9 we are essentially converting an integral over the region $\triangle ABC$ into an integral over (one of) its sides—this looks suspiciously like Stokes' Theorem. In Volume III, we will indeed be able to present a much nicer proof of Theorem 9, which does not depend on a special coordinate system, and which makes explicit the role of Stokes' Theorem. Moreover, we will be able to derive other important consequences of the same results. However, for the moment, we are more interested in two questions. How did Gauss think of the Theorema Egregium? and What does it really mean?

The paper which we have just examined was based on an earlier paper which Gauss did not publish (also included in the Princeton University Library translation). From the earlier paper it appears that Gauss first proved the result in Theorem 9. Notice that this result gives the Theorema Egregium as a corollary, for it implies that

$$K(p) = \lim_{\triangle ABC \rightarrow p} \frac{\angle A + \angle B + \angle C - \pi}{\text{area } \triangle ABC},$$

and this limit is defined totally in terms of the Riemannian metric on the surface. After realizing this, Gauss probably said to himself: "Since K depends only on the metric, it should be possible to show this by a direct computation; and if any one can do the computation, I certainly can."

To answer the second question—What does the Theorema Egregium really mean?—requires a more serious effort. The original definition of K seemed perfectly satisfactory—it has immediate geometric appeal and is even fairly easy to compute. The only defect of the definition is that the concept being defined turns out to be too good; it turns out to be invariant under isometries, while its definition is not.

One of the dogmas of modern mathematics is that for any object that is invariant in any sort of way, a definition must be found that exhibits this invariance directly (even if such a definition is harder to understand than the original!). The definition of determinants is a good example. An elementary treatment of determinants usually begins by defining the determinant of a *matrix*, either by writing down a messy formula, or in an inductive way that really amounts to the messy formula. It is then shown that $\det(A \cdot B) = \det A \cdot \det B$; from this

it follows that one can define the determinant of a *linear transformation* to be the determinant of its matrix with respect to any basis. This naturally leads one to seek a definition of the determinant of a linear transformation $T: V \rightarrow V$ which does not require a choice of basis. After one has defined $\Omega^k(V)$, it is possible to define $\det T$ to be the constant such that $T^*: \Omega^n(V) \rightarrow \Omega^n(V)$ is $\det T$ times the identity. This definition is indeed independent of a choice of basis, but when one looks a little harder at it, one sees that it isn't all that different from the messy formula defining the determinant of a matrix. Indeed, one proves that $\dim \Omega^n(V) \neq 0$ by writing down an explicit non-zero element of it (in terms of a basis!) which involves permutations in exactly the same way as the original definition of determinants. Finally, if one can tolerate even more complicated constructions, the “exterior algebra” of V can be used to produce a definition of $\det T$ which is completely independent of bases, and does not even mention permutations. In fact, the sign of a permutation σ can then be *defined* as the determinant of the linear transformation $T: \mathbb{R}^n \rightarrow \mathbb{R}^n$ with $T(e) = e_{\sigma(i)}$. This approach is expounded in Chevalley's book, *The Construction and Study of Certain Important Algebras*.

The definition of curvature follows a similar course. We first defined the curvature of a surface in a way which depends on an imbedding in \mathbb{R}^3 ; our final goal is a definition of curvature which depends only on the Riemannian metric on the surface. It should be noted that we already have a candidate—the formula in the Theorema Egregium may be used as a definition of curvature! It must still be checked that this definition does not depend on the coordinate system (an uninviting task), but at least the definition involves only a coordinate system on the surface, not an imbedding of the surface in \mathbb{R}^3 . Presumably, few mathematicians would accept this definition as a reasonable one. As we proceed to frame more acceptable definitions of curvature, we will rely, just as in the case of determinants, on more complicated and abstract constructions, so it is important that we follow the historical evolution of the definition of curvature, in order not to lose sight of its geometric significance.

One further comparison with the case of determinants will point out the direction which our investigations will have to take. It seems safe to assert that the modern invariant definitions of determinants would never have come into being if mathematicians had always considered only determinants of 2×2 matrices—our perception of the structure is complicated too much by the simplicity of this special case. Similarly for curvature. The essence of curvature is revealed more fully only when one transcends the limits of intuition and considers manifolds of arbitrary dimensions, conceived as existing in their own right, not as subsets of a Euclidean space.

ADDENDUM
THE FORMULA OF
BERTRAND AND PUISEUX;
DIQUET'S FORMULA

Consider the function \sqrt{g} which was used in the proof of Theorem 9. This function is defined on some $[0, \delta] \times [0, 2\pi]$ and

$$(1) \quad \sqrt{g}(\rho, 0) = \sqrt{g}(\rho, 2\pi) \quad \text{for } \rho \in [0, \delta]$$

$$(2) \quad \sqrt{g}(0, \phi) = 0$$

$$(3) \quad \frac{\partial \sqrt{g}}{\partial \rho}(0, \phi) = \lim_{\rho \rightarrow 0} \frac{\partial \sqrt{g}}{\partial \rho}(\rho, \phi) = 1.$$

We have also noted that on $(0, \delta] \times [0, 2\pi]$ we have

$$(4) \quad \begin{aligned} \frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) &= -\sqrt{g}(\rho, \phi) \cdot K(\exp(\rho, \phi)) \\ &= -\sqrt{g}(\rho, \phi) \cdot \bar{K}(\rho, \phi), \quad \text{say.} \end{aligned}$$

This shows (appealing once again to the standard theorem of calculus used before) that

$$(5) \quad \frac{\partial^2 \sqrt{g}}{\partial \rho^2}(0, \phi) = \lim_{\rho \rightarrow 0} \frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) = 0.$$

Differentiating equation (4) yields

$$(6) \quad \frac{\partial^3 \sqrt{g}}{\partial \rho^3}(\rho, \phi) = -\frac{\partial \sqrt{g}}{\partial \rho}(\rho, \phi) \cdot \bar{K}(\rho, \phi) - \sqrt{g}(\rho, \phi) \frac{\partial \bar{K}}{\partial \rho}(\rho, \phi).$$

We note that the term $\partial \bar{K} / \partial \rho(\rho, \phi)$ makes sense even for $\rho = 0$; it is just a directional derivative of \bar{K} , which is a C^∞ function on M_p . Consequently, $\partial \bar{K} / \partial \rho(\rho, \phi)$ approaches a limit as $\rho \rightarrow 0$. From (6) we thus obtain

$$\begin{aligned}
 (7) \quad \frac{\partial^3 \sqrt{g}}{\partial \rho^3}(0, \phi) &= \lim_{\rho \rightarrow 0} \frac{\partial^3 \sqrt{g}}{\partial \rho^3}(\rho, \phi) \\
 &= -K(p), \quad \text{using (2) and (3), and noting that} \\
 &\quad \bar{K}(0, \phi) = K(p).
 \end{aligned}$$

Using (2), (3), (5), (7), we now have the Taylor polynomial expansion

$$\boxed{\sqrt{g}(\rho, \phi) = \rho - \frac{K(p)\rho^3}{6} + o(\rho^3).}$$

[There is still a technical detail which must be taken care of. We actually want to know that the remainder

$$R(\rho) = \sqrt{g}(\rho, \phi) - \rho + \frac{K(p)\rho^3}{6}$$

satisfies

$$\lim_{\rho \rightarrow 0} \frac{R(\rho)}{\rho^3} \rightarrow 0 \quad \text{uniformly in } \phi.$$

This can be seen from the proof that the Taylor polynomial approximates the function; the proof involves L'Hôpital's Theorem, which in turn depends on the Cauchy mean value theorem (*Calculus*, pg. 201), whose role will be made explicit. We have

$$\begin{aligned}
 \lim_{\rho \rightarrow 0} \frac{\sqrt{g}(\rho, \phi) - \rho + K(p)\rho^3/6}{\rho^3} &= \lim_{\rho \rightarrow 0} \frac{\frac{\partial \sqrt{g}}{\partial \rho}(\bar{\rho}, \phi) - 1 + K(p)\bar{\rho}^2/2}{3\bar{\rho}^2} \\
 &\quad 0 < \bar{\rho} < \rho, \text{ by the} \\
 &\quad \text{Cauchy mean value theorem} \\
 &= \lim_{\rho \rightarrow 0} \frac{\frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\bar{\bar{\rho}}, \phi) + K(p)\bar{\bar{\rho}}}{6\bar{\bar{\rho}}} \quad 0 < \bar{\bar{\rho}} < \bar{\rho} \\
 &= \lim_{\rho \rightarrow 0} \frac{\frac{\partial^3 \sqrt{g}}{\partial \rho^3}(\bar{\bar{\bar{\rho}}}, \phi) + K(p)}{6} \quad 0 < \bar{\bar{\bar{\rho}}} < \bar{\bar{\rho}} \\
 &= 0,
 \end{aligned}$$

with the final equality coming from (7).]

10. PROPOSITION (BERTRAND AND PUISEUX; 1848). Let $C(\rho)$ be the circumference of the “geodesic circle” of radius ρ around $p \in M$, consisting of the endpoints of geodesic segments of length ρ which start at p . Then

$$K(p) = \lim_{\rho \rightarrow 0} 3 \cdot \frac{2\pi\rho - C(\rho)}{\pi\rho^3}.$$

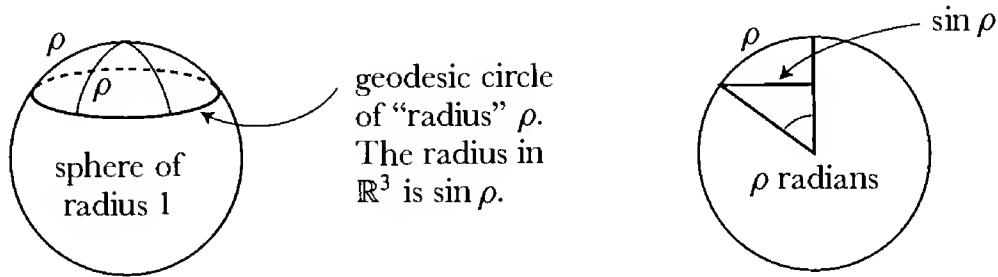

PROOF. Clearly

$$\begin{aligned} C(\rho) &= \int_0^{2\pi} \left\| \frac{\partial}{\partial \phi} \Big|_{\exp(\rho, \phi)} \right\| d\phi = \int_0^{2\pi} \sqrt{g}(\rho, \phi) d\phi \\ &= \int_0^{2\pi} \left(\rho - \frac{K(p)\rho^3}{6} \right) d\phi + \int_0^{2\pi} o(\rho^3) d\phi \\ &= 2\pi \left(\rho - \frac{K(p)\rho^3}{6} \right) + o(\rho^3). \end{aligned}$$

So

$$K(p) = 3 \cdot \frac{2\pi\rho - C(\rho)}{\pi\rho^3} + \frac{o(\rho^3)}{\rho^3}. \quad \blacklozenge$$

According to Proposition 10, on a surface of positive curvature, like a sphere, geodesic circles are always “too small”, while on surfaces of negative curvature,

they are always “too large”. Notice that Proposition 10 gives another interpretation of curvature totally in terms of the Riemannian metric on M . There is yet another formula of the same type.

11. PROPOSITION (DIQUET; 1848). Let $A(\rho)$ be the area enclosed by the geodesic circle of radius ρ around $p \in M$. Then

$$K(p) = \lim_{\rho \rightarrow 0} 12 \cdot \frac{\pi\rho^2 - A(\rho)}{\pi\rho^4}.$$

PROOF. Clearly

$$\begin{aligned}
 A(\rho) &= \int_{\substack{\text{inclosed} \\ \text{region}}} dV = \int_0^{2\pi} \int_0^\rho \sqrt{g}(\rho, \phi) d\rho d\phi \\
 &= \int_0^{2\pi} \int_0^\rho \left(\rho - \frac{K(p)\rho^3}{6} \right) d\rho d\phi + \int_0^{2\pi} \int_0^\rho o(\rho^3) d\rho d\phi \\
 &= 2\pi \left(\frac{\rho^2}{2} - \frac{K(p)\rho^4}{24} \right) + o(\rho^4),
 \end{aligned}$$

which easily yields the desired result. ♦

CHAPTER 4

THE CURVATURE OF HIGHER DIMENSIONAL MANIFOLDS

A. AN INAUGURAL LECTURE

On June 10, 1854 the faculty of Göttingen University heard a lecture entitled *Über die Hypothesen, welche der Geometrie zu Grunde liegen* (On the Hypotheses which lie at the Foundations of Geometry). This lecture was delivered by Georg Friedrich Bernhard Riemann, who had been born just a year before Gauss' paper of 1827. Although the lecture was not published until 1866, the ideas contained within it proved to be the most influential in the entire history of differential geometry. To be sure, mathematicians had not neglected the study of surfaces in the meantime; in fact, Gauss' work had inspired a tremendous amount of work along these lines. But the results obtained in those years can all be proved with much greater ease after we have followed the long series of developments initiated by the turning point in differential geometry which Riemann's lecture provided.

A short account of the life and character of Riemann can be found in the biography by Dedekind* which is included in Riemann's collected works (published by Dover). His interest in many fields of mathematical physics, together with a demand for perfection in all he did, delayed until 1851 the submission of his doctoral dissertation *Grundlagen für eine allgemeine Theorie der Functionen einer veränderlichen complexen Grösse* (Foundations for a general theory of functions of a complex variable). Gauss' official report to the Philosophical Faculty of the University of Göttingen stated "The dissertation submitted by Herr Riemann offers convincing evidence of the author's thorough and penetrating investigations in those parts of the subject treated in the dissertation, of a creative, active truly mathematical mind, and of a gloriously fertile originality."

Riemann was now qualified to seek the position of Privatdocent (a lecturer who received no salary, but was merely forwarded fees paid by those students

* Even for those who can only plod through German, this is preferable to the account in E. T. Bell's *Men of Mathematics*, which is hardly more than a translation of Dedekind, written in a racy style and interlarded with supercilious remarks of questionable taste.

who elected to attend his lectures). To attain this position he first had to submit an “inaugural paper” (Habilitationsschrift). Again there were delays, and it was not until the end of 1853 that Riemann submitted the Habilitationsschrift, *Über die Darstellbarkeit einer Function durch eine trigonometrische Reihe* (On the representability of a function by a trigonometric series). Now Riemann still had to give a probationary inaugural lecture on a topic chosen by the faculty, from a list of three proposed by the candidate. The first two topics which Riemann submitted were ones on which he had already worked, and he had every reason to expect that one of these two would be picked; for the third topic he chose the foundations of geometry. Contrary to all traditions, Gauss passed over the first two, and picked instead the third, in which he had been interested for years. At this time Riemann was also investigating the connection between electricity, magnetism, light, and gravitation, in addition to acting as an assistant in a seminar on mathematical physics. The strain of carrying out another major investigation, aggravated perhaps by the hardships of poverty, brought on a temporary breakdown. However, Riemann soon recovered, disposed of some other work which had to be completed, and then finished his inaugural lecture in about seven more weeks.

Riemann hoped to make his lecture intelligible even to those members of the faculty who knew little mathematics. Consequently, hardly any formulas appear and the analytic investigations are completely suppressed. Although Dedekind describes the lecture as a masterpiece of exposition, it is questionable how many of the faculty comprehended it. In making the following translation,* I was aided by the fact that I already had some idea what the mathematical results were supposed to be. The uninitiated reader will probably experience a great deal of difficulty merely understanding what Riemann is trying to say (the proofs of Riemann’s assertions are spread out over the next several chapters). We can be sure, however, that one member of the faculty appreciated Riemann’s work. Dedekind tells us that Gauss sat at the lecture “which surpassed all his expectations, in the greatest astonishment, and on the way back from the faculty meeting he spoke to Wilhelm Weber, with the greatest appreciation, and with an excitement rare for him, about the depth of the ideas presented by Riemann”.

*The original is contained, of course, in Riemann’s collected works. Two English translations are readily available, one in Volume 2 of Smith’s *Source Book in Mathematics* (Dover), and one in Clifford’s *Mathematical Papers* (Chelsea).

On the Hypotheses which lie at The Foundations of Geometry

Plan of the Investigation.

As is well known, geometry presupposes the concept of space, as well as assuming the basic principles for constructions in space. It gives only nominal definitions of these things, while their essential specifications appear in the form of axioms. The relationship between these presuppositions is left in the dark; we do not see whether, or to what extent, any connection between them is necessary, or *a priori* whether any connection between them is even possible.

From Euclid to Legendre, the most famous of the modern reformers of geometry, this darkness has been dispelled neither by the mathematicians nor by the philosophers who have concerned themselves with it. This is undoubtedly because the general concept of multiply extended quantities, which includes spatial quantities, remains completely unexplored. I have therefore first set myself the task of constructing the concept of a multiply extended quantity from general notions of quantity. It will be shown that a multiply extended quantity is susceptible of various metric relations, so that Space constitutes only a special case of a triply extended quantity. From this however it is a necessary consequence that the theorems of geometry cannot be deduced from general notions of quantity, but that those properties which distinguish Space from other conceivable triply extended quantities can only be deduced from experience. Thus arises the problem of seeking out the simplest data from which the metric relations of Space can be determined, a problem which by its very nature is not completely determined, for there may be several systems of simple data which suffice to determine the metric relations of Space; for the present purposes, the most important system is that laid down as a foundation of geometry by Euclid. These data are — like all data — not logically necessary, but only of empirical certainty, they are hypotheses; one can therefore investigate their likelihood, which is certainly very great within the bounds of observation, and afterwards decide upon the legitimacy of extending them beyond the bounds of observation, both in the direction of the immeasurably large, and in the direction of the immeasurably small.

I. Concept of an n fold extended quantity.

In proceeding to attempt the solution of the first of these problems, the development of the concept of multiply extended quantity, I feel particularly entitled to request an indulgent hearing, as I am little practiced in these tasks

of a philosophical nature where the difficulties lie more in the concepts than in the construction, and because I could not make use of any previous studies, except for some very brief hints on the subject which Privy Councilor Gauss has given in his second memoir on Biquadratic Residues, in the *Gottingen Gelehrte Anzeige* and in the *Gottingen Jubilee-book*, and some philosophical researches of Herbart.

1.

Notions of quantity are possible only when there already exists a general concept which admits particular instances. These instances form either a continuous or a discrete manifold, depending on whether or not a continuous transition of instances can be found between any two of them; individual instances are called points in the first case and elements of the manifold in the second. Concepts whose particular instances form a discrete manifold are so numerous that some concept can always be found, at least in the more highly developed languages, under which any given collection of things can be comprehended (and consequently, in the study of discrete quantities, mathematicians could unhesitatingly proceed from the principle that given objects are to be regarded as all of one kind). On the other hand, opportunities for creating concepts whose instances form a continuous manifold occur so seldom in everyday life that color and the position of sensible objects are perhaps the only simple concepts whose instances form a multiply extended manifold. More frequent opportunities for creating and developing these concepts first occur in higher mathematics.

Particular portions of a manifold, distinguished by a mark or by a boundary, are called quanta. Their quantitative comparison is effected in the case of discrete quantities by counting, in the case of continuous quantities by measurement. Measuring involves the superposition of the quantities to be compared; it therefore requires a means of transporting one quantity to be used as a standard for the others. Otherwise, one can compare two quantities only when one is a part of the other, and then only as to "more" or "less", not as to "how much". The investigations which can be carried out in this case form a general division of the science of quantity, independent of measurement, where quantities are regarded, not as existing independent of position and not as expressible in terms of a unit, but as regions in a manifold. Such investigations have become a necessity for several parts of mathematics, e.g., for the treatment of many-valued analytic functions, and the dearth of such studies is one of the principal reasons why the celebrated theorem of Abel and the contributions of Lagrange, Pfaff and Jacobi to the general theory of differential equations have remained unfruitful for so long. From this portion of the science of extended quantity,

a portion which proceeds without any further assumptions, it suffices for the present purposes to emphasize two points, which will make clear the essential characteristic of an n fold extension. The first of these concerns the generation of the concept of a multiply extended manifold, the second involves reducing position fixing in a given manifold to numerical determinations.

2.

In a concept whose instances form a continuous manifold, if one passes from one instance to another in a well-determined way, the instances through which one has passed form a simply extended manifold, whose essential characteristic is, that from any point in it a continuous movement is possible in only two directions, forwards and backwards. If one now imagines that this manifold passes to another, completely different one, and once again in a well-determined way, that is, so that every point passes to a well-determined point of the other, then the instances form, similarly, a doubly extended manifold. In a similar way, one obtains a triply extended manifold when one imagines that a doubly extended one passes in a well-determined way to a completely different one, and it is easy to see how one can continue this construction. If one considers the process as one in which the objects vary, instead of regarding the concept as fixed, then this construction can be characterized as a synthesis of a variability of $n + 1$ dimensions from a variability of n dimensions and a variability of one dimension.

3.

I will now show, conversely, how one can break up a variability, whose boundary is given, into a variability of one dimension and a variability of lower dimension. One considers a piece of a manifold of one dimension — with a fixed origin, so that points of it may be compared with one another — varying so that for every point of the given manifold it has a definite value, continuously changing with this point. In other words, we take within the given manifold a continuous function of position, which, moreover, is not constant on any part of the manifold. Every system of points where the function has a constant value then forms a continuous manifold of fewer dimensions than the given one. These manifolds pass continuously from one to another as the function changes; one can therefore assume that they all emanate from one of them, and generally speaking this will occur in such a way that every point of the first passes to a definite point of any other; the exceptional cases, whose investigation is important, need not be considered here. In this way, the determination of position in the given manifold is reduced to a numerical determination and to the determination of

position in a manifold of fewer dimensions. It is now easy to show that this manifold has $n - 1$ dimensions, if the given manifold is an n fold extension. By an n time repetition of this process, the determination of position in an n fold extended manifold is reduced to n numerical determinations, and therefore the determination of position in a given manifold is reduced, whenever this is possible, to a finite number of numerical determinations. There are, however, also manifolds in which the fixing of position requires not a finite number, but either an infinite sequence or a continuous manifold of numerical measurements. Such manifolds form, e.g., the possibilities for a function in a given region, the possible shapes of a solid figure, etc.

II. Metric relations of which a manifold of n dimensions is susceptible, on the assumption that lines have a length independent of their configuration, so that every line can be measured by every other.

Now that the concept of an n fold extended manifold has been constructed, and its essential characteristic has been found in the fact that position fixing in the manifold can be reduced to n numerical determinations, there follows, as the second of the problems proposed above, an investigation of the metric relations of which such a manifold is susceptible, and of the conditions which suffice to determine them. These metric relations can be investigated only in abstract terms, and their interdependence exhibited only through formulas. Under certain assumptions, however, one can resolve them into relations which are individually capable of geometric representation, and in this way it becomes possible to express the results of calculation geometrically. Thus, although an abstract investigation with formulas certainly cannot be avoided, the results can be presented in geometric garb. The foundations of both parts of the question are contained in the celebrated treatise of Privy Councilor Gauss on curved surfaces.

1.

Measurement requires an independence of quantity from position, which can occur in more than one way. The hypothesis which first presents itself, and which I shall develop here, is just this, that the length of lines is independent of their configuration, so that every line can be measured by every other. If position-fixing is reduced to numerical determinations, so that the position of a point in the given n fold extended manifold is expressed by n varying quantities x_1, x_2, x_3 , and so forth up to x_n , then specifying a line amounts to giving the quantities x as functions of one variable. The problem then is, to set up a mathematical

expression for the length of a line, for which purpose the quantities x must be thought of as expressible in units. I will treat this problem only under certain restrictions, and I first limit myself to lines in which the ratios of the quantities dx — the increments in the quantities x — vary continuously; one can then regard the lines as broken up into elements within which the ratios of the quantities dx may be considered to be constant, and the problem then reduces to setting up a general expression for the line element ds at every point, an expression which will involve the quantities x and the quantities dx . I assume, secondly, that the length of the line element remains unchanged, up to first order, when all the points of this line element suffer the same infinitesimal displacement, whereby I simply mean that if all the quantities dx increase in the same ratio, the line element changes by the same ratio. Under these assumptions, the line element can be an arbitrary homogeneous function of the first degree in the quantities dx which remains the same when all the quantities dx change sign, and in which the arbitrary constants are functions of the quantities x . To find the simplest cases, I first seek an expression for the $(n - 1)$ fold extended manifolds which are everywhere equidistant from the origin of the line element, i.e., I seek a continuous function of position which distinguishes them from one another. This must either decrease or increase in all directions from the origin; I will assume that it increases in all directions and therefore has a minimum at the origin. Then if its first and second differential quotients are finite, the first order differential must vanish and the second order differential cannot be negative; I assume that it is always positive. This differential expression of the second order remains constant if ds remains constant and increases quadratically when the quantities dx , and thus also ds , all increase in the same ratio; it is therefore $= \text{constant} \cdot ds^2$ and consequently $ds =$ the square root of an everywhere positive homogeneous function of the second degree in the quantities dx , in which the coefficients are continuous functions of the quantities x . In Space, if one expresses the location of a point by rectilinear coordinates, then $ds = \sqrt{\Sigma(dx)^2}$; Space is therefore included in this simplest case. The next simplest case would perhaps include the manifolds in which the line element can be expressed as the fourth root of a differential expression of the fourth degree. Investigation of this more general class would actually require no essentially different principles, but it would be rather time consuming and throw proportionally little new light on the study of Space, especially since the results cannot be expressed geometrically; I consequently restrict myself to those manifolds where the line element can be expressed by the square root of a differential expression of the second degree. One can transform such an expression into another similar one by substituting for the n independent variables, functions of n new independent variables.

However, one cannot transform any expression into any other in this way; for the expression contains $n\frac{n+1}{2}$ coefficients which are arbitrary functions of the independent variables; by the introduction of new variables one can satisfy only n conditions, and can therefore make only n of the coefficients equal to given quantities. There remain $n\frac{n-1}{2}$ others, already completely determined by the nature of the manifold to be represented, and consequently $n\frac{n-1}{2}$ functions of position are required to determine its metric relations. Manifolds, like the Plane and Space, in which the line element can be brought into the form $\sqrt{\Sigma dx^2}$ thus constitute only a special case of the manifolds to be investigated here; they clearly deserve a special name, and consequently, these manifolds, in which the square of the lines element can be expressed as the sum of the squares of complete differentials, I propose to call flat. In order to survey the essential differences of the manifolds representable in the assumed form, it is necessary to eliminate the features depending on the mode of presentation, which is accomplished by choosing the variable quantities according to a definite principle.

2.

For this purpose, one constructs the system of shortest lines emanating from a given point; the position of an arbitrary point can then be determined by the initial direction of the shortest line in which it lies, and its distance, in this line, from the initial point. It can therefore be expressed by the ratios of the quantities dx^0 , i.e., the quantities dx at the origin of this shortest line, and by the length s of this line. In place of the dx^0 one now introduces linear expressions $d\alpha$ formed from them in such a way that the initial value of the square of the line element will be equal to the sum of the squares of these expressions, so that the independent variables are: the quantity s and the ratio of the quantities $d\alpha$. Finally, in place of the $d\alpha$ choose quantities x_1, x_2, \dots, x_n proportional to them, but such that the sum of their squares equals s^2 . If one introduces these quantities, then for infinitely small values of x the square of the line element = Σdx^2 , but the next order term in its expansion equals a homogeneous expression of the second degree in the $n\frac{n-1}{2}$ quantities $(x_1 dx_2 - x_2 dx_1), (x_1 dx_3 - x_3 dx_1), \dots$, and is consequently an infinitely small quantity of the fourth order, so that one obtains a finite quantity if one divides it by the square of the infinitely small triangle at whose vertices the variables have the values $(0, 0, 0, \dots), (x_1, x_2, x_3, \dots), (dx_1, dx_2, dx_3, \dots)$. This quantity remains the same as long as the quantities x and dx are contained in the same binary linear forms, or as long as the two shortest lines from the initial point to x and from the initial point to dx remain in the same surface element, and therefore depends only on the position and direction

of that element. It obviously = zero if the manifold in question is flat, i.e., if the square of the line element is reducible to Σdx^2 , and can therefore be regarded as the measure of deviation from flatness in this surface direction at this point. When multiplied by $-\frac{3}{4}$ it becomes equal to the quantity which Privy Councilor Gauss has called the curvature of a surface. Previously, $n^{\frac{n-1}{2}}$ functions of position were found necessary in order to determine the metric relations of an n fold extended manifold representable in the assumed form; hence if the curvature is given in $n^{\frac{n-1}{2}}$ surface directions at every point, then the metric relations of the manifold may be determined, provided only that no identical relations can be found between these values, and indeed in general this does not occur. The metric relations of these manifolds, in which the line element can be represented as the square root of a differential expression of the second degree, can thus be expressed in a way completely independent of the choice of the varying quantities. A similar path to the same goal could also be taken in those manifolds in which the line element is expressed in a less simple way, e.g., by the fourth root of a differential expression of the fourth degree. The line element in this more general case would not be reducible to the square root of a quadratic sum of differential expressions, and therefore in the expression for the square of the line element the deviation from flatness would be an infinitely small quantity of the second dimension, whereas for the other manifolds it was an infinitely small quantity of the fourth dimension. This peculiarity of the latter manifolds therefore might well be called plainness in the smallest parts. For present purposes, however, the most important peculiarity of these manifolds, on whose account alone they have been examined here, is this, that the metric relations of the doubly extended ones can be represented geometrically by surfaces and those of the multiply extended ones can be reduced to those of the surfaces contained within them, which still requires a brief discussion.

3.

In the conception of surfaces, the inner metric relations, which involve only the lengths of paths within them, are always bound up with the way the surfaces are situated with respect to points outside them. We may, however, abstract from external relations by considering deformations which leave the lengths of lines within the surfaces unaltered, i.e., by considering arbitrary bendings — without stretching — of such surfaces, and by regarding all surfaces obtained from one another in this way as equivalent. Thus, for example, arbitrary cylindrical or conical surfaces count as equivalent to a plane, since they can be formed from a plane by mere bending, under which the inner metric relations remain the same; and all theorems about the plane — hence all of planimetry

— retain their validity. On the other hand, they count as essentially different from the sphere, which cannot be transformed into the plane without stretching. According to the previous investigations, the inner metric relations at every point of a doubly extended quantity, if its line element can be expressed as the square root of a differential expression of the second degree, which is the case with surfaces, is characterized by the curvature. For surfaces, this quantity can be given a visual interpretation as the product of the two curvatures of the surface at this point, or by the fact that its product with an infinitely small triangle formed from shortest lines is, in proportion to the radius, half the excess of the sum of its angles over two right angles. The first definition would presuppose the theorem that the product of the two radii of curvatures is unaltered by mere bendings of a surface, the second, that at each point the excess over two right angles of the sum of the angles of any infinitely small triangle is proportional to its area. To give a tangible meaning to the curvature of an n fold extended manifold at a given point, and in a given surface direction through it, we first mention that a shortest line emanating from a point is completely determined if its initial direction is given. Consequently we obtain a certain surface if we prolong all the initial directions from the given point which lie in the given surface element, into shortest lines; and this surface has a definite curvature at the given point, which is equal to the curvature of the n fold extended manifold at the given point, in the given surface direction.

4.

Before applying these results to Space, it is still necessary to make some general considerations about flat manifolds, i.e., about manifolds in which the square of the line element can be represented as the sum of squares of complete differentials.

In a flat n fold extended manifold the curvature in every direction, at every point, is zero; but according to the preceding investigation, in order to determine the metric relations it suffices to know that at each point the curvature is zero in $n \frac{n-1}{2}$ independent surface-directions. The manifolds whose curvature is everywhere $= 0$ can be considered as a special case of those manifolds whose curvature is everywhere constant. The common character of those manifolds whose curvature is constant may be expressed as follows: figures can be moved in them without stretching. For obviously figures could not be freely shifted and rotated in them if the curvature were not the same in all directions, at all points. On the other hand, the metric properties of the manifold are completely determined by the curvature; they are therefore exactly the same in all the directions around any one point as in the directions around any other, and thus

the same constructions can be effected starting from either; consequently, in the manifolds with constant curvature figures may be given any arbitrary position. The metric relations of these manifolds depend only on the value of the curvature, and it may be mentioned, as regards the analytic presentation, that if one denotes this value by α , then the expression for the line element can be put in the form

$$\frac{1}{1 + \frac{\alpha}{4} \Sigma x^2} \sqrt{\Sigma dx^2}$$

5.

The consideration of *surfaces* with constant curvature may serve for a geometric illustration. It is easy to see that the surfaces whose curvature is positive can always be rolled onto a sphere whose radius is the reciprocal of the curvature; but in order to survey the multiplicity of these surfaces, let one of them be given the shape of a sphere, and the others the shape of surfaces of rotation which touch it along the equator. The surfaces with greater curvature than the sphere will then touch the sphere from inside and take a form like the portion of the surface of a ring, which is situated away from the axis; they could be rolled upon zones of spheres with smaller radii, but would go round more than once. Surfaces with smaller positive curvature are obtained from spheres of larger radii by cutting out a portion bounded by two great semi-circles, and bringing together the cut-lines. The surface of curvature zero will be a cylinder standing on the equator; the surfaces with negative curvature will touch this cylinder from outside and be formed like the part of the surface of a ring which is situated near the axis. If one regards these surfaces as possible positions for pieces of surface moving in them, as Space is for bodies, then pieces of surface can be moved in all these surfaces without stretching. The surfaces with positive curvature can always be so formed that pieces of surface can even be moved arbitrarily without bending, namely as spherical surfaces, but those with negative curvature cannot. Aside from this independence of position for surface pieces, in surfaces with zero curvature there is also an independence of position for directions, which does not hold in the other surfaces.

III. Applications to Space.

1.

Following these investigations into the determination of the metric relations of an n fold extended quantity, the conditions may be given which are sufficient and necessary for determining the metric relations of Space, if we assume

beforehand the independence of lines from configuration and the possibility of expressing the line element as the square root of a second order differential expression, and thus flatness in the smallest parts.

First, these conditions may be expressed by saying that the curvature at every point equals zero in three surface directions, and thus the metric relations of Space are implied if the sum of the angles of a triangle always equals two right angles.

But secondly, if one assumes with Euclid not only the existence of lines independently of configuration, but also of bodies, then it follows that the curvature is everywhere constant, and the angle sum in all triangles is determined if it is known in one.

In the third place, finally, instead of assuming the length of lines to be independent of place and direction, one might assume that their length and direction is independent of place. According to this conception, changes or differences in position are complex quantities expressible in three independent units.

2.

In the course of the previous considerations, the relations of extension or regionality were first distinguished from the metric relations, and it was found that different metric relations were conceivable along with the same relations of extension; then systems of simple metric specifications were sought by means of which the metric relations of Space are completely determined, and from which all theorems about it are a necessary consequence. It remains now to discuss the question how, to what degree, and to what extent these assumptions are borne out by experience. In this connection there is an essential difference between mere relations of extension and metric relations, in that among the first, where the possible cases form a discrete manifold, the declarations of experience are to be sure never completely certain, but they are not inexact, while for the second, where the possible cases form a continuous manifold, every determination from experience always remains inexact — be the probability ever so great that it is nearly exact. This circumstance becomes important when these empirical determinations are extended beyond the limits of observation into the immeasurably large and the immeasurably small; for the latter may obviously become ever more inexact beyond the boundary of observation, but not so the former.

When constructions in Space are extended into the immeasurably large, unboundedness is to be distinguished from infinitude; one belongs to relations of extension, the other to metric relations. That Space is an unbounded triply

extended manifold is an assumption which is employed for every apprehension of the external world, by which at every moment the domain of actual perception is supplemented, and by which the possible locations of a sought for object are constructed; and in these applications it is continually confirmed. The unboundedness of space consequently has a greater empirical certainty than any experience of the external world. But its infinitude does not in any way follow from this; quite to the contrary, Space would necessarily be finite if one assumed independence of bodies from position, and thus ascribed to it a constant curvature, as long as this curvature had ever so small a positive value. If one prolonged the initial directions lying in a surface direction into shortest lines, one would obtain an unbounded surface with constant positive curvature, and thus a surface which in a flat triply extended manifold would take the form of a sphere, and consequently be finite.

3.

Questions about the immeasurably large are idle questions for the explanation of Nature. But the situation is quite different with questions about the immeasurably small. Upon the exactness with which we pursue phenomena into the infinitely small, does our knowledge of their causal connections essentially depend. The progress of recent centuries in understanding the mechanisms of Nature depends almost entirely on the exactness of construction which has become possible through the invention of the analysis of the infinite and through the simple principles discovered by Archimedes, Galileo, and Newton, which modern physics makes use of. By contrast, in the natural sciences where the simple principles for such constructions are still lacking, to discover causal connections one pursues phenomenon into the spatially small, just so far as the microscope permits. Questions about the metric relations of Space in the immeasurably small are thus not idle ones.

If one assumes that bodies exist independently of position, then the curvature is everywhere constant, and it then follows from astronomical measurements that it cannot be different from zero; or at any rate its reciprocal must be an area in comparison with which the range of our telescopes can be neglected. But if such an independence of bodies from position does not exist, then one cannot draw conclusions about metric relations in the infinitely small from those in the large; at every point the curvature can have arbitrary values in three directions, provided only that the total curvature of every measurable portion of Space is not perceptibly different from zero. Still more complicated relations can occur if the line element cannot be represented, as was presupposed, by the square root of a differential expression of the second degree. Now it seems that

the empirical notions on which the metric determinations of Space are based, the concept of a solid body and that of a light ray, lose their validity in the infinitely small; it is therefore quite definitely conceivable that the metric relations of Space in the infinitely small do not conform to the hypotheses of geometry; and in fact one ought to assume this as soon as it permits a simpler way of explaining phenomena.

The question of the validity of the hypotheses of geometry in the infinitely small is connected with the question of the basis for the metric relations of Space. In connection with this question, which may indeed still be ranked as part of the study of Space, the above remark is applicable, that in a discrete manifold the principle of metric relations is already contained in the concept of the manifold, but in a continuous one it must come from something else. Therefore, either the reality underlying Space must form a discrete manifold, or the basis for the metric relations must be sought outside it, in binding forces acting upon it.

An answer to these questions can be found only by starting from that conception of phenomena which has hitherto been approved by experience, for which Newton laid the foundation, and gradually modifying it under the compulsion of facts which cannot be explained by it. Investigations like the one just made, which begin from general concepts, can serve only to insure that this work is not hindered by unduly restricted concepts, and that progress in comprehending the connection of things is not obstructed by traditional prejudices.

This leads us away into the domain of another science, the realm of physics, into which the nature of the present occasion does not allow us to enter.

B. WHAT DID RIEMANN SAY?

Upon a first reading, Riemann's lecture may appear to have almost no mathematical content. But this is only because the analytic investigations, which occur in Part II, have been drastically condensed, while Part I explains, in general philosophical terms, important mathematical concepts which succeeding generations of investigators were eventually able to express with mathematical precision; finally, Part III of the lecture deals with applications of the mathematical discoveries to questions in physics, a process which is perhaps not yet complete.

In this commentary on Riemann's lecture, we will follow closely the order of Riemann's exposition, referring often to the various sections (1, 2, etc.) within each part (I, II, III). It should not be expected that all details will be cleared up, even in the remaining portions of this chapter, for the complete consideration of Riemann's ideas will occupy several of the succeeding chapters. Consequently, the remaining parts of Chapter 4 may be the hardest reading encountered in either of the two volumes of these notes. Nevertheless, we hope that in the end a clear view of all these ideas will be obtained.

In the "Plan of the Investigation", Riemann begins by accounting for the confusion over the status of non-Euclidean geometry, which at this time was still not completely accepted. In 1829, Lobachevsky and Bolyai had independently constructed a system of geometry which began by assuming that through a point not on a line there was more than one line parallel to it (as opposed to the assumption that there is only one parallel line, which is equivalent to Euclid's Fifth Postulate); but it was still supposed by some that contradictions in this system would eventually be found.

Riemann attributes the difficulties encountered in the study of non-Euclidean geometry to the fact that geometers had never separated what we would call the topological properties of space from its metric properties; in the axiomatic development of geometry, even the notion of space itself is undefined, and its properties are developed through the axioms.

Riemann proposes to distinguish the metric properties from the topological properties, and promises that we will discover how different metric structures can be put on the triply extended quantity which constitutes Space, so that one cannot possibly expect to deduce the parallel postulate of Euclid from topological considerations alone. This implies that experimental data must be used to determine what metric properties Space actually has, and raises the question which data we should seek, and what we can expect to say about the regions of Space too distant, or too small, to be investigated experimentally.

In Part I, “Concept of an n fold extended quantity”, Riemann is clearly trying to define a manifold.

It is impossible to tell from this lecture, intended for non-mathematicians, how far Riemann had advanced toward the precise solution of this problem, and whether he had any way of expressing concretely the notion of a metric or topological space, which is essentially prerequisite to the definition of a manifold. However, it is quite obvious that the notion was thoroughly clear in his own mind and that he recognized that manifolds were characterized by the fact that they are locally like n -dimensional Euclidean space. It is also clear that he understood the importance of infinite dimensional spaces, such as the set of all real-valued functions on a space (it is interesting that quite recently some of these infinite dimensional spaces have been given the structure of “infinite dimensional manifolds”, and differential geometric methods have been applied to them with great success).

Part II contains nearly all the mathematical results, and the discussion of this Part will take up most of the present chapter.

The difficulties in Part II begin right with the title, “Metric relations of which a manifold of n dimensions is susceptible, on the assumption that lines have a length independent of their configuration, so that every line can be measured by every other”. To understand what Riemann means, it is necessary to recall the process by which lengths are assigned to curves in the plane or 3-dimensional space of analytic geometry. In this case, we begin with the notion of distance between pairs of points, which amounts to saying that we first assign a length to *straight* lines; the length of other lines is then defined as the least upper bound of inscribed curves made up of straight lines, a process which can be reduced to integration. In this method of assigning lengths to curves, it may be said that all curves are measured by means of straight lines.

By contrast, Riemann proposes to consider a uniform method of assigning lengths to all curves in a manifold, a method which does not depend on first distinguishing a particular class of curves. This is to be done by measuring the lengths of tangent vectors, so that the lengths of curves can be defined by an integral (a restriction to C^1 curves is first indicated). Riemann assumes that this “length” function f is continuous on each tangent space and also positive homogeneous—the length $f(\lambda v)$ of λv is $|\lambda|$ times the length $f(v)$ of v .

Now there are many kinds of positive homogeneous functions on a finite dimensional vector space; any subset of the vector space which is symmetric with respect to the origin, and intersects each ray through 0 just once, can be used as the set of vectors of length 1. Riemann notes that the partial derivative of f^2 (with respect to some basis of the tangent space M_p) must vanish at

$0 \in M_p$, and that the matrix of second order partial derivatives is positive semi-

definite. He then assumes, as the simplest possibility, that it is actually positive definite. This means that f can be expressed as $\sqrt{\sum g_{ij}(p) dx^i \cdot dx^j}$ for certain numbers $g_{ij}(p)$. An assignment to each tangent space M_p of such a norm, or more precisely the inner product from which it comes, is, of course, what we now call a Riemannian metric on the manifold M .

Riemann points out that it is merely to save time, and to allow geometric descriptions of the results, that he restricts his attention to the special case. Certain more general cases, though not the most general of all, were investigated by Finsler in his thesis (1918), and are now known as Finsler metrics; it seems clear, however, that Riemann must have already known the basic facts about these more general metrics (some information on Finsler metrics is given in the Addendum).

Having restricted his attention to "Riemannian manifolds", Riemann now asks the crucial question: when does the introduction of a new coordinate system change the metric $\sum g_{ij} dy^i \otimes dy^j$ into some given metric $\sum a_{ij} dx^i \otimes dx^j$; in other words, when are two Riemannian manifolds locally isometric? Riemann here presents one of his famous "counting arguments", which enabled him to guess results that in some cases were not rigorously proved until a hundred years later. Riemann argues that the expression $\sum g_{ij} dx^i \otimes dx^j$ contains $n\frac{n+1}{2}$ functions (not n^2 , for $g_{ij} = g_{ji}$) while a new coordinate system involves only n functions, so that we can change only n of the g_{ij} , leaving $n\frac{n-1}{2}$ other functions which depend on the metric; consequently, Riemann argues, there should be some set of $n\frac{n-1}{2}$ functions which will determine the metric completely.

In section 2 of Part II, Riemann indicates how such functions are to be found. We are going to apply a standard technique for the study of differentiable functions—we examine the Taylor polynomials approximating the functions g_{ij} . If x is a coordinate system on M , with $x(p) = 0$, and the Riemannian metric is given by $\langle \ , \ \rangle = \sum g_{ij} dx^i \otimes dx^j$, then for the Taylor expansion of the

function $g_{ij} \circ x^{-1}: \mathbb{R}^n \rightarrow \mathbb{R}$ we have

$$\begin{aligned} g_{ij} \circ x^{-1}(t) &= (g_{ij} \circ x^{-1})(0) + \sum_{k=1}^n D_k(g_{ij} \circ x^{-1})(0)t^k \\ &\quad + \frac{1}{2} \sum_{k,l=1}^n D_{k,l}(g_{ij} \circ x^{-1})(0)t^k t^l + o(|t|^2). \end{aligned}$$

Hence on M we have

$$(*) \quad g_{ij} = g_{ij}(p) + \sum_{k=1}^n \frac{\partial g_{ij}}{\partial x^k}(p)x^k + \frac{1}{2} \sum_{k,l=1}^n \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l}(p)x^k x^l + o(|x|^2),$$

where $o(|x|^2)$ denotes a function f on M such that

$$\lim_{q \rightarrow p} \frac{f(q)}{|x(q)|^2} = 0.$$

However, and this is the important device Riemann introduces, we will select a very special coordinate system around each point $p \in M$. We choose an orthonormal basis $X_1, \dots, X_n \in M_p$, and define a coordinate system $\chi: M_p \rightarrow \mathbb{R}^n$ on M_p by $\chi(\sum a^i X_i) = (a^1, \dots, a^n)$. Then we let x be the coordinate system $\chi \circ \exp^{-1}$. (This coordinate system is introduced at the very beginning

of section 2, but it takes a little work to decipher Riemann's description of it.)

The coordinate system x is not uniquely determined, for it depends on the choice of the orthonormal basis $X_1, \dots, X_n \in M_p$; but any two differ by an element of $O(n)$, so it will not be hard to take into account the way any of our results depend on this choice. These coordinate systems are called **Riemannian normal coordinates** at p . Notice that since $\exp_*: (M_p)_0 \rightarrow M_p$ is the identity (upon identifying $(M_p)_0$ with M_p), we have

$$\left. \frac{\partial}{\partial x^i} \right|_p = \exp_* X_i = X_i \in M_p.$$

We can quickly give some information about the first two terms in the expansion (*) of g_{ij} :

1. PROPOSITION. In a Riemannian normal coordinate system x at p we have

$$g_{ij}(p) = \delta_{ij}$$

$$\frac{\partial g_{ij}}{\partial x^k}(p) = 0.$$

PROOF. The first set of equations is clear, for

$$g_{ij}(p) = \left\langle \frac{\partial}{\partial x^i} \Big|_p, \frac{\partial}{\partial x^j} \Big|_p \right\rangle = \langle X_i, X_j \rangle = \delta_{ij}.$$

To prove the second set of equations, we recall the equations for a geodesic γ :

$$\frac{d^2 \gamma^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0.$$

In Riemannian normal coordinates the geodesics through p are just $\exp \circ c$, where c is a straight line in M_p . This means that for all n -tuples (ξ^1, \dots, ξ^n) , the geodesics through p are the curves γ with $\gamma^k(t) = \xi^k t$. Hence

$$\sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \xi^i \xi^j = 0 \quad \text{for the geodesic } \gamma^k(t) = \xi^k t.$$

In particular, since $p = \gamma(0)$ is on all these geodesics, we have

$$\sum_{i,j=1}^n \Gamma_{ij}^k(p) \xi^i \xi^j = 0 \quad \text{for all } n\text{-tuples } (\xi^1, \dots, \xi^n).$$

This shows that all $\Gamma_{ij}^k(p)$ are 0: choosing all $\xi^\alpha = 0$ except $\xi^i = 1$ gives $\Gamma_{ii}^k = 0$; then choosing all $\xi^\alpha = 0$ except $\xi^i = \xi^j = 1$ gives

$$0 = \Gamma_{ij}^k(p) + \Gamma_{ji}^k(p) + \Gamma_{ii}^k(p) + \Gamma_{jj}^k(p) = 2\Gamma_{ij}^k(p).$$

It follows that

$$[ij, k] = \sum_{\alpha=1}^n g_{\alpha l} \Gamma_{ij}^l = 0 \quad \text{at } p.$$

Making use of equation (*) on pg. I.331, we have finally,

$$\frac{\partial g_{ij}}{\partial x^k} = [ik, j] + [jk, i] = 0 \quad \text{at } p. \quad \spadesuit$$

In view of Proposition 1, we can now use (*) to expand the squared norm $\| \|^2$ as

$$\begin{aligned} \| \|^2 &= \sum_{i,j=1}^n g_{ij} dx^i dx^j \\ &= \sum_{i=1}^n dx^i dx^i + \frac{1}{2} \sum_{i,j;k,l} \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l}(p) x^k x^l dx^i dx^j + o(|x|^2). \end{aligned}$$

[This is an equation for tangent vectors near p , and $o(|x|^2)$ now denotes a function f on tangent vectors; in order to have

$$\lim_{q \rightarrow p} \frac{f(v_q)}{|x|^2} = 0,$$

we must restrict v_q to be of some bounded length.] Riemann's main assertion involves the term

$$\frac{1}{2} \sum_{i,j;k,l} \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l}(p) x^k x^l dx^i dx^j = \sum_{i,j;k,l} c_{ij,kl} x^k x^l dx^i dx^j, \quad \text{say.}$$

Riemann asserts that there are numbers $C_{ij,kl}$ such that we can write

$$\sum_{i,j;k,l} c_{ij,kl} x^k x^l dx^i dx^j = \sum_{i,j;k,l} C_{ij,kl} (x^k dx^i - x^i dx^k) \cdot (x^l dx^j - x^j dx^l).$$

This assertion immediately suggests three questions—Why did Riemann suspect this was true? How did he prove it? What is its significance?

We will begin by giving a partial answer to the third of these questions. Notice that the equation in question is supposed to hold for all tangent vectors v at all points q in a neighborhood of p . Consequently, the numbers $dx^i(v)$ [and $x^i(q)$] can take on all [sufficiently small] values. The coordinate system x and the Riemannian metric $\langle \cdot, \cdot \rangle$ are used to obtain the n^4 numbers $c_{ij,kl} = \frac{1}{2} \partial^2 g_{ij} / \partial x^k \partial x^l(p)$; but beyond this, the above equation has nothing to do with the manifold at all. If we define a quadratic polynomial Q in $2n$ variables by

$$Q(X, Y) = Q(X_1, \dots, X_n, Y_1, \dots, Y_n) = \sum_{i,j;k,l} c_{ij,kl} X_i X_j Y_k Y_l,$$

then Riemann is asserting that this quadratic polynomial can be written as

$$Q(X, Y) = \sum_{i,j;k,l} C_{ij,kl} (X_i Y_k - X_k Y_i) \cdot (X_j Y_l - X_l Y_j).$$

To obtain the geometric consequences of this fact, we observe what it says when we select two vectors $v_p, w_p \in M_p$ and let $X_i = dx^i(v_p)$ and $Y_i = dx^i(w_p)$; denoting $Q(X, Y)$ by $Q(v_p, w_p)$, we have

$$\begin{aligned} Q(v_p, w_p) &= \sum_{i,j,k,l} c_{ij,kl} dx^i(v_p) dx^j(v_p) \cdot dx^k(w_p) dx^l(w_p) \\ &= \sum_{i,j,k,l} C_{ij,kl} [(dx^i \wedge dx^k)(v_p, w_p)] \cdot [(dx^j \wedge dx^l)(v_p, w_p)]. \end{aligned}$$

[We can also write

$$Q = \sum_{i,j,k,l} c_{ij,kl} dx^i dx^j \otimes dx^k dx^l = \sum_{i,j,k,l} C_{ij,kl} (dx^i \wedge dx^k) \cdot (dx^j \wedge dx^l),$$

a little more simply.] Now suppose $v'_p, w'_p \in M_p$ span the same subspace as v_p, w_p , so that we can write

$$\begin{aligned} v'_p &= a_{11}v_p + a_{21}w_p \\ w'_p &= a_{12}v_p + a_{22}w_p \end{aligned} \quad \det(a_{ij}) \neq 0.$$

The right side of the above equation for $Q(v_p, w_p)$ shows that

$$Q(v'_p, w'_p) = [\det(a_{ij})]^2 \cdot Q(v_p, w_p),$$

since each $dx^\alpha \wedge dx^\beta$ is multiplied by the factor $\det(a_{ij})$. If we use $\|v_p, w_p\|$ to denote the area of the parallelogram spanned by v_p and w_p , then we also have

$$\|v'_p, w'_p\|^2 = [\det(a_{ij})]^2 \cdot \|v_p, w_p\|^2.$$

Consequently,

$$\frac{Q(v'_p, w'_p)}{\|v'_p, w'_p\|^2} = \frac{Q(v_p, w_p)}{\|v_p, w_p\|^2}.$$

We therefore have a way of assigning a number to every 2-dimensional subspace of the tangent space at p . (Riemann sticks to the original quadratic function of the x^i and dx^i , which puts him in the position of having to divide by the squared area of a very strange triangle, with one vertex at x^i , and one at dx^i .)

It is easy to see that if we pick a different Riemannian normal coordinate system at p , then the resulting function on the 2-dimensional subspaces of M_p will be the same, for $Q(v_p, w_p) = Q(dx^1(v_p), \dots, dx^n(v_p), dx^1(w_p), \dots, dx^n(w_p))$ will change by $(\det B)^2$, where $B \in O(n)$, so that $\det B = \pm 1$. We will examine later the significance of this new function on 2-dimensional subspaces of the tangent space. For the present we take up the other questions—Why did Riemann think it was true, and how did he prove it?

Of course, an answer to the first question is not only doomed to be mere conjecture, but is always foolhardy to put forth, for there is no accounting for genius. The best suggestion I can offer is that the dependence of $Q(v_p, w_p)$ on the span of v_p and w_p alone is certainly an attractive one, and as we shall see later, in one special case which Riemann may have investigated first, the result appears in a rather natural way. It is also impossible to say for sure how Riemann proved the result, for his own investigations were never published. I have used the remarks by H. Weber in Riemann's collected works (pp. 405–409), as well as the commentary given by Herman Weyl in a special edition of Riemann's lecture. There are two parts to the proof, a purely algebraic one about quadratic functions, which determines what relations the numbers $c_{ij,kl}$ ought to satisfy, and an analytic one which establishes these relations.

For the algebraic part, we will be considering a quadratic function Q of $2n$ variables

$$Q(X, Y) = Q(X_1, \dots, X_n, Y_1, \dots, Y_n) = \sum_{i,j;k,l} c_{ij,kl} X_i X_j Y_k Y_l.$$

Note that for our Q we have

$$c_{ij,kl} = c_{ji,kl} = c_{ij,lk},$$

(using $g_{ij} = g_{ji}$, and $\partial^2/\partial x^k \partial x^l = \partial^2/\partial x^l \partial x^k$). If $A = (a_{ij})$ is a 2×2 matrix, we will use $A(X, Y)$ to denote the $2n$ -tuple

$$\begin{aligned} A(X, Y) &= (a_{11}X + a_{21}Y, a_{12}X + a_{22}Y) \\ &= (a_{11}X_1 + a_{21}Y_1, \dots, a_{11}X_n + a_{21}Y_n, a_{12}X_1 + a_{22}Y_1, \dots, a_{12}X_n + a_{22}Y_n). \end{aligned}$$

2. PROPOSITION. Let Q be a quadratic function of $2n$ variables,

$$Q(X, Y) = \sum_{i,j;k,l} c_{ij,kl} X_i X_j Y_k Y_l,$$

where

$$(1) \quad c_{ij,kl} = c_{ji,kl} = c_{ij,lk}.$$

Then

$$Q(A(X, Y)) = (\det A)^2 Q(X, Y)$$

for all 2×2 matrices A if and only if:

$$(2) \quad c_{ij,kl} = c_{kl,ij}$$

$$(3) \quad c_{li,jk} + c_{lj,ki} + c_{lk,ij} = 0.$$

PROOF. First of all, the equation $Q(A(X, Y)) = (\det A)^2 Q(X, Y)$ clearly holds for all 2×2 matrices A if and only if it holds for the non-singular ones, since both sides of the equation are continuous functions of A , and the non-singular matrices are dense.

Now it is well known that all non-singular 2×2 matrices can be written as a product of the matrices

$$\begin{pmatrix} a & 0 \\ 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 0 \\ 0 & a \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}.$$

[This comes from the fact that any non-singular matrix can be obtained from the identity matrix by a sequence of elementary row operations, and every row operation may be accomplished by multiplying by one of the above matrices.] So our condition holds for all A if and only if it holds for the above matrices. We can disregard the last matrix, since

$$\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

For the matrix $A = \begin{pmatrix} a & 0 \\ 0 & 1 \end{pmatrix}$, the condition $Q(A(X, Y)) = (\det A)^2 Q(X, Y)$ becomes simply

$$Q(aX, Y) = a^2 Q(X, Y),$$

which is automatically true. The same result holds for the second matrix on our list, so all the conditions finally come down to

$$(a) \quad Q(Y, X) = Q(X, Y) \quad A = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

$$(b) \quad Q(X + Y, Y) = Q(X, Y) \quad A = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}.$$

Now equation (a) becomes

$$\sum_{i,j;k,l} c_{ij,kl} X_i X_j Y_k Y_l = \sum_{i,j;k,l} c_{ij,kl} Y_i Y_j X_k X_l.$$

Since this must be a polynomial identity, we obtain (2) immediately, by looking at the coefficient of $X_i X_j Y_k Y_l$ on both sides.

Equation (b) becomes

$$\sum_{i,j;k,l} c_{ij,kl} (X_i + Y_i)(X_j + Y_j) Y_k Y_l = \sum_{i,j;k,l} c_{ij,kl} X_i X_j Y_k Y_l,$$

or

$$\sum_{i,j;k,l} c_{ij,kl} [X_i Y_j Y_k Y_l + X_j Y_i Y_k Y_l + Y_i Y_j Y_k Y_l] = 0.$$

Letting $X = 0$, we obtain

$$(b1) \quad \sum_{i,j;k,l} c_{ij,kl} Y_i Y_j Y_k Y_l = 0$$

and then, in consequence,

$$(b2) \quad \sum_{i,j;k,l} c_{ij,kl} [X_i Y_j Y_k Y_l + X_j Y_i Y_k Y_l] = 0.$$

On the other hand, (b2) implies (b1), so (b) is equivalent to (b2) alone. Finally, since $c_{ij,kl} = c_{ji,kl}$, equation (b2) is equivalent to

$$(b3) \quad \sum_{i,j;k,l} c_{ij,kl} X_i Y_j Y_k Y_l = 0.$$

Looking at the coefficient of a particular $X_i Y_j Y_k Y_l$ we obtain

$$c_{ij,kl} + c_{ij,lk} + c_{ik,jl} + c_{ik,lj} + c_{il,jk} + c_{il,kj} = 0.$$

Using the symmetry with respect to the last two indices, this is equivalent to equation (3). ♦

3. PROPOSITION. A quadratic function

$$Q(X, Y) = \sum_{i,j;k,l} c_{ij,kl} X_i X_j Y_k Y_l$$

with

$$(1) \quad c_{ij,kl} = c_{ji,kl} = c_{ij,kl}$$

satisfies the two equivalent conditions of Proposition 2 if and only if it can be written as

$$Q(X, Y) = \sum_{i,j;k,l} C_{ij,kl} (X_i Y_k - X_k Y_i) \cdot (X_j Y_l - X_l Y_j).$$

PROOF. If Q can be written this way, then we will clearly have $Q(A(X, Y)) = (\det A)^2 Q(X, Y)$ for all A . Conversely, suppose this holds for all A , so that we also have

$$(2) \quad c_{ij,kl} = c_{kl,ij}$$

$$(3) \quad c_{li,jk} + c_{lj,ki} + c_{lk,ij} = 0.$$

We begin by writing four equivalent expressions for Q :

$$\begin{aligned} Q(X, Y) &= \sum c_{ij,kl} X_i X_j Y_k Y_l \\ &= \sum c_{jk,il} X_j X_k Y_i Y_l \\ &= \sum c_{il,jk} X_i X_l Y_j Y_k \\ &= \sum c_{kl,ij} X_k X_l Y_i Y_j. \end{aligned}$$

Now, by (3) we have

$$c_{jk,il} = -c_{ji,lk} - c_{jl,ki},$$

so

$$\begin{aligned} \sum_{i,j,k,l} c_{jk,il} X_j X_k Y_i Y_l &= - \sum_{i,j,k,l} c_{ji,lk} X_j X_k Y_i Y_l - \sum_{i,j,k,l} c_{jl,ki} X_j X_k Y_i Y_l \\ &= - \sum_{i,j,k,l} c_{ji,lk} X_j X_k Y_i Y_l - \sum_{i,j,k,l} c_{kl,ji} X_j X_k Y_i Y_l \\ &\quad \text{(interchanging } j \text{ and } k \text{ in the second sum)} \\ &= -2 \sum_{i,j,k,l} c_{ij,kl} X_j X_k Y_i Y_l, \quad \text{using (1) and (2).} \end{aligned}$$

If we apply a similar process to the third expression for Q , use (2) on the fourth, and leave the first unaltered, we obtain

$$\begin{aligned} Q(X, Y) &= \sum c_{ij,kl} X_i X_j Y_k Y_l \\ \frac{1}{2} Q(X, Y) &= - \sum c_{ij,kl} X_j X_k Y_i Y_l \\ \frac{1}{2} Q(X, Y) &= - \sum c_{ij,kl} X_i X_l Y_j Y_k \\ Q(X, Y) &= \sum c_{ij,kl} X_k X_l Y_i Y_j. \end{aligned}$$

Adding, we obtain the desired result,

$$3Q(X, Y) = \sum_{i,j,k,l} c_{ij,kl} (X_i Y_k - X_k Y_i) \cdot (X_j Y_l - X_l Y_j). \quad \blacklozenge$$

We now proceed with the hardest part of the investigation, a hairy calculation indeed.

4. PROPOSITION. In a Riemannian normal coordinate system x at p , the numbers

$$c_{ij,kl} = \frac{1}{2} \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l}(p)$$

satisfy

$$\begin{aligned} c_{ij,kl} &= c_{kl,ij} \\ c_{li,jk} + c_{lj,ki} + c_{lk,ij} &= 0. \end{aligned}$$

PROOF. We begin with an equation derived in the proof of Proposition 1. For the geodesic $\gamma^k(t) = \xi^k t$ we have

$$\sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \xi^i \xi^j = 0;$$

multiplying by t^2 , we have

$$\sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) x^i(\gamma(t)) x^j(\gamma(t)) = 0.$$

Since these geodesics go through all points in a neighborhood of p , we have the following relation between the functions Γ_{ij}^k and x^i :

$$(1) \quad \sum_{i,j=1}^n \Gamma_{ij}^k x^i x^j = 0.$$

Since the tangent vector to the geodesic $\gamma^k(t) = \xi^k t$ has constant length, we also obtain

$$\left\langle \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle = \sum_{i=1}^n (\xi^i)^2,$$

which leads, in the same way, to the equation

$$(2) \quad \sum_{i,j=1}^n g_{ij} x^i x^j = \sum_{i=1}^n (x^i)^2.$$

Now equation (1) leads to

$$\sum_{i,j=1}^n [ij, k] x^i x^j = 0,$$

i.e., to

$$\sum_{i,j=1}^n \frac{1}{2} \left(\frac{\partial g_{ik}}{\partial x^j} + \frac{\partial g_{jk}}{\partial x^i} - \frac{\partial g_{ij}}{\partial x^k} \right) x^i x^j = 0.$$

Interchanging the indices i and j in the second term, we can write

$$(3) \quad \sum_{i,j=1}^n \left(\frac{\partial g_{ik}}{\partial x^j} - \frac{1}{2} \frac{\partial g_{ij}}{\partial x^k} \right) x^i x^j = 0.$$

Our penultimate goal is to break this equation up into two sums, each of which is individually 0; the conditions on the c 's, which are our ultimate goal, will then follow fairly easily. To achieve this, our antepenultimate goal is to prove that $x^\beta = \sum_{\alpha} g_{\beta\alpha} x^\alpha$; these equations are at least reasonable, for they imply (2). To prove these relations, we first introduce the functions \bar{x}^β defined by

$$\bar{x}^\beta = \sum_{\alpha=1}^n g_{\beta\alpha} x^\alpha.$$

Note that

$$\frac{\partial \bar{x}^\beta}{\partial x^\gamma} = \sum_{\alpha=1}^n \frac{\partial g_{\beta\alpha}}{\partial x^\gamma} x^\alpha + g_{\beta\gamma}.$$

Substituting in (3), we obtain

$$\begin{aligned} 0 &= \sum_{j=1}^n \left(\sum_{i=1}^n \frac{\partial g_{ik}}{\partial x^j} x^i \right) x^j - \frac{1}{2} \sum_{i=1}^n \left(\sum_{j=1}^n \frac{\partial g_{ij}}{\partial x^k} x^j \right) x^i \\ &= \sum_{j=1}^n \left(\frac{\partial \bar{x}^k}{\partial x^j} - g_{kj} \right) x^j - \frac{1}{2} \sum_{i=1}^n \left(\frac{\partial \bar{x}^i}{\partial x^k} - g_{ik} \right) x^i \\ &= \sum_{j=1}^n \frac{\partial \bar{x}^k}{\partial x^j} x^j - \bar{x}^k - \frac{1}{2} \left(\sum_{i=1}^n \frac{\partial \bar{x}^i}{\partial x^k} x^i - \bar{x}^k \right) \\ &= \sum_{j=1}^n \frac{\partial \bar{x}^k}{\partial x^j} x^j - \frac{1}{2} \left(\sum_{i=1}^n \frac{\partial \bar{x}^i}{\partial x^k} x^i + \bar{x}^k \right) \\ &= \sum_{j=1}^n \frac{\partial \bar{x}^k}{\partial x^j} x^j - \frac{1}{2} \cdot \frac{\partial \left(\sum_{i=1}^n x^i \bar{x}^i \right)}{\partial x^k}. \end{aligned}$$

Now by (2) and the definition of \bar{x}^i , we have

$$\sum_{i=1}^n x^i \bar{x}^i = \sum_{i=1}^n (x^i)^2,$$

so we obtain

$$\begin{aligned} 0 &= \sum_{j=1}^n \frac{\partial \bar{x}^k}{\partial x^j} x^j - x^k \\ &= \sum_{j=1}^n \frac{\partial (\bar{x}^k - x^k)}{\partial x^j} x^j. \end{aligned}$$

This equation shows that along any geodesic $\gamma(t) = \xi^i t$ we have

$$\frac{d[\bar{x}^k - x^k](\gamma(t))}{dt} = 0,$$

so that $\bar{x}^k - x^k$ is constant along the geodesic. Since $g_{ij}(p) = \delta_{ij}$, we clearly have $\bar{x}^k(p) = x^k(p)$. Moreover, these geodesics pass through all points in a neighborhood of p . Thus $\bar{x}^k = x^k$ in a neighborhood of p , so that we finally obtain the desired equations

$$(4) \quad \sum_{\alpha=1}^n g_{k\alpha} x^\alpha = x^k.$$

Now we differentiate (4) to obtain

$$\sum_{\alpha=1}^n \frac{\partial g_{k\alpha}}{\partial x^l} x^\alpha + g_{kl} = \delta_{kl};$$

multiplying by x^l and summing, we obtain

$$\sum_{\alpha, l=1}^n \frac{\partial g_{k\alpha}}{\partial x^l} x^\alpha x^l = \sum_{l=1}^n -g_{kl} x^l + \delta_{kl} x^l,$$

which, together with (4) gives

$$\sum_{\alpha, l=1}^n \frac{\partial g_{k\alpha}}{\partial x^l} x^\alpha x^l = -x^k + x^k = 0,$$

and we have thus obtained the first part of our penultimate goal,

$$(5) \quad \sum_{i,j=1}^n \frac{\partial g_{ik}}{\partial x^j} x^i x^j = 0.$$

Together with (3), it implies the other part,

$$(6) \quad \sum_{i,j=1}^n \frac{\partial g_{ij}}{\partial x^k} x^i x^j = 0.$$

We now obtain the desired equations as follows. Along the geodesic $\gamma^k(t) = \xi^k t$ we have, by (6),

$$(7) \quad \sum_{i,j=1}^n \frac{\partial g_{ij}}{\partial x^k} (\gamma(t)) \xi^i \xi^j t^2 = 0.$$

This implies that

$$(8) \quad \sum_{i,j=1}^n \frac{\partial g_{ij}}{\partial x^k} (\gamma(t)) \xi^i \xi^j = 0$$

for $t \neq 0$, and hence even for $t = 0$, by continuity. Differentiating (7) with respect to t gives

$$\begin{aligned} 0 &= \sum_{i,j=1}^n \frac{\partial g_{ij}}{\partial x^k} (\gamma(t)) \xi^i \xi^j \cdot 2t + \sum_{i,j,l=1}^n \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l} (\gamma(t)) \xi^l \xi^i \xi^j t^2 \\ &= \sum_{i,j,l=1}^n \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l} (\gamma(t)) \xi^l \xi^i \xi^j t^2, \quad \text{by (8);} \end{aligned}$$

consequently,

$$0 = \sum_{i,j,l=1}^n \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l} (\gamma(t)) \xi^i \xi^j \xi^l$$

for all $t \neq 0$, and hence also for $t = 0$. Setting $t = 0$, we obtain

$$\sum_{i,j,l=1}^n \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l} (p) \xi^i \xi^j \xi^l = 0.$$

This equation holds for *all* n -tuples ξ^1, \dots, ξ^n . From this we easily derive

$$(A) \quad c_{ij,kl} + c_{il,jk} + c_{jl,ik} = 0.$$

Applying the same process to (5), we obtain

$$(B) \quad c_{ki,jl} + c_{kj,li} + c_{kl,ij} = 0.$$

In (B) we interchange k and l , to obtain

$$c_{li,jk} + c_{lj,ki} + c_{kl,ij} = 0.$$

Comparing this equation with (A), we obtain the first of the desired relations,

$$c_{ij,kl} = c_{kl,ij}.$$

Moreover, using this relation with either (A) or (B), we obtain the second of the desired relations,

$$c_{li,jk} + c_{lj,ki} + c_{lk,ij} = 0.$$

And thus we are done! ♦

When we put all these results together we see that the quadratic function

$$Q(v_p, w_p) = \frac{1}{2} \sum_{i,j;k,l} \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l} dx^i(v_p) dx^j(v_p) dx^k(w_p) dx^l(w_p)$$

can be written

$$Q(v_p, w_p) = \frac{1}{3} \sum_{i,j;k,l} c_{ij,kl} (dx^i \wedge dx^k) \cdot (dx^j \wedge dx^l)(v_p, w_p).$$

We thus see that the quadratic function Q , obtained from the Taylor expansion of $\| \cdot \|^2$ in Riemannian normal coordinates, has special properties which allow us to define, for any 2-dimensional subspace $W \subset M_p$, a number

$$Q(W) = \frac{Q(v_p, w_p)}{\|v_p, w_p\|^2} \quad v_p, w_p \text{ any basis for } W.$$

The work of the last four Propositions, which establishes this fact, is completely suppressed in Riemann's account, where the final result is merely stated, at the

beginning of section 2 of Part II. Riemann then makes some remarkable claims. First, Riemann interprets Q for a surface:

- (1) If M is 2-dimensional and $W = M_p$, then $-3Q(W)$ is just the Gaussian curvature $K(p)$ given by Theorem 3-7; we thus have an intrinsic definition of K , obtained by picking a special class of coordinate systems determined by the metric. (Riemann needs the factor $-3/4$ because he divides $Q(v_p, w_p)$ by the square of the area of the *triangle* spanned by v_p and w_p .)

At the end of section 2, Riemann interprets Q for an n -manifold:

- (2) If M is n -dimensional, $W \subset M_p$ is a 2-dimensional subspace, and $\mathcal{O} \subset W$ is a neighborhood of $0 \in W$ on which \exp is a diffeomorphism, then $-3Q(W)$ is the Gaussian curvature at p of the surface $\exp(\mathcal{O})$, with the metric it inherits as a submanifold of M .

But the most important claim is made in section 2. In an n -dimensional vector space there are $n\frac{n-1}{2}$ "independent" 2-dimensional subspaces: if v_1, \dots, v_n is a basis, we can choose the subspaces spanned by v_i and v_j , for $i < j$. Riemann claims that the metric $\langle \cdot, \cdot \rangle$ is determined if $Q(W)$ is known for $n\frac{n-1}{2}$ independent 2-dimensional subspaces $W \subset M_q$ at each point q , for example, if Q is known for the subspaces spanned by each $\partial/\partial x^i|_q$ and $\partial/\partial x^j|_q$ ($i < j$).

A very special case of this general claim is the following, which we will henceforth call the *Test Case*:

- (3) If M is n -dimensional and $Q = 0$ for $n\frac{n-1}{2}$ independent 2-dimensional subspaces of each M_q , then M is **flat**, that is, M is locally isometric to \mathbb{R}^n with its usual inner product.

In connection with the Test Case, it should be pointed out that a local isometry with \mathbb{R}^n is the best we can hope for, since there are Riemannian manifolds which are not homeomorphic to \mathbb{R}^n , but which are locally isometric to \mathbb{R}^n , and hence have $Q = 0$ everywhere. The simplest example of such a manifold, the "flat torus", is constructed as follows. The torus T can be obtained from \mathbb{R}^2 by identifying (x, y) with (x', y') if and only if

$$y' - y, x' - x \in \mathbb{Z}$$

(compare pg. I.372). The map $\pi: \mathbb{R}^2 \rightarrow T$, defined by taking (x, y) to its equivalence class, is locally a diffeomorphism, and there is clearly a unique metric $\langle \cdot, \cdot \rangle$ on T such that $\pi^*\langle \cdot, \cdot \rangle$ is the usual Riemannian metric on \mathbb{R}^2 ; consequently, $(T, \langle \cdot, \cdot \rangle)$ is locally isometric to \mathbb{R}^2 with its usual Riemannian

metric. Notice that the usual torus in \mathbb{R}^3 , with the induced Riemannian metric, is *not* flat; it has positive Gaussian curvature on the part furthest from the axis,

and negative Gaussian curvature on the part nearest the axis. However, if we consider $S^1 \subset \mathbb{R}^2$, then it is easy to see that $S^1 \times S^1 \subset \mathbb{R}^2 \times \mathbb{R}^2$, with the induced Riemannian metric, is flat.

One other remark should probably be made about the Test Case. At first sight, the Test Case might seem to be little more than a theorem about functions whose second partial derivatives are everywhere zero. However, it is actually quite different from this simple sort of result, since the value of Q at different points is defined in terms of different coordinate systems, each chosen specifically for one point.

Now our aim in the rest of this chapter is to prove assertions (1), (2), and (3). (The general claim that Q determines the metric will be considered later, as will the information given in sections 4 and 5 of Part II.) However, we will defer the proofs of assertions (1), (2), and (3) to another section of this chapter, not only in order to provide ourselves with a brief respite, but also to allow Riemann to add one or two more brilliant ideas.

C. A PRIZE ESSAY

The second edition of Riemann's collected works includes an unpublished paper, in Latin, which was submitted to the Paris Academy in 1861, to compete for a prize on a question involving heat conduction. In 1868, ten years after it had been offered, the prize was finally withdrawn. Because the way of obtaining the results of his essay were not fully explained, the prize was not awarded to Riemann, whose health prevented the more detailed handling of the subject which he had intended.

An extract from this paper is given below.* It should not be very hard to read, but the significance of the equations obtained there is only suggested by Riemann's final remarks; in the next part of this chapter we will have a great deal more to add. In the translation I have made some minor changes of notation.

An Extract From Riemann's Paper of 1861

Second Part

On the transformation of the expression $\sum_{i,j} g_{ij} dy^i dy^j$
into the given form $\sum_{i,j} a_{ij} dx^i dx^j$.

When the inquiry of the third Academy is restricted to homogeneous bodies, in which the resulting conductivities are constants, we develop the first condition that the expression $\sum_{i,j} g_{ij} dy^i dy^j$, in which the y^i are functions of the x^i , can be transformed into the form $\sum_{i,j} a_{ij} dx^i dx^j$ with given constant coefficients a_{ij} .

The expression $\sum_{i,j} a_{ij} dx^i dx^j$, if it is, as we shall suppose, a positive form in the dx^i , can always be put in the simplified form $\sum_i (dx^i)^2$. Thus if $\sum_{i,j} g_{ij} dy^i dy^j$ can be transformed into the form $\sum_{i,j} a_{ij} dx^i dx^j$, it can likewise be reduced to the form $\sum_i (dx^i)^2$ and vice versa. We therefore ask whether it can be put in the form $\sum_i (dx^i)^2$.

* Certain omissions, indicated by " . . . ", are considered in Addendum 2 to Chapter 6.

Let $G = \det(g_{ij})$ and let γ_{ij} be the cofactor; in this way $\sum_i g_{ij}\gamma_{ij} = G$ and $\sum_i g_{ij}\gamma_{ik} = 0$ if $j \neq k$.

If $\sum_{i,j} g_{ij} dy^i dy^j = \sum_i (dx^i)^2$ for arbitrary values of the dx^i , substituting $d + \delta$ for d leads also to $\sum_{i,j} g_{ij} dy^i \delta y^j = \sum_i dx^i \delta x^i$ for arbitrary values of the dx^i and δx^i .

Consequently, if the dy^i are expressed in terms of the dx^i and the δx^i in terms of the δy^i , it follows that

$$(1) \quad \frac{\partial x^\beta}{\partial y^\alpha} = \sum_i g_{\alpha i} \frac{\partial y^i}{\partial x^\beta}$$

and consequently

$$(2) \quad \frac{\partial y^i}{\partial x^\beta} = \sum_\alpha \frac{\gamma_{\alpha i}}{G} \frac{\partial x^\beta}{\partial y^\alpha}.$$

Thus we further deduce, seeing that

$$\sum_\alpha \frac{\partial y^i}{\partial x^\alpha} \frac{\partial x^\alpha}{\partial y^i} = 1 \quad \text{and} \quad \sum_\alpha \frac{\partial y^i}{\partial x^\alpha} \frac{\partial x^\alpha}{\partial y^j} = 0 \quad \text{if } i \neq j,$$

$$(3) \quad \sum_\alpha \frac{\partial x^\alpha}{\partial y^i} \frac{\partial x^\alpha}{\partial y^j} = g_{ij}, \quad (4) \quad \sum_\alpha \frac{\partial y^i}{\partial x^\alpha} \frac{\partial y^j}{\partial x^\alpha} = \frac{\gamma_{ij}}{G}$$

and differentiating formula (3),

$$\sum_\alpha \frac{\partial^2 x^\alpha}{\partial y^i \partial y^k} \frac{\partial x^\alpha}{\partial y^j} + \sum_\alpha \frac{\partial^2 x^\alpha}{\partial y^j \partial y^k} \frac{\partial x^\alpha}{\partial y^i} = \frac{\partial g_{ij}}{\partial y^k}.$$

Now from these expressions for

$$\frac{\partial g_{ij}}{\partial y^k}, \quad \frac{\partial g_{ik}}{\partial y^j}, \quad \frac{\partial g_{jk}}{\partial y^i}$$

we can write

$$(5) \quad 2 \sum_\alpha \frac{\partial^2 x^\alpha}{\partial y^j \partial y^k} \frac{\partial x^\alpha}{\partial y^i} = \frac{\partial g_{ij}}{\partial y^k} + \frac{\partial g_{ik}}{\partial y^j} - \frac{\partial g_{jk}}{\partial y^i}$$

and if these quantities are designated by p_{ijk} , then

$$(6) \quad 2 \frac{\partial^2 x^\alpha}{\partial y^j \partial y^k} = \sum_i \frac{\partial y^i}{\partial x^\alpha} p_{ijk}.$$

Differentiating the quantities p_{ijk} again yields

$$\frac{\partial p_{ijk}}{\partial y^l} - \frac{\partial p_{ijl}}{\partial y^k} = 2 \sum_\nu \frac{\partial^2 x^\nu}{\partial y^j \partial y^k} \frac{\partial^2 x^\nu}{\partial y^i \partial y^l} - 2 \sum_\nu \frac{\partial^2 x^\nu}{\partial y^j \partial y^l} \frac{\partial^2 x^\nu}{\partial y^i \partial y^k},$$

whence finally, substituting the values found in (6) and (4),

$$(I) \quad \frac{\partial^2 g_{ik}}{\partial y^j \partial y^l} + \frac{\partial^2 g_{jl}}{\partial y^i \partial y^k} - \frac{\partial^2 g_{il}}{\partial y^j \partial y^k} - \frac{\partial^2 g_{jk}}{\partial y^i \partial y^l} + \frac{1}{2} \sum_{\alpha, \beta} (p_{\alpha j l} p_{\beta i k} - p_{\alpha i l} p_{\beta j k}) \frac{\gamma_{\alpha \beta}}{G} = 0.$$

The functions g_{ij} must necessarily satisfy these equations whenever $\sum_{i,j} g_{ij} dy^i dy^j$ can be transformed into the form $\sum_i (dx^i)^2$: we denote the left side of this equation by

$$(ij, kl).$$

... Given an acquaintance with the traditional methods, it is demonstrated without difficulty that these ... conditions when they are satisfied, suffice

D. THE BIRTH OF THE RIEMANN CURVATURE TENSOR

All the developments in this part of the chapter have their origin in the following question, which Riemann considers in the paper of Part C: When is a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$ *flat* (locally isometric to \mathbb{R}^n with its usual Riemannian metric)? In other words, when is there a coordinate system x^1, \dots, x^n on M for which

$$(1) \quad \langle \cdot, \cdot \rangle = \sum_{i=1}^n dx^i \otimes dx^i ?$$

We are going to seek an answer to this question in as straightforward a manner as possible; the quadratic function Q will not be used at all, but at the end it will make a surprise appearance.

We begin by choosing an arbitrary coordinate system y , in terms of which the metric $\langle \cdot, \cdot \rangle$ can be written

$$(2) \quad \langle \cdot, \cdot \rangle = \sum_{i,j=1}^n g_{ij} dy^i \otimes dy^j;$$

and we then seek conditions on the g_{ij} in order for (1) to hold for some coordinate system x . Since this is a purely local question, we can assume that y^1, \dots, y^n is just the standard coordinate system on \mathbb{R}^n .

If we express the dx^i in terms of the dy^j , and equate the coefficients of $dy^i \otimes dy^j$ in (2) with the resulting coefficients in (1), we find that the coordinate system x^1, \dots, x^n has the desired property if and only if

$$(3) \quad \sum_{\alpha} \frac{\partial x^{\alpha}}{\partial y^i} \frac{\partial x^{\alpha}}{\partial y^j} = g_{ij}.$$

From equation (3) we can immediately derive another, for we obtain

$$\begin{aligned} \sum_{j,\beta} g_{ij} \frac{\partial y^j}{\partial x^{\alpha}} \frac{\partial y^{\beta}}{\partial x^{\alpha}} &= \sum_{j,\beta,\alpha} \frac{\partial x^{\alpha}}{\partial y^i} \frac{\partial x^{\alpha}}{\partial y^j} \frac{\partial y^j}{\partial x^{\beta}} \frac{\partial y^{\beta}}{\partial x^{\alpha}} \\ &= \sum_{\alpha,\beta} \frac{\partial x^{\alpha}}{\partial y^i} \delta_{\beta}^{\alpha} \frac{\partial y^{\beta}}{\partial x^{\alpha}} \\ &= \sum_{\alpha} \frac{\partial x^{\alpha}}{\partial y^i} \frac{\partial y^{\alpha}}{\partial x^{\alpha}} = \delta_i^{\alpha}, \end{aligned}$$

which shows that if the coordinate system x^1, \dots, x^n has the desired property, then

$$(4) \quad \sum_{\beta} \frac{\partial y^i}{\partial x^{\beta}} \frac{\partial y^j}{\partial x^{\beta}} = g^{ij}.$$

Conversely, (4) implies (3). These results are just the equations (3) and (4) that Riemann obtains. Notice that Riemann begins with the square of the norm $\| \|^2 = \sum g_{ij} dy^i \cdot dy^j$, and then uses polarization to obtain the inner product, which he writes as $\sum g_{ij} dy^i \delta y^j$. Riemann also treats the two coordinate systems x and y on an equal footing throughout, so that his derivations of (3) and (4) are somewhat different. From (4) we obtain

$$\begin{aligned} \sum_{i,j} g^{ij} \frac{\partial x^{\mu}}{\partial y^i} \frac{\partial x^{\nu}}{\partial y^j} &= \sum_{\beta,i,j} \frac{\partial y^i}{\partial x^{\beta}} \frac{\partial y^j}{\partial x^{\beta}} \frac{\partial x^{\mu}}{\partial y^i} \frac{\partial x^{\nu}}{\partial y^j} \\ &= \sum_{\beta} \delta_{\beta}^{\mu} \delta_{\beta}^{\nu}, \end{aligned}$$

and thus the coordinate system x^1, \dots, x^n has the desired property if and only if

$$(4') \quad \sum_{i,j} g^{ij} \frac{\partial x^{\mu}}{\partial y^i} \frac{\partial x^{\nu}}{\partial y^j} = \delta_{\mu\nu}.$$

This equation, which we will find more useful than (4), can be derived directly from (3) in the following way. If $A = (a_{ij}) = (\partial x^i / \partial y^j)$, and $G = (g_{ij})$, then (3) says that

$$A^t \cdot A = G,$$

where A^t is the transpose of A ; this is equivalent to

$$G^{-1} = A^{-1} \cdot (A^t)^{-1},$$

and hence to

$$AG^{-1}A^t = I,$$

which is just (4'). In particular, this shows immediately that (4') is equivalent to (3).

Now equation (3) is a partial differential equation for the functions x^{α} . In Chapter I.6 we developed a general theory for partial differential equations, but we notice at once that (3) is not an equation of the type to which our theory

applies. Our first task will thus be to obtain from (3) an equation that we do know how to handle. The situation is very much like, and may profitably be compared to, that which occurs in Problem I.7-19, where the analysis of a certain set of partial differential equations is reduced to Theorem I.6-1, together with the Poincaré Lemma. To treat equation (3), we begin by differentiating (about all we can do), to obtain

$$\sum_{\alpha} \frac{\partial^2 x^{\alpha}}{\partial y^i \partial y^k} \frac{\partial x^{\alpha}}{\partial y^j} + \sum_{\alpha} \frac{\partial^2 x^{\alpha}}{\partial y^j \partial y^k} \frac{\partial x^{\alpha}}{\partial y^i} = \frac{\partial g_{ij}}{\partial y^k}.$$

By writing down this equation for

$$\frac{\partial g_{ij}}{\partial y^k}, \quad \frac{\partial g_{ik}}{\partial y^j}, \quad \frac{\partial g_{jk}}{\partial y^i},$$

and combining, we obtain an equation equivalent to Riemann's,

$$(5) \quad \sum_{\alpha} \frac{\partial^2 x^{\alpha}}{\partial y^j \partial y^k} \frac{\partial x^{\alpha}}{\partial y^i} = \frac{1}{2} \left(\frac{\partial g_{ij}}{\partial y^k} + \frac{\partial g_{ik}}{\partial y^j} - \frac{\partial g_{jk}}{\partial y^i} \right) = [jk, i].$$

Thus, the symbols $[jk, i]$, which came up naturally in the calculus of variations, also come up naturally in this different context. After Riemann's *Habilitations* lecture was published, in 1866, several mathematicians independently derived his results or considered related questions. Christoffel, in particular, introduced these combinations of the partial derivatives of the g_{ij} 's, and the symbols $[ij, k]$ and Γ_{ij}^k are called the **Christoffel symbols** of the **first** and **second kinds**, respectively (Christoffel actually used $[ij]_k$ and $\{ij\}^k$, which do not accommodate themselves to the summation convention). In the next chapter we will see one important use which Christoffel made of these symbols.

At this point we will depart slightly from Riemann's treatment, in order to obtain equations to which Theorem I.6-1 directly applies. From (5) we obtain

$$\begin{aligned} \sum_{i, \gamma} g^{i\gamma} \frac{\partial x^{\lambda}}{\partial y^{\gamma}} [jk, i] &= \sum_{\alpha, i, \gamma} \frac{\partial^2 x^{\alpha}}{\partial y^j \partial y^k} \frac{\partial x^{\alpha}}{\partial y^i} \frac{\partial x^{\lambda}}{\partial y^{\gamma}} g^{i\gamma} \\ &= \sum_{\alpha} \frac{\partial^2 x^{\alpha}}{\partial y^j \partial y^k} \left(\sum_{i, \gamma} \frac{\partial x^{\alpha}}{\partial y^i} \frac{\partial x^{\lambda}}{\partial y^{\gamma}} g^{i\gamma} \right) \\ &= \sum_{\alpha} \frac{\partial^2 x^{\alpha}}{\partial y^j \partial y^k} \delta_{\alpha\lambda} \quad \text{by (4')}, \end{aligned}$$

so we obtain, finally,

$$(6) \quad \frac{\partial^2 x^\lambda}{\partial y^j \partial y^k} = \sum_{\gamma=1}^n \Gamma_{jk}^\gamma \frac{\partial x^\lambda}{\partial y^\gamma}$$

(which is easily seen to be equivalent to Riemann's equation (6)); we will also write this equation as

$$\frac{\partial \left(\frac{\partial x^\lambda}{\partial y^j} \right)}{\partial y^k} = \sum_{\gamma=1}^n \Gamma_{jk}^\gamma \frac{\partial x^\lambda}{\partial y^\gamma}.$$

Notice that the index λ plays no special role here; all functions x^λ satisfy the *same* equation. Thus, for each λ the n -tuple of functions

$$\alpha = \left(\frac{\partial x^\lambda}{\partial y^1}, \dots, \frac{\partial x^\lambda}{\partial y^n} \right) \quad \alpha: \mathbb{R}^n \rightarrow \mathbb{R}^n$$

satisfies the set of partial differential equations

$$(*) \quad \frac{\partial \alpha}{\partial y^k}(y) = f_k(y, \alpha(y)),$$

where $f_k: \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ is given by

$$f_k^j(y, z) = \sum_{\gamma=1}^n \Gamma_{jk}^\gamma(y) \cdot z^\gamma.$$

Since this is true for every λ , the equation $(*)$ has n solutions whose initial values at some point, 0 say, are linearly independent. Since constant linear combinations of solutions of $(*)$ are also solutions, it follows that $(*)$ has solutions with arbitrary initial conditions at 0. From Theorem I.6-1 we thus obtain necessary integrability conditions,

$$\frac{\partial f_k}{\partial y^l} - \frac{\partial f_l}{\partial y^k} + \sum_{\mu=1}^n \frac{\partial f_k}{\partial z^\mu} f_l^\mu - \sum_{\mu=1}^n \frac{\partial f_l}{\partial z^\mu} f_k^\mu = 0.$$

In our case, looking at the j^{th} components of these equations, we obtain

$$\sum_{\gamma=1}^n \frac{\partial \Gamma_{jk}^\gamma}{\partial y^l} z^\gamma - \sum_{\gamma=1}^n \frac{\partial \Gamma_{jl}^\gamma}{\partial y^k} z^\gamma + \sum_{\mu=1}^n \Gamma_{jk}^\mu \sum_{\gamma=1}^n \Gamma_{\mu l}^\gamma z^\gamma - \sum_{\mu=1}^n \Gamma_{jl}^\mu \sum_{\gamma=1}^n \Gamma_{\mu k}^\gamma z^\gamma = 0.$$

Since these relations must hold for all $z = (z^1, \dots, z^n)$, we obtain

$$(**) \quad 0 = R^\gamma_{jlk} \stackrel{\text{def}}{=} \frac{\partial \Gamma^\gamma_{kj}}{\partial y^l} - \frac{\partial \Gamma^\gamma_{lj}}{\partial y^k} + \sum_{\mu=1}^n (\Gamma^\mu_{kj} \Gamma^\gamma_{l\mu} - \Gamma^\mu_{lj} \Gamma^\gamma_{k\mu})$$

as necessary conditions that $\sum g_{ij} dy^i \otimes dy^j = \sum dx^i \otimes dx^i$ for some coordinate system $x = (x^1, \dots, x^n)$. Notice that the set of equations $R^\gamma_{jlk} = 0$ is equivalent to the set of equations

$$R_{ijlk} \stackrel{\text{def}}{=} \sum_{\gamma=1}^n g_{i\gamma} R^\gamma_{jlk} = 0.$$

The quantities R_{ijlk} can be expressed in another way, after a little calculation. Note first that

$$\begin{aligned} \sum_{\gamma=1}^n g_{i\gamma} \frac{\partial \Gamma^\gamma_{jk}}{\partial y^l} &= \frac{\partial}{\partial y^l} \left(\sum_{\gamma=1}^n g_{i\gamma} \Gamma^\gamma_{jk} \right) - \sum_{\gamma=1}^n \Gamma^\gamma_{jk} \frac{\partial g_{i\gamma}}{\partial y^l} \\ &= \frac{\partial [jk, i]}{\partial y^l} - \sum_{\gamma=1}^n \Gamma^\gamma_{jk} ([il, \gamma] + [\gamma l, i]). \end{aligned}$$

Substituting into (**), and remembering the definition of $[ij, k]$, we obtain

$$(***) \quad \begin{aligned} R_{ijlk} &= \frac{1}{2} \left(\frac{\partial^2 g_{ik}}{\partial y^j \partial y^l} + \frac{\partial^2 g_{jl}}{\partial y^i \partial y^k} - \frac{\partial^2 g_{il}}{\partial y^j \partial y^k} - \frac{\partial^2 g_{jk}}{\partial y^i \partial y^l} \right) \\ &\quad + \sum_{\alpha, \beta=1}^n g^{\alpha\beta} ([jl, \alpha] \cdot [ik, \beta] - [il, \alpha] \cdot [jk, \beta]). \end{aligned}$$

The condition $R_{ijlk} = 0$ is just the condition (I) which Riemann obtains (note that Riemann's p_{ijk} equals $2[jk, i]$)—the quantity which we have denoted by R_{ijlk} is what Riemann denotes by $2(ij, kl)$; the factor of 2 is not particularly significant, nor is the interchange of l and k , for it is easily seen that $R_{ijlk} = -R_{ijkl}$.

The notation R^i_{jkl} has been picked in anticipation of the following result.

5. PROPOSITION. On a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$ there is a tensor of type $\binom{3}{1}$ whose components in any coordinate system y are

$$R^i_{jkl} = \frac{\partial \Gamma^i_{jl}}{\partial y^k} - \frac{\partial \Gamma^i_{jk}}{\partial y^l} + \sum_{\mu=1}^n (\Gamma^\mu_{jl} \Gamma^i_{\mu k} - \Gamma^\mu_{jk} \Gamma^i_{\mu l})$$

(where $\langle \cdot, \cdot \rangle = \sum g_{ij} dy^i \otimes dy^j$, and the Christoffel symbols Γ are defined as usual).

PROOF. We just compute that the components transform “correctly”!! In other words, if $R'^i{}_{jlk}$ are defined by the same formula, with respect to the coordinate system y' , we show that

$$R'^{\alpha}{}_{\beta\gamma\delta} = \sum_{i,j,k,l} R^i{}_{jkl} \frac{\partial y^j}{\partial y'^{\beta}} \frac{\partial y^k}{\partial y'^{\gamma}} \frac{\partial y^l}{\partial y'^{\delta}} \frac{\partial y'^{\alpha}}{\partial y^i}.$$

To do this, all one needs is the result from Problem I.9-22,

$$\Gamma'^{\nu}{}_{\alpha\beta} = \sum_{i,j,k} \Gamma^k{}_{ij} \frac{\partial y^i}{\partial y'^{\alpha}} \frac{\partial y^j}{\partial y'^{\beta}} \frac{\partial y'^{\nu}}{\partial y^k} + \sum_{\mu=1}^n \frac{\partial^2 y^{\mu}}{\partial y'^{\alpha} \partial y'^{\beta}} \frac{\partial y'^{\nu}}{\partial y^{\mu}},$$

and plenty of perseverance.

SLIGHTLY MORE MOTIVATED PROOF. Begin with the equation

$$\sum_{i,j} g_{ij} dy^i \otimes dy^j = \langle \ , \ \rangle = \sum_{i,j} g'_{ij} dy'^i \otimes dy'^j,$$

and repeat the whole sequence of computations which we performed in the special case that $g'_{ij} = \delta_{ij}$. The result will be the desired transformation law. (The integrability conditions (**)) then follow as a necessary condition for the existence of a coordinate system y' with $g'_{ij} = \delta_{ij}$, for in such a coordinate system we clearly have $R'^i{}_{jkl} = 0$, which in turn implies that all $R^i{}_{jkl} = 0$.) ♦

We have thus stumbled onto a new tensor, the **Riemann curvature tensor**, which in the coordinate system y equals

$$\sum_{i,j,k,l} R^i{}_{jkl} dy^j \otimes dy^k \otimes dy^l \otimes \frac{\partial}{\partial y^i}.$$

Eventually we hope to have a useful invariant definition of this tensor; this will involve an enormous amount of exploration. For the time being, we simply accept the classical definition, which arises naturally as an integrability condition, and explain how it is connected with curvature. In the process we will obtain an invariant, but extraordinarily clumsy, definition of the curvature tensor.

It will be convenient to introduce a bit of modern terminology, and denote by R the tensor with components $R^i{}_{jkl}$. Since this tensor is of type $\binom{3}{1}$ it may be regarded as a function taking three vectors to another vector. The value of R on $X, Y, Z \in M_p$ will be denoted by

$$R(Y, Z)X \in M_p,$$

and hence we have

$$R\left(\left.\frac{\partial}{\partial y^k}\right|_p, \left.\frac{\partial}{\partial y^l}\right|_p\right)\left.\frac{\partial}{\partial y^j}\right|_p = \sum_{i=1}^n R^i{}_{jkl}(p) \cdot \left.\frac{\partial}{\partial y^i}\right|_p$$

(the reason for choosing the notation $R(Y, Z)X$ comes out in Proposition 6).

The numbers $R_{ijkl} = \sum_{\gamma} g_{i\gamma} R^{\gamma}{}_{jkl}$ are also the components of a tensor, of type $\binom{4}{0}$, but it is unnecessary to perform any calculations to verify this. Clearly

$$R_{ijkl}(p) = \left\langle R\left(\left.\frac{\partial}{\partial y^k}\right|_p, \left.\frac{\partial}{\partial y^l}\right|_p\right)\left.\frac{\partial}{\partial y^j}\right|_p, \left.\frac{\partial}{\partial y^i}\right|_p \right\rangle,$$

so the tensor in question is just the multilinear map

$$(X, Y, Z, W) \mapsto \langle R(Z, W)Y, X \rangle.$$

This function of four tangent vectors is closely connected with the quadratic function introduced in Part B of this chapter:

6. PROPOSITION. Let x be a Riemannian normal coordinate system at p , and Q the quadratic function on $M_p \times M_p$ defined by

$$Q(X, Y) = \sum_{i,j,k,l} c_{ij,kl} dx^i(X) dx^j(X) dx^k(Y) dx^l(Y),$$

where

$$c_{ij,kl} = \frac{1}{2} \frac{\partial^2 g_{ij}}{\partial x^k \partial x^l}.$$

Then

$$Q(X, Y) = -\frac{1}{3} \langle R(X, Y)Y, X \rangle.$$

PROOF. We have seen that

$$\begin{aligned} 3Q(X, Y) &= \sum_{i,j,k,l} c_{ij,kl} (dx^i \wedge dx^k) \cdot (dx^j \wedge dx^l)(X, Y) \\ &= \sum_{i,j,k,l} c_{ij,kl} dx^i(X) dx^j(X) dx^k(Y) dx^l(Y) \\ &\quad + \sum_{i,j,k,l} c_{ij,kl} dx^k(X) dx^l(X) dx^i(Y) dx^j(Y) \\ &\quad - \sum_{i,j,k,l} c_{ij,kl} dx^j(X) dx^k(X) dx^i(Y) dx^l(Y) \\ &\quad - \sum_{i,j,k,l} c_{ij,kl} dx^i(X) dx^l(X) dx^j(Y) dx^k(Y). \end{aligned}$$

By switching indices we can rewrite this as

$$\begin{aligned}
 3Q(X, Y) &= \sum_{i,j,k,l} c_{ik,jl} dx^i(X) dx^j(Y) dx^k(X) dx^l(Y) && \text{[interchange } j \text{ and } k] \\
 &+ \sum_{i,j,k,l} c_{jl,ik} && \text{[interchange } i \text{ and } l] \\
 &- \sum_{i,j,k,l} c_{il,jk} && \text{[change } i \text{ to } l; j \text{ to } i; l \text{ to } j] \\
 &- \sum_{i,j,k,l} c_{jk,il} && \text{[change } i \text{ to } k; k \text{ to } l; l \text{ to } i] \\
 &= \sum_{i,j,k,l} (c_{ik,jl} + c_{jl,ik} - c_{il,jk} - c_{jk,il}) dx^i \otimes dx^j \otimes dx^k \otimes dx^l(X, Y, X, Y).
 \end{aligned}$$

Now in Riemannian normal coordinates, the Christoffel symbols $[ij, k]$ are all 0 at p , since all $\partial g_{ij}/\partial x^k$ are 0 at p . Referring to equation (***) we thus have

$$\begin{aligned}
 3Q(X, Y) &= \sum_{i,j,k,l} R_{ijkl}(p) dx^i \otimes dx^j \otimes dx^k \otimes dx^l(X, Y, X, Y) \\
 &= - \sum_{i,j,k,l} R_{ijkl}(p) dx^i \otimes dx^j \otimes dx^k \otimes dx^l(X, Y, X, Y) \\
 &= -\langle R(X, Y)Y, X \rangle. \spadesuit
 \end{aligned}$$

We are now ready to verify some of Riemann's claims.

7. PROPOSITION. Let $(M, \langle \cdot, \cdot \rangle)$ be a 2-dimensional Riemannian manifold, and let $X, Y \in M_p$ be linearly independent. Let $\|X, Y\|$ denote the area of the parallelogram spanned by X and Y . Then

$$K(p) = \frac{\langle R(X, Y)Y, X \rangle}{\|X, Y\|^2} \quad [= \langle R(X, Y)Y, X \rangle \text{ if } X \text{ and } Y \text{ are orthonormal}]$$

is the same as the Gaussian curvature at p defined by the formula in Theorem 3-7 (in particular, this proves that the formula in Theorem 3-7 is indeed independent of the coordinate system).

FIRST PROOF. Let (x, y) be a coordinate system on a neighborhood of p . It obviously suffices to verify the theorem when $X = \partial/\partial x|_p$ and $Y = \partial/\partial y|_p$,

since by Proposition 6, and the results of Part B, the numerator is multiplied by the same factor as the denominator when we change to any other pair of vectors. In this case,

$$\begin{aligned}\langle R(X, Y)Y, X \rangle &= \left\langle R\left(\frac{\partial}{\partial x}\Big|_p, \frac{\partial}{\partial y}\Big|_p\right) \frac{\partial}{\partial y}\Big|_p, \frac{\partial}{\partial x}\Big|_p \right\rangle \\ &= R_{1212}(p).\end{aligned}$$

If we write

$$\langle \cdot, \cdot \rangle = E dx \otimes dx + F dx \otimes dy + F dy \otimes dx + G dy \otimes dy,$$

so that

$$\begin{aligned}g_{11} &= E \\ g_{12} &= g_{21} = F \\ g_{22} &= G,\end{aligned}$$

then (by the formula on pg. I.308)

$$\|X, Y\|^2 = EG - F^2,$$

so we must prove that

$$4R_{1212}(EG - F^2) = 4(EG - F^2)^2 K,$$

where the right side is given by the formula in Theorem 3-7. This is a fairly straightforward calculation from (***) on page 188. The first term in (***) corresponds to the last in the formula for $4(EG - F^2)^2 K$, and the second corresponds to the first three in the latter formula. In carrying out the calculation, note that

$$\begin{aligned}g^{11} &= \frac{G}{EG - F^2} \\ g^{12} &= g^{21} = \frac{-F}{EG - F^2} \\ g^{22} &= \frac{E}{EG - F^2};\end{aligned}$$

the denominators cancel out the unwanted factor in $4R_{1212}(EG - F^2)$.

SECOND PROOF (OUTLINE). Let (r, φ) be the coordinate system around p which is introduced on page 136. We know that in this coordinate system

$$\langle \cdot, \cdot \rangle = dr \otimes dr + G d\varphi \otimes d\varphi$$

for some function G , and (see page 145) that

$$K(p) = -\frac{\partial^3 \sqrt{G}}{\partial r^3}(p).$$

Introduce a Riemannian normal coordinate system x^1, x^2 by the equations

$$x^1 = r \cos \varphi, \quad x^2 = r \sin \varphi.$$

We can then calculate the g_{ij} in terms of G , and use these results to show that the quantity

$$\mathcal{Q} \left(\left. \frac{\partial}{\partial x^1} \right|_p, \left. \frac{\partial}{\partial x^2} \right|_p \right) = 2c_{11,22}(p)$$

is equal to $-K(p)/3$. The result then follows from Proposition 6. ♦

8. PROPOSITION. Let $(M, \langle \cdot, \cdot \rangle)$ be a Riemannian manifold, and let W be a 2-dimensional subspace of M_p , spanned by $X, Y \in M_p$. Let $\mathcal{O} \subset W$ be a neighborhood of $0 \in M_p$ on which \exp is a diffeomorphism, let $i: \exp(\mathcal{O}) \rightarrow M$ be the inclusion, and let \bar{R} be the Riemann curvature tensor for $\exp(\mathcal{O})$ with the induced Riemannian metric $i^*\langle \cdot, \cdot \rangle$. Then

$$\langle \bar{R}(X, Y)Y, X \rangle = \langle R(X, Y)Y, X \rangle.$$

Consequently,

$$\frac{\langle R(X, Y)Y, X \rangle}{\|X, Y\|^2}$$

is the Gaussian curvature at p of the surface $\exp(\mathcal{O})$.

FIRST PROOF. It obviously suffices to prove the theorem when X and Y are orthonormal. Choose a Riemannian normal coordinate system at p with $X = \partial/\partial x^1|_p$, $Y = \partial/\partial x^2|_p$; then x^1, x^2 is a coordinate system on $\exp(\mathcal{O})$. Now we are trying to prove that $\bar{R}_{1212}(p) = R_{1212}(p)$. But in (**), the terms involving Christoffel symbols vanish at p . The theorem is now obvious, since the functions \bar{g}_{ij} ($i, j = 1, 2$) defining the metric $i^*\langle \cdot, \cdot \rangle$ are just the corresponding g_{ij} restricted to $\exp(\mathcal{O})$, and they have the same mixed partial derivatives with respect to x^1 and x^2 .

SECOND PROOF. It is even more obvious that the quadratic form \bar{Q} associated with $(\exp(\mathcal{O}), i^*\langle \cdot, \cdot \rangle)$ is the restriction to W of the quadratic form Q on M_p , for they are the second non-zero terms in the Taylor expansion of the same metric. ♦

9. COROLLARY. Let $(M, \langle \cdot, \cdot \rangle)$ be a Riemannian manifold, let $X, Y \in M_p$ span a 2-dimensional subspace W of M_p , and let $\mathcal{O} \subset W$ be a neighborhood of 0 on which \exp is a diffeomorphism. If Q is the quadratic form on M defined previously, then

$$\frac{-3Q(X, Y)}{\|X, Y\|^2} = \frac{\langle R(X, Y)Y, X \rangle}{\|X, Y\|^2} = K,$$

where K is the Gaussian curvature at p of the surface $\exp(\mathcal{O})$.

The quantity $\langle R(X, Y)Y, X \rangle / \|X, Y\|^2$ appearing in Corollary 9 is called the **sectional curvature** $K(W)$ of W . It would seem that the function $(X, Y) \mapsto \langle R(X, Y)Y, X \rangle$ contains only a small portion of the total information contained in the curvature tensor, but Propositions 10 and 12, which follow, show that R satisfies certain identities which allow it to be determined in terms of the metric $\langle \cdot, \cdot \rangle$ and the quadratic function Q which it determines.

10. PROPOSITION. The curvature tensor satisfies the following identities:

(1) $R(X, Y)Z = -R(Y, X)Z$, hence

$$\langle R(X, Y)Z, W \rangle = -\langle R(Y, X)Z, W \rangle.$$

(2) $\langle R(X, Y)Z, W \rangle = -\langle R(X, Y)W, Z \rangle$.

(3) $R(X, Y)Z + R(Y, Z)X + R(Z, X)Y = 0$, hence

$$\langle R(X, Y)Z, W \rangle + \langle R(Y, Z)X, W \rangle + \langle R(Z, X)Y, W \rangle = 0.$$

(4) $\langle R(X, Y)Z, W \rangle = \langle R(Z, W)X, Y \rangle$.

PROOF. In a coordinate system x , these relations are equivalent to

$$(1) \quad R^i_{jkl} = -R^i_{jlk} \quad \text{or} \quad R_{ijkl} = -R_{ijlk}$$

$$(2) \quad R_{ijkl} = -R_{jikl}$$

$$(3) \quad R^i_{jkl} + R^i_{klj} + R^i_{ljk} = 0 \quad \text{or} \quad R_{ijkl} + R_{iklj} + R_{iljk} = 0$$

$$(4) \quad R_{klij} = R_{ijkl}.$$

These are immediate from (**) and (***). ♦

Notice that $\langle R(X, Y)Z, W \rangle$ is skew-symmetric in both (X, Y) and (Z, W) , which again shows that $\langle R(X, Y)Y, X \rangle$ changes by $\det(a_{ij})^2$ when X and Y are replaced by $a_{11}X + a_{21}Y, a_{21}X + a_{22}Y$. For later use, we insert a result which shows that the fourth property of R is a formal consequence of the others.

11. PROPOSITION. Let V be a vector space and $\mathcal{R}: V \times V \times V \times V \rightarrow \mathbb{R}$ a multilinear map satisfying

- (1) $\mathcal{R}(X, Y, Z, W) = \mathcal{R}(Y, X, Z, W)$
- (2) $\mathcal{R}(X, Y, Z, W) = \mathcal{R}(X, Y, W, Z)$
- (3) $\mathcal{R}(X, Y, Z, W) + \mathcal{R}(Y, Z, X, W) + \mathcal{R}(Z, X, Y, W) = 0.$

Then \mathcal{R} also satisfies

- (4) $\mathcal{R}(X, Y, Z, W) = \mathcal{R}(Z, W, X, Y).$

PROOF. The proof is a tricky manipulation, cleverly systematized by the following diagram from Milnor's *Morse Theory*.

Equation (3) shows that the sum of the numbers at the vertices of triangle W is zero. The sums of the vertices of triangles X , Y , and Z are also seen to be zero, using (1) and (2). Adding these identities for the top two triangles, and subtracting the identities for the bottom ones, we see that twice the top vertex minus twice the bottom vertex is zero. ♦

12. PROPOSITION. Let V be a vector space and $\mathcal{R}_i: V \times V \times V \times V \rightarrow \mathbb{R}$ two multilinear maps satisfying (1)–(4) of Proposition 11. Suppose $\mathcal{R}_1(X, Y, X, Y) = \mathcal{R}_2(X, Y, X, Y)$ for all $X, Y \in V$. Then $\mathcal{R}_1 = \mathcal{R}_2$.

PROOF. It clearly suffices to prove that a multilinear \mathcal{R} satisfying (1)–(4) is 0 if $\mathcal{R}(X, Y, X, Y) = 0$ for all $X, Y \in V$. Now we have

$$\begin{aligned}
 0 &= \mathcal{R}(X, Y + W, X, Y + W) \\
 &= \mathcal{R}(X, Y, X, Y) + \mathcal{R}(X, Y, X, W) + \mathcal{R}(X, W, X, Y) + \mathcal{R}(X, W, X, W) \\
 &= \mathcal{R}(X, Y, X, W) + \mathcal{R}(X, W, X, Y) \\
 &= 2\mathcal{R}(X, Y, X, W).
 \end{aligned}$$

Using (1) and (2), we easily see that \mathcal{R} is alternating, and hence skew-symmetric. Consequently, (3) gives

$$3\mathcal{R}(X, Y, Z, W) = 0. \spadesuit$$

Propositions 10 and 12 tell us that the curvature tensor R is completely determined by the values of $\langle R(X, Y)Y, X \rangle$, and hence by the quadratic function Q . [This means that in a sense we can frame a coordinate-free definition of the curvature tensor, but it would certainly be an awkward one. Moreover, given a multilinear map $\mathcal{R}: V \times V \times V \times V \rightarrow \mathbb{R}$, satisfying (1)–(4), it is a fairly difficult exercise to work out a formula for \mathcal{R} in terms of the quantities $\mathcal{R}(X, Y, X, Y)$.] In terms of a coordinate system, we see that the tensor $\mathcal{R}(X, Y, Z, W) = \langle R(X, Y)Z, W \rangle$ is determined by the components R_{ijij} , of which there are $n\frac{n-1}{2}$ with $i < j$. According to Riemann, these $n\frac{n-1}{2}$ functions must determine the metric completely; in other words, the tensor \mathcal{R} must determine the metric.*

Recall that we have selected one special case of this assertion as our Test Case, which can now be restated as follows: If $R = 0$, then the manifold is flat. We are ready to present the first, and longest, of our proofs of the Test Case. It is separated into three Steps, and all our subsequent proofs, no matter how elegant and brief, essentially contain these same three Steps.

Recall that for a coordinate system y^1, \dots, y^n we have the formula (pg. I.331)

$$(*) \quad \frac{\partial g_{ij}}{\partial y^k} = [ik, j] + [jk, i],$$

which is equivalent to the definition of the Christoffel symbols, as well as the formula (pg. I.331)

$$(**) \quad \frac{\partial g^{ij}}{\partial y^k} = - \sum_{l=1}^n (g^{il} \Gamma_{lk}^j + g^{lj} \Gamma_{lk}^i),$$

which can be derived from it.

*This is not really the same as saying that R determines the metric, since we can't determine $R(X, Y)Z$ from $\mathcal{R}(X, Y, Z, W) = \langle R(X, Y)Z, W \rangle$ unless the metric is already known! In fact, any numbers R_{ijkl} satisfying the identities of Proposition 6 can be realized as the components, at a point, of R for some metric (the R_{ijkl} determine the second derivatives of the metric at the point).

13. THEOREM (THE TEST CASE; FIRST VERSION). Let $(M, \langle \cdot, \cdot \rangle)$ be an n -dimensional Riemannian manifold for which the curvature tensor R is 0. Then M is locally isometric to \mathbb{R}^n with its usual Riemannian metric.

PROOF. This is a purely local question, so we assume that M is \mathbb{R}^n , with the standard coordinate system y^1, \dots, y^n , and the Riemannian metric

$$\langle \cdot, \cdot \rangle = \sum_{i,j=1}^n g_{ij} dy^i \otimes dy^j.$$

Step 1. We claim that there are functions (h_1, \dots, h_n) , with any desired initial conditions $(h_1(0), \dots, h_n(0))$, satisfying the equations

$$(*) \quad \frac{\partial h_j}{\partial y^k} = \sum_{\gamma=1}^n \Gamma_{jk}^{\gamma} h_{\gamma}.$$

The reason for this is, of course, that the relations $R^{\gamma}_{jlk} = 0$, which express the vanishing of R , are just the integrability conditions for $(*)$, as we have already seen.

In particular, for $\alpha = 1, \dots, n$ we can choose such a set $(h^{(\alpha)}_1, \dots, h^{(\alpha)}_n)$ satisfying the initial condition

$$(h^{(\alpha)}_1(0), \dots, h^{(\alpha)}_n(0))_0 = X_{\alpha},$$

where $X_1, \dots, X_n \in \mathbb{R}^n_0$ is orthonormal with respect to $\langle \cdot, \cdot \rangle_0$.

Step 2. We claim that if (h_1, \dots, h_n) satisfies $(*)$, then $h = dx$ for some function x , i.e., $h_j = \partial x / \partial y^j$. In terms of the form

$$\eta = h_1 dy^1 + \dots + h_n dy^n,$$

we are just saying that η is exact. We know (Corollary I.7-15) that this is true if and only if

$$\frac{\partial h_j}{\partial y^k} = \frac{\partial h_k}{\partial y^j}.$$

Glancing at $(*)$, we see that this is indeed true, since $\Gamma_{jk}^{\gamma} = \Gamma_{kj}^{\gamma}$.

Now choose functions x^{α} with $h^{(\alpha)}_j = \partial x^{\alpha} / \partial y^j$. Then the functions x^{α} satisfy

$$(\dagger) \quad \frac{\partial^2 x^{\alpha}}{\partial y^j \partial y^k} = \sum_{\gamma=1}^n \Gamma_{jk}^{\gamma} \frac{\partial x^{\alpha}}{\partial y^{\gamma}} \quad \left[\begin{array}{l} \text{these are the equations (6),} \\ \text{obtained earlier, page 187} \end{array} \right]$$

and

$$\left(\frac{\partial x^\alpha}{\partial y^j}(0) \right) = \begin{pmatrix} X_1 \\ \vdots \\ X_n \end{pmatrix};$$

this matrix is non-singular, so x^1, \dots, x^n is a coordinate system in a neighborhood of 0.

Step 3. We claim that x is the desired coordinate system, i.e., that

$$(\dagger) \quad \delta_{\mu\nu} = \sum_{i,j=1}^n g^{ij} \frac{\partial x^\mu}{\partial y^i} \frac{\partial x^\nu}{\partial y^j} \quad [\text{equation (4'), page 185}].$$

We know that this equation holds at 0, by the choice of the initial conditions $\partial x^\alpha / \partial y^j(0)$. So it suffices to show that the right side of (\dagger) has all partial derivatives $\partial / \partial y^k$ equal to 0. But

$$\begin{aligned} \frac{\partial}{\partial y^k} \left(\sum_{i,j} g^{ij} \frac{\partial x^\mu}{\partial y^i} \frac{\partial x^\nu}{\partial y^j} \right) &= \sum_{i,j} \frac{\partial g^{ij}}{\partial y^k} \frac{\partial x^\mu}{\partial y^i} \frac{\partial x^\nu}{\partial y^j} \\ &\quad + \sum_{i,j} g^{ij} \frac{\partial^2 x^\mu}{\partial y^i \partial y^k} \frac{\partial x^\nu}{\partial y^j} + \sum_{i,j} g^{ij} \frac{\partial x^\mu}{\partial y^i} \frac{\partial^2 x^\nu}{\partial y^j \partial y^k} \\ &= \sum_{i,j} \frac{\partial g^{ij}}{\partial y^k} \frac{\partial x^\mu}{\partial y^i} \frac{\partial x^\nu}{\partial y^j} + \sum_{i,j} g^{ij} \sum_{\gamma} \Gamma_{ik}^{\gamma} \frac{\partial x^\mu}{\partial y^\gamma} \frac{\partial x^\nu}{\partial y^j} \\ &\quad + \sum_{i,j} g^{ij} \sum_{\gamma} \Gamma_{jk}^{\gamma} \frac{\partial x^\mu}{\partial y^i} \frac{\partial x^\nu}{\partial y^\gamma} \quad \text{by } (\dagger). \end{aligned}$$

Switching some indices, we thus have

$$\begin{aligned} \frac{\partial}{\partial y^k} \left(\sum_{i,j} g^{ij} \frac{\partial x^\mu}{\partial y^i} \frac{\partial x^\nu}{\partial y^j} \right) &= \sum_{i,j} \frac{\partial x^\mu}{\partial y^i} \frac{\partial x^\nu}{\partial y^j} \left(\frac{\partial g^{ij}}{\partial y^k} + \sum_{\gamma} g^{\gamma j} \Gamma_{\gamma k}^i + \sum_{\gamma} g^{i \gamma} \Gamma_{\gamma k}^j \right) \\ &= 0 \quad \text{by } (**). \end{aligned}$$

This completes the proof of the theorem. ♦

As a brief review of the proof, we note that

Step 1 uses the *integrability conditions*, $R = 0$, to obtain certain forms $\sum_i h^{(\alpha)}_i dy^i$, with any desired initial conditions;

Step 2 uses *symmetry of the Christoffel symbols*, $\Gamma_{ij}^k = \Gamma_{ji}^k$, to prove that $\sum_i h^{(\alpha)}_i dy^i = dx^\alpha$ for some x^α ;

Step 3 uses the *definition of the Christoffel symbols* $[ij, k]$ to prove that the vectors $\partial/\partial x^\alpha$ are orthonormal.

Despite its length, the proof is essentially a straightforward application of the integrability conditions for partial differential equations. As Riemann says, at the end of the section in Part C, “Given an acquaintance with the traditional methods, it is demonstrated without difficulty that these . . . conditions, when they are satisfied, suffice.”

We have thus proved one special case of Riemann’s assertion that the curvature determines the metric. We will not return to the more general assertion until Chapter 7, for our immediate task will be to begin systematizing all the results which have been uncovered so far.

ADDENDUM FINSLER METRICS

A **Minkowski metric** on a vector space V is a function $F: V \rightarrow \mathbb{R}$ such that

$$\begin{aligned} F(v) &> 0 && \text{for all } v \neq 0 \\ F(\lambda v) &= |\lambda|F(v). \end{aligned}$$

Clearly F is completely determined by its “unit sphere” $\{v : F(v) = 1\}$; the unit sphere is symmetric with respect to $0 \in V$, and intersects every ray through 0 exactly once. Moreover, any such set is clearly the unit sphere for some F . The

function F is never C^∞ at 0 , but F^2 may be, in which case we will simply say that F is C^∞ . The general metric which Riemann mentions is essentially an assignment of a C^∞ Minkowski metric F_p to each tangent space M_p , in such a way that F_p varies smoothly with p . We will call such an assignment simply a “metric” on M .

If $c: [a, b] \rightarrow M$ is a curve in a manifold M with such a metric, then we can define the **length** of c to be

$$\int_a^b F_{c(t)}(c'(t)) dt.$$

If $p: [\bar{a}, \bar{b}] \rightarrow [a, b]$ is an increasing diffeomorphism, and we denote $F_{c(t)}(c'(t))$ by $g(t)$, then

$$\begin{aligned} \text{length of } c \circ p &= \int_{\bar{a}}^{\bar{b}} F_{c(p(t))}((c \circ p)'(t)) dt \\ &= \int_{\bar{a}}^{\bar{b}} F_{c(p(t))}(p'(t) \cdot c'(p(t))) dt \\ &= \int_{p^{-1}(a)}^{p^{-1}(b)} p'(t) g(p(t)) dt \\ &= \int_a^b g(t) dt = \text{length of } c. \end{aligned}$$

The same result clearly holds if p is decreasing; thus, the length of a curve is independent of parameterization. It is to insure this result that we require our metric to satisfy $F(\lambda v) = |\lambda| \cdot F(v)$.

Although a C^∞ metric F on a manifold M is not a tensor, it can be used to construct a tensor on the manifold TM . To do this, we first consider a C^∞ function $f: V \rightarrow \mathbb{R}$ on a vector space V . For any two vectors $v, w \in V$ we can form the second derivative

$$f_{**}(v)(w) = \left. \frac{d^2}{dt^2} \right|_{t=0} f(v + tw);$$

this is a sort of second order directional derivative at v . If v_1, \dots, v_n is a basis for V , and $\phi: \mathbb{R}^n \rightarrow \mathbb{R}$ is defined by

$$\phi(a^1, \dots, a^n) = f\left(\sum_{i=1}^n a^i v_i\right),$$

then

$$f_{**}\left(\sum_{i=1}^n b^i v_i\right)\left(\sum_{i=1}^n c^i v_i\right) = \sum_{i,j} \frac{\partial^2 \phi}{\partial x^i \partial x^j}(b) \cdot c^i c^j.$$

The map $f_{**}(v): V \rightarrow \mathbb{R}$ is called the **Hessian** of f at $v \in V$. When F is a Minkowski metric, it is clear from the definition that

$$(F^2)_{**}(v)(v) = 2[F(v)]^2.$$

[This Hessian may be compared with the Hessian f_{**} defined in Problem I.5-17 for a function $f: M \rightarrow \mathbb{R}$, at a point $p \in M$ where $f_*p = 0$. The latter is a bilinear function on M_p , whereas the present $f_{**}(v)$ is a quadratic function on V . The associated bilinear function is easily seen to be

$$(w_1, w_2) \mapsto \left. \frac{\partial^2}{\partial s \partial t} \right|_{(s,t)=0} f(v + sw_1 + tw_2),$$

and in terms of a basis it is given by

$$\left(\sum_{i=1}^n c^i v_i, \sum_{i=1}^n d^i v_i\right) \mapsto \sum_{i,j} \frac{\partial^2 \phi}{\partial x^i \partial x^j} b \cdot c^i d^j,$$

the same formula which occurs in Problem I.5-17. Our Hessian is defined even at points where $f_* \neq 0$ because we are working with a vector space, and

identifying it with its tangent space at v ; this amounts to saying that we are considering only linear changes of coordinates, all of which leave the quantity defined by this formula invariant.]

Now if M is a manifold, with a C^∞ metric F , and $v \in M_p$, then the tangent space $(TM)_v$ of TM at v can be identified with M_p ; in accordance with this identification, we denote a vector in $(TM)_v$ by w_v . We can now define a tensor \mathcal{F} on TM by

$$\mathcal{F}(w_v) = \frac{1}{2}(F_p^2)_{**}(v)(w).$$

If F is the norm $\| \cdot \|$ associated with a Riemannian metric $\langle \cdot, \cdot \rangle$, then it is easy to see that

$$\mathcal{F}(w_v) = \langle v, w \rangle_p,$$

and in general we always have

$$[F(v_p)]^2 = \mathcal{F}(v_v).$$

If x is a coordinate system on M , and $(x \circ \pi, \dot{x})$ is the corresponding coordinate system on TM (defined on pg. I.81), then

$$\mathcal{F} = \sum_{i,j=1}^n g_{ij} d\dot{x}^i \cdot d\dot{x}^j,$$

where

$$g_{ij}(v_p) = \frac{1}{2} \frac{\partial^2 (F_p^2)}{\partial \dot{x}^i \partial \dot{x}^j}(v_p).$$

Classically, one dealt only with the functions g_{ij} , defined by this formula, and checked that the function

$$\sum_{i=1}^n b^i \frac{\partial}{\partial x^i} \Big|_p \mapsto \sum_{i,j=1}^n g_{ij} b^i b^j$$

was independent of the coordinate system x .

A **Finsler metric** is defined to be a metric F such that the quadratic function $\mathcal{F}: (TM)_v \rightarrow \mathbb{R}$ is positive definite for all $v \in TM$. In terms of a coordinate system x , this means that

$$(g_{ij}(v_p)) = \frac{1}{2} \left(\frac{\partial^2 (F_p^2)}{\partial \dot{x}^i \partial \dot{x}^j}(v_p) \right) \quad \text{is a positive definite matrix.}$$

To interpret this condition geometrically, we consider once again a function $f: V \rightarrow \mathbb{R}$. Suppose that for all v we have $f_{**}(v)(w) > 0$ for all $w \neq 0$.

Then for all v , and each straight line through v , the function \bar{f} obtained by restricting f to this line has an everywhere positive second derivative. By a

standard theorem (*Calculus*, pg. 220) this means that the function \bar{f} is convex (the set of points above or on its graph is a convex subset of the plane). It is easy to see that consequently the function f itself must be convex (the set of points on or above its graph is a convex subset of $V \times \mathbb{R}$). Conversely, convexity of f implies that $f_{**}(v)(w) \geq 0$. Our stronger condition $f_{**}(v)(w) > 0$ might be called “very-strict-convexity of f ”.

When we apply this to a Finsler metric, we see that each function F_p^2 is convex on M_p , so that each $C_p = \{(v, r) \in M_p \times \mathbb{R} : r \geq F_p^2(v)\}$ is a convex subset of $M_p \times \mathbb{R}$. It is easy to see that this is equivalent to convexity of the “unit ball” $\{w : F_p(w) \leq 1\}$, which may be regarded as the intersection of C_p and the hyperplane $r = 1$ in $M_p \times \mathbb{R}$. Note that convexity of the unit ball is equivalent to the “triangle inequality”

$$F_p(w_1 + w_2) \leq F_p(w_1) + F_p(w_2).$$

In general, a function $\| \cdot \| : V \rightarrow \mathbb{R}$ on a finite dimensional space V is called a **Banach space norm** if

$$\begin{aligned} \|v\| &> 0 && \text{for } v \neq 0 \\ \|\lambda v\| &= |\lambda| \cdot \|v\| \\ \|v + w\| &\leq \|v\| + \|w\| \end{aligned}$$

(if V is infinite dimensional, the definition is more involved). So a Finsler metric on M is a C^∞ Banach space norm on each M_p , varying smoothly with p (and with the unit balls on each M_p satisfying a very-strict-convexity requirement).

Although we will not develop the theory of Finsler, or more general, metrics here, we will mention a few facts. In the case of a Finsler metric, since the matrix $(g_{ij}(v_p))$ is non-degenerate, we can define $g^{ij}(v_p)$ so that

$$\sum_{j=1}^n g^{ij}(v_p) \cdot g_{jk}(v_p) = \delta_k^i.$$

The reader may seek an invariant description of the $g^{ij}(v_p)$. We can also define the symbols

$$[ij, k] = \frac{1}{2} \left(\frac{\partial g_{ik}}{\partial x^j} + \frac{\partial g_{jk}}{\partial x^i} - \frac{\partial g_{ij}}{\partial x^k} \right)$$

$$\Gamma_{ij}^k = \sum_{l=1}^n g^{kl} [ij, l],$$

as before, except that they are now functions on TM . It turns out that the critical paths for length are curves $c: [a, b] \rightarrow M$ which, when parameterized by arclength, satisfy

$$\frac{d^2 x^k(c(s))}{ds^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(c'(s)) \cdot \frac{d\dot{x}^i(c(s))}{ds} \frac{d\dot{x}^j(c(s))}{ds} = 0.$$

It also turns out, just as in the Riemannian case, that sufficiently small pieces of these critical paths are actually paths of shortest length. However, this is false for more general Minkowski metrics.

We shall not pursue the subject of Finsler metrics much further, but we will add some remarks about Minkowski metrics F on a vector space V . A Minkowski metric F can be used to define a “distance” function on $V \times V$, by $(v, w) \mapsto F(w - v)$ (however, it is easy to see that this distance function satisfies the triangle inequality, and is consequently a metric, if and only if F is a Banach space norm on V). This is just the procedure by which, in analytic geometry, we define the distance between two points in \mathbb{R}^n ; in this case, we choose $F(x) = (\sum (x^i)^2)^{1/2}$, motivated, of course, by the Pythagorean Theorem. After the Pythagorean Theorem has been incorporated into our definition of distance in this way, it is interesting to ask what content, if any, remains to this theorem. The answer is, that the Pythagorean Theorem has been declared true only for right triangles with sides parallel to the axes, but remains true for all right triangles. This is because, when $F(x) = (\sum (x^i)^2)^{1/2}$, the isometries of \mathbb{R}^n are transitive on the unit sphere. That is to say, if p and q are in the unit

sphere, then there is a linear transformation $\phi: \mathbb{R}^n \rightarrow \mathbb{R}^n$ with $\phi(p) = q$ and $F(\phi(x)) = F(x)$ for all x .

This same transitivity property holds for any F which is the norm $\| \cdot \|$ associated to a positive definite inner product $\langle \cdot, \cdot \rangle$ on an n -dimensional vector space V , since there is an isomorphism $f: \mathbb{R}^n \rightarrow V$ such that $f^*\langle \cdot, \cdot \rangle$ is the usual inner product on \mathbb{R}^n (Theorem I.9-3). It turns out that this property actually characterizes the Minkowski metrics F which arise from inner products. To prove this, we need an auxiliary concept, and a result from linear algebra.

An **ellipsoid** on a vector space V is a set of the form $\{v \in V : \langle v, v \rangle \leq 1\}$ for some positive definite inner product $\langle \cdot, \cdot \rangle$. In particular, consider such an inner product $\langle \cdot, \cdot \rangle$ on \mathbb{R}^n , which also has its standard inner product $\langle \cdot, \cdot \rangle$. The ellipsoid $\{v \in V : \langle v, v \rangle \leq 1\}$ really looks like an ellipsoid, because of the

following well-known result:

14. PROPOSITION (EXISTENCE OF PRINCIPAL AXES). If $\langle \cdot, \cdot \rangle$ is any positive definite inner product on \mathbb{R}^n , then there is a basis for \mathbb{R}^n which is orthonormal for $\langle \cdot, \cdot \rangle$ and also *orthogonal* with respect to $\langle \cdot, \cdot \rangle$.

PROOF. For each $x \in \mathbb{R}^n$, the map $y \mapsto \langle x, y \rangle$ is a linear functional, so there is a unique $Tx \in \mathbb{R}^n$ such that

$$\langle Tx, y \rangle = \langle x, y \rangle \quad \text{for all } y.$$

It is easy to see that $x \mapsto Tx$ is a linear transformation $T: \mathbb{R}^n \rightarrow \mathbb{R}^n$. Moreover,

$$\langle Tx, y \rangle = \langle x, y \rangle = \langle y, x \rangle = \langle Ty, x \rangle = \langle x, Ty \rangle,$$

so T is self-adjoint with respect to $\langle \cdot, \cdot \rangle$. Thus T has a basis x_1, \dots, x_n of eigenvalues, $Tx_i = \lambda_i x_i$, and the x_i can be picked orthogonal with respect

to $\langle \cdot, \cdot \rangle$. Now

$$\begin{aligned}\lambda_j \langle x_i, x_j \rangle &= \lambda_j \langle T x_i, x_j \rangle = \lambda_i \lambda_j \langle x_i, x_j \rangle \\ &= \lambda_i \langle x_i, T x_j \rangle \\ &= \lambda_i \langle x_i, x_j \rangle.\end{aligned}$$

So $\langle x_i, x_j \rangle = 0$ if $\lambda_i \neq \lambda_j$. On the other hand, if two or more x_i have the same λ_i , then in the m -dimensional subspace which they span we can pick m eigenvectors which are orthogonal with respect to $\langle \cdot, \cdot \rangle$. So we can assume that $\langle x_i, x_j \rangle = 0$ for $i \neq j$. Now we just normalize each x_i with respect to $\langle \cdot, \cdot \rangle$. ♦

We now use this result to prove the basic lemma for our main assertion.

15. LEMMA. Let B be a bounded neighborhood of 0 in an n -dimensional vector space V . Then among all ellipsoids containing B there exists a unique one of smallest volume. (We assign a volume to the ellipsoids by choosing an isomorphism of V with \mathbb{R}^n . Choosing a different isomorphism clearly does not change the property of having the “smallest volume”.)

PROOF. First we prove existence. We might as well assume that $V = \mathbb{R}^n$. Moreover, we can assume that B is closed, since an ellipsoid containing B also contains \bar{B} . Choose r and R so that

$$\{x \in \mathbb{R}^n : |x| \leq r\} \subset B \subset \{x \in \mathbb{R}^n : |x| \leq R\}.$$

Every orthogonal basis $b = (v_1, \dots, v_n)$ of \mathbb{R}^n determines an ellipsoid $E(b)$ with principal axes v_1, \dots, v_n [equivalently, b determines an inner product on \mathbb{R}^n , namely the one which makes v_1, \dots, v_n *orthonormal*]. To prove existence it obviously suffices to consider only ellipsoids of volume $\leq \alpha R^n$, where α is the volume of the unit ball. Now the principal axes v_1, \dots, v_n of any ellipsoid containing B must have lengths $a_i \geq r$. Consequently, if this ellipsoid has volume $\leq \alpha R^n$, so that $\prod_i a_i \leq R^n$, then each $a_i \leq R^n / r^{n-1}$.

Consider the set $\{b = (v_1, \dots, v_n) : B \subset E(b) \text{ and length } v_i \leq R^n / r^{n-1}\}$. This is a compact subset of the n -fold product $\mathbb{R}^n \times \dots \times \mathbb{R}^n$. Hence $b \mapsto \text{volume } E$ takes on its minimum on this set. This proves existence.

Now consider two different ellipsoids containing B , with the same volume. Choose an isomorphism of V with \mathbb{R}^n which makes the first of these ellipsoids correspond to the ordinary unit ball $\{x \in \mathbb{R}^n : f_1(x) \leq 1\}$, where $f_1(x) = \sum (x^i)^2$. Proposition 14 shows that after a rotation of the axes, the second of

the ellipsoids corresponds to $\{x \in \mathbb{R}^n : f_2(x) \leq 1\}$, where

$$f_2(x) = a_1(x^1)^2 + \cdots + a_n(x^n)^2.$$

The volume of this ellipsoid is $\prod_{i=1}^n 1/\sqrt{a_i}$ times the volume of the unit ball. Since the two ellipsoids are assumed to have the same volume, this means that

$$\prod_{i=1}^n a_i = 1.$$

Now consider the ellipsoid

$$E = \left\{ x \in \mathbb{R}^n : \frac{f_1 + f_2}{2}(x) \leq 1 \right\}.$$

Clearly E also contains B . Now the semi-axes of E have length

$$\frac{1}{\sqrt{\frac{1+a_i}{2}}},$$

so the volume of E is the volume of the unit ball times

$$\prod_{i=1}^n \frac{1}{\sqrt{\frac{1+a_i}{2}}}.$$

Recall that for $a, b > 0$ we have

$$\sqrt{ab} \leq \frac{a+b}{2} \quad \text{with equality if and only if } a = b.$$

Consequently,

$$\prod_{i=1}^n \frac{1}{\sqrt{\frac{1+a_i}{2}}} \leq \prod_{i=1}^n \frac{1}{\sqrt[4]{a_i}} = \frac{1}{\sqrt[4]{\prod_{i=1}^n a_i}} = 1,$$

and strict equality holds if some $a_i \neq 1$, i.e., if the original two ellipsoids are different. This means that if two different ellipsoids containing B have the same volume, then there is another ellipsoid containing B with smaller volume. This clearly proves uniqueness of the ellipsoid with smallest volume. ♦

16. THEOREM. Let $F: V \rightarrow \mathbb{R}$ be a continuous Minkowski metric on an n -dimensional vector space V . Suppose that for all p and q in the unit sphere $\{v \in V : F(v) = 1\}$, there is a linear transformation $\phi: V \rightarrow V$ such that $\phi(p) = q$ and $F(\phi(v)) = F(v)$ for all $v \in V$. Then F is the norm determined by some positive definite inner product.

PROOF. Let $B = \{v : F(v) \leq 1\}$, and let E be the unique ellipsoid containing B of smallest volume. Clearly, there must be some point p with $F(p) = 1$ and $p \in \text{boundary } E$. Let q be any other point with $F(q) = 1$, and $\phi: V \rightarrow V$

a linear transformation with $\phi(p) = q$ such that $F(\phi(v)) = F(v)$ for all $v \in V$. It follows easily from the latter property that $\phi(E) \supset B$. Moreover, $\phi(B) = B$, so ϕ is volume preserving. By uniqueness of the ellipsoid E , it follows that $\phi(E) = E$. Consequently, $q = \phi(p) \in \text{boundary } E$. In other words, every point q with $F(q) = 1$ is in boundary E . This means that $E = B$. ♦

CHAPTER 5

THE ABSOLUTE DIFFERENTIAL CALCULUS (THE RICCI CALCULUS); OR, THE DEBAUCH OF INDICES

Although Riemann essentially defined the curvature tensor, the (classical) notion of a tensor did not even exist in his time. The development of the “Calculus of Tensors” is due mainly to Ricci, and was carried out in the years 1887–1896; in 1901 he and his student Levi-Civita gave a detailed description in a memoir *Methods de calcul differential absolu et leurs applications*. In addition to a comprehensive use of tensors, what distinguished the Absolute Differential Calculus, and gave it its name, was an important construction which greatly simplified all the concepts of Riemannian geometry, especially the curvature tensor. Instead of checking that the horrible formula used to define R^i_{jkl} transforms correctly, we are going to check that an equally mysterious—but not quite so horrible—formula transforms correctly, and thus defines a tensor; then we will define the curvature tensor in terms of this one.

In 1869, in one of the earliest papers which took up Riemann’s ideas, Christoffel had already made the observation which Ricci made the basis for his calculus. Suppose that Y is a vector field, and

$$\begin{aligned} Y &= \sum_{j=1}^n \lambda^j \frac{\partial}{\partial x^j} \\ &= \sum_{j=1}^n \lambda'^j \frac{\partial}{\partial x'^j}. \end{aligned}$$

Consider the following symbols, defined in terms of the Christoffel symbols of the second kind for the coordinate systems x and x' :

$$\begin{aligned} \lambda^j_{;h} &= \frac{\partial \lambda^j}{\partial x^h} + \sum_{v=1}^n \lambda^v \Gamma^j_{hv} \\ \lambda'^j_{;h} &= \frac{\partial \lambda'^j}{\partial x'^h} + \sum_{v=1}^n \lambda'^v \Gamma'^j_{hv}. \end{aligned}$$

It is easy to check that for these symbols—the sums of partial derivatives of the λ^j and certain linear combinations of them—we have

$$\lambda'^{\alpha}_{;\beta} = \sum_{h,j=1}^n \lambda^j_{;h} \frac{\partial x^h}{\partial x'^{\beta}} \frac{\partial x'^{\alpha}}{\partial x^j}.$$

For the calculation we use the formula on page 189 together with the formula

$$\lambda'^{\alpha} = \sum_{j=1}^n \lambda^j \frac{\partial x'^{\alpha}}{\partial x^j};$$

when we compute $\partial \lambda'^{\alpha} / \partial x'^{\beta}$, the extra terms involving second partial derivatives of the x'^{α} just cancel out with the extra terms in the transformation formula for the Christoffel symbols. This calculation shows that there is a certain tensor field of type $\binom{1}{1}$ which equals

$$\sum_{h,j=1}^n \lambda^j_{;h} dx^h \otimes \frac{\partial}{\partial x^j}$$

in the x coordinate system. In classical terms, “if the λ^j transform like a tensor of type $\binom{0}{1}$, then the $\lambda^j_{;h}$ transform like a tensor of type $\binom{1}{1}$ ”. Similarly, if the λ_i transform like a tensor of type $\binom{1}{0}$, then the quantities

$$\lambda_{i;h} = \frac{\partial \lambda_i}{\partial x^h} - \sum_{v=1}^n \lambda_v \Gamma_{hi}^v$$

are easily seen to transform like a tensor of type $\binom{2}{0}$, so that there is a tensor of type $\binom{2}{0}$ which equals

$$\sum_{i,h=1}^n \lambda_{i;h} dx^i \otimes dx^h$$

in the x coordinate system. Generally, given a tensor of type $\binom{k}{l}$, with components

$$A_{i_1 \dots i_k}^{j_1 \dots j_l},$$

there is a new tensor, of type $\binom{k+1}{l}$, with components

$$\begin{aligned} A_{i_1 \dots i_k;h}^{j_1 \dots j_l} &= \frac{\partial A_{i_1 \dots i_k}^{j_1 \dots j_l}}{\partial x^h} + \sum_{s=1}^l \sum_{v=1}^n A_{i_1 \dots i_k}^{j_1 \dots j_{s-1} v j_{s+1} \dots j_l} \Gamma_{hv}^{j_s} \\ &\quad - \sum_{r=1}^k \sum_{v=1}^n A_{i_1 \dots i_{r-1} v i_{r+1} \dots i_k}^{j_1 \dots j_l} \Gamma_{hv}^{i_r}. \end{aligned}$$

The proof is again just an enormous calculation. At the other extreme from this most general case is the special case of a tensor field of type $\binom{0}{0}$ on M , i.e., a function $f: M \rightarrow \mathbb{R}$. Here we simply define

$$f_{;h} = \frac{\partial f}{\partial x^h},$$

so that in this case at least the identity of the tensor field

$$\sum_{h=1}^n f_{;h} dx^h = \sum_{h=1}^n \frac{\partial f}{\partial x^h} dx^h$$

is no mystery—it is just df .

The tensor of type $\binom{k+1}{l}$ which we thus obtain from a tensor A of type $\binom{k}{l}$ is called the **covariant derivative** of A , since it is covariant of one order greater than A . It is also called the “absolute derivative” of A ; here the word “absolute” means that it doesn’t depend on a particular coordinate system. Various notations for the covariant derivative are encountered—one sometimes sees $\lambda_{i|h}^j$, or $\lambda_{i,h}^j$, or even λ_{ih}^j . Use of a semi-colon should avoid all possible confusion!

A partial answer to the question “What does the covariant derivative really mean?” is given by the following observation.

1. PROPOSITION. Let x be a Riemannian normal coordinate system at the point $p \in M$, and A a tensor of type $\binom{k}{l}$ on M , with

$$A = \sum A_{i_1 \dots i_k}^{j_1 \dots j_l} dx^{i_1} \otimes \dots \otimes dx^{i_k} \otimes \frac{\partial}{\partial x^{j_1}} \otimes \dots \otimes \frac{\partial}{\partial x^{j_l}}.$$

Then the components *at the point* p of the covariant derivative of A are just the ordinary partial derivatives

$$(*) \quad A_{i_1 \dots i_k; h}^{j_1 \dots j_l}(p) = \frac{\partial A_{i_1 \dots i_k}^{j_1 \dots j_l}}{\partial x^h}(p).$$

PROOF. In a Riemannian normal coordinate system at p , the Christoffel symbols $[ij, k]$, and hence also the Γ_{ij}^k , are all 0 at p . ♦

Proposition 1 can even be used to *define* covariant derivatives. The Riemannian normal coordinate systems at p are a natural set of coordinate systems, determined by the metric $\langle \ , \ \rangle$; any two such systems at p differ only by an

element of $O(n)$, and it is easy to see from this that a definition of the covariant derivative by means of $(*)$ would not depend on which one was picked. With a little work, one could then deduce the general expression for the components of the covariant derivative of A in any coordinate system. In succeeding chapters we will be giving still other interpretations of the covariant derivative.

The operation of covariant differentiation obeys many rules analogous to those for ordinary differentiation.

2. PROPOSITION. Covariant differentiation is a derivation and commutes with sums and contractions. For example, if A and B are tensors of type $\binom{2}{2}$ and C is a tensor of type $\binom{1}{1}$, then

$$\begin{aligned}(A_{i_1 i_2}^{j_1 j_2} C_{i_3}^{j_3})_{;h} &= A_{i_1 i_2;h}^{j_1 j_2} C_{i_3}^{j_3} + A_{i_1 i_2}^{j_1 j_2} C_{i_3;h}^{j_3} \\ (A_{i_1 i_2}^{j_1 j_2} + B_{i_1 i_2}^{j_1 j_2})_{;h} &= A_{i_1 i_2;h}^{j_1 j_2} + B_{i_1 i_2;h}^{j_1 j_2} \\ \left(\sum_{v=1}^n A_{i_1 v}^{v j_2} \right)_{;h} &= \sum_{v=1}^n A_{i_1 v;h}^{v j_2}.\end{aligned}$$

Consequently, we have, for example,

$$\left(\sum_{v=1}^n A_{v i_2}^{j_1 j_2} C_{i_3}^v \right)_{;h} = \sum_{v=1}^n A_{v i_2;h}^{j_1 j_2} C_{i_3}^v + A_{v i_2}^{j_1 j_2} C_{i_3;h}^v.$$

PROOF. Compute. Because of Proposition 1, the computations become trivial if one uses Riemannian normal coordinates. ♦

There is one tensor which we have on any manifold, the identity map of each M_p into itself, with coordinates δ_i^j in any coordinate system. For the covariant derivative we have

$$\begin{aligned}\delta_{i;h}^j &= \frac{\partial \delta_i^j}{\partial x^h} + \sum_{v=1}^n \delta_i^v \Gamma_{hv}^j - \sum_{v=1}^n \delta_v^j \Gamma_{hi}^v \\ &= \Gamma_{hi}^j - \Gamma_{hi}^j \\ &= 0,\end{aligned}$$

which shouldn't be very surprising (what else could it be?). Aside from these general formulas, there are two of crucial importance. The first of them is about the covariant derivative of the tensors $\langle \ , \ \rangle$ and $\langle \ , \ \rangle^*$.

3. PROPOSITION (RICCI'S LEMMA). The g_{ij} and g^{ij} behave like constants in covariant differentiation; that is,

$$\begin{aligned} g_{ij;k} &= 0 \\ g^{ij};_k &= 0. \end{aligned}$$

PROOF. The proof is, of course, a calculation. For the g_{ij} we have

$$\begin{aligned} g_{ij;k} &= \frac{\partial g_{ij}}{\partial x^k} - \sum_{v=1}^n g_{vj} \Gamma_{ki}^v - \sum_{v=1}^n g_{iv} \Gamma_{kj}^v \\ &= \frac{\partial g_{ij}}{\partial x^k} - [ik, j] - [jk, i] \\ &= 0, \end{aligned}$$

by equation (*) on page 196. Similarly, the second equation is equivalent to the following equation (**). It can also be obtained from the first equation and Proposition 2, since $\sum_j g^{ij} g_{jl} = \delta_l^i$ and $\delta_{l,k}^i = 0$. ♦

The second crucial formula involves “second order” covariant derivatives. If A is a tensor of type $\binom{k}{l}$, with components $A_{i_1 \dots i_k}^{j_1 \dots j_l}$, then the operation of covariant differentiation can be applied to the tensor B with components

$$B_{i_1 \dots i_k h}^{j_1 \dots j_l} = A_{i_1 \dots i_k; h}^{j_1 \dots j_l};$$

there results a tensor C with components

$$C_{i_1 \dots i_k h \eta}^{j_1 \dots j_l} = B_{i_1 \dots i_k h; \eta}^{j_1 \dots j_l} = (A_{i_1 \dots i_k; h}^{j_1 \dots j_l})_{; \eta}.$$

These components are denoted by

$$A_{i_1 \dots i_k; h; \eta}^{j_1 \dots j_l} \quad \text{or simply} \quad A_{i_1 \dots i_k; h \eta}^{j_1 \dots j_l}.$$

For example, if we start with a function f [a tensor of type $\binom{0}{0}$], then

$$f_{;i} = \frac{\partial f}{\partial x^i}$$

and

$$\begin{aligned} f_{;ij} &= (f_{;i})_{;j} = \frac{\partial \left(\frac{\partial f}{\partial x^i} \right)}{\partial x^j} - \sum_{v=1}^n \frac{\partial f}{\partial x^v} \Gamma_{ji}^v \\ &= \frac{\partial^2 f}{\partial x^i \partial x^j} - \sum_{v=1}^n \frac{\partial f}{\partial x^v} \Gamma_{ji}^v. \end{aligned}$$

Notice that

$$f_{;ij} = f_{;ji}$$

by symmetry of the Γ_{ij}^ν . The same result definitely does not hold for other tensors; instead we have the following basic result.

4. PROPOSITION (RICCI'S IDENTITIES). If the λ^i and λ_i are components of tensors of type $\binom{0}{1}$ and $\binom{1}{0}$, respectively, then

$$\lambda^i_{;jk} - \lambda^i_{;kj} = - \sum_{l=1}^n \lambda^l R^i_{ljk}$$

$$\lambda_{i;jk} - \lambda_{i;kj} = \sum_{l=1}^n \lambda_l R^l_{ijk},$$

where

$$R^i_{jkl} = \frac{\partial \Gamma^i_{lj}}{\partial x^k} - \frac{\partial \Gamma^i_{kj}}{\partial x^l} + \sum_{\mu=1}^n \Gamma^{\mu}_{lj} \Gamma^i_{k\mu} - \Gamma^{\mu}_{kj} \Gamma^i_{l\mu}.$$

(There are similar identities for tensors of type $\binom{k}{l}$, but we will ignore them.*)

PROOF. Compute. ♦

[The second identity is a consequence of the first, for if we are given λ_i and define

$$\lambda^i = \sum_{\alpha=1}^n g^{i\alpha} \lambda_{\alpha}, \quad \text{so that} \quad \lambda_i = \sum_{\alpha=1}^n g_{i\alpha} \lambda^{\alpha},$$

then

$$\begin{aligned} \lambda_{i;jk} - \lambda_{i;kj} &= \left(\sum_{\alpha=1}^n g_{i\alpha} \lambda^{\alpha} \right)_{;jk} - \left(\sum_{\alpha=1}^n g_{i\alpha} \lambda^{\alpha} \right)_{;kj} \\ &= \sum_{\alpha=1}^n g_{i\alpha} (\lambda^{\alpha}_{;jk} - \lambda^{\alpha}_{;kj}) \quad \text{using Proposition 2} \end{aligned}$$

* For those who cannot bear to be left in ignorance, the general Ricci identity is

$$A^{j_1 \dots j_l}_{i_1 \dots i_k; h\eta} - A^{j_1 \dots j_l}_{i_1 \dots i_k; \eta h} = \sum_{r=1}^k \sum_{\nu=1}^n A^{j_1 \dots j_l}_{i_1 \dots i_{r-1} \nu i_{r+1} \dots i_k} R^{\nu}_{i_r h \eta} - \sum_{s=1}^l \sum_{\nu=1}^n A^{j_1 \dots j_{s-1} \nu j_{s+1} \dots j_l}_{i_1 \dots i_k} R^{j_s}_{\nu h \eta}.$$

$$\begin{aligned}
 &= - \sum_{\alpha=1}^n \sum_{l=1}^n g_{i\alpha} \lambda^l R^{\alpha}{}_{ljk} \\
 &= - \sum_{l=1}^n \lambda^l R_{iljk} && \text{(by definition of } R_{iljk}\text{)} \\
 &= \sum_{l=1}^n \lambda^l R_{lijk} && \text{by Proposition 4-10} \\
 &= \sum_{l=1}^n \sum_{\alpha=1}^n g_{l\alpha} \lambda^l R^{\alpha}{}_{ijk} \\
 &= \sum_{\alpha=1}^n \lambda_{\alpha} R^{\alpha}{}_{ijk},
 \end{aligned}$$

and similarly the first identity is a consequence of the second.]

5. COROLLARY. The $R^i{}_{jkl}$ are the components of a tensor of type $\binom{3}{1}$.

PROOF. Let Z be a vector field, with

$$Z = \sum_{i=1}^n \lambda^i \frac{\partial}{\partial x^i},$$

and let A be the tensor field with components $\lambda^i{}_{;jk}$. The first equation in Proposition 4 shows that

$$\begin{aligned}
 (*) \quad B\left(\frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k}\right) &= A\left(\frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k}\right) - A\left(\frac{\partial}{\partial x^k}, \frac{\partial}{\partial x^j}\right) \\
 &= \sum_{i=1}^n (\lambda^i{}_{;jk} - \lambda^i{}_{;kj}) \frac{\partial}{\partial x^i} \\
 &= - \sum_{i=1}^n \left(\sum_{l=1}^n \lambda^l R^i{}_{ljk} \right) \frac{\partial}{\partial x^i} \\
 &= - \sum_{l=1}^n \lambda^l \left(\sum_{i=1}^n R^i{}_{ljk} \frac{\partial}{\partial x^i} \right).
 \end{aligned}$$

This shows, in particular, that $B(\partial/\partial x^j|_p, \partial/\partial x^k|_p)$ does not depend on the vector field Z , but on the vector $Z(p)$ alone. So if we define

$$R(X, Y)Z = -B(X, Y),$$

then R is a tensor of type $\binom{3}{1}$, and

$$\begin{aligned} B\left(\frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k}\right) &= -R\left(\frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k}\right) Z \\ &= -\sum_{l=1}^n \lambda^l R\left(\frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k}\right) \frac{\partial}{\partial x^l}. \end{aligned}$$

Since this is true for all n -tuples $\{\lambda^l\}$, comparison with equation (*) shows that the components of R are indeed $R^i{}_{ljk}$. ♦

[Classically, this corollary would be deduced from the following general principle (compare Problem I.4-5(i)):

Suppose we are given a set of numbers $T^i{}_{ljk}$ for the coordinate system x , a set $T'^i{}_{ljk}$ for the coordinate system x' , etc. Suppose also that

$$C^i{}_{jk} = \sum_{l=1}^n \lambda^l T^i{}_{ljk}, \quad C'^i{}_{jk} = \sum_{l=1}^n \lambda'^l T'^i{}_{ljk}, \quad \text{etc.,}$$

are the components of a tensor for all tensors of type $\binom{0}{1}$ with components λ^l in the coordinate system x , and components λ'^l in the coordinate system x' , etc. Then $T^i{}_{ljk}$ are the components of a tensor.

The classical proof is by a calculation. We have

$$\begin{aligned} \sum_{\delta=1}^n \lambda'^{\delta} T'^{\alpha}{}_{\delta\beta\gamma} &= C'^{\alpha}{}_{\beta\gamma} = \sum_{i,j,k} C^i{}_{jk} \frac{\partial x'^{\alpha}}{\partial x^i} \frac{\partial x^j}{\partial x'^{\beta}} \frac{\partial x^k}{\partial x'^{\gamma}} \\ &= \sum_{i,j,k,l} \lambda^l T^i{}_{ljk} \frac{\partial x'^{\alpha}}{\partial x^i} \frac{\partial x^j}{\partial x'^{\beta}} \frac{\partial x^k}{\partial x'^{\gamma}} \\ &= \sum_{i,j,k,l,\delta} \lambda'^{\delta} T^i{}_{ljk} \frac{\partial x^l}{\partial x'^{\delta}} \frac{\partial x'^{\alpha}}{\partial x^i} \frac{\partial x^j}{\partial x'^{\beta}} \frac{\partial x^k}{\partial x'^{\gamma}}. \end{aligned}$$

Since this is true for arbitrary λ , we can choose all λ'^{δ} but one equal to zero; this gives the desired transformation formulas.]

Corollary 5 represents only one minor application of the Ricci identities. A more significant application is obtained when we consider a manifold with vanishing curvature tensor. In this case, we have

$$\begin{aligned} \lambda^i{}_{;jk} &= \lambda^i{}_{;kj} \\ \lambda_{i;jk} &= \lambda_{i;kj}. \end{aligned}$$

Thus, in manifolds with a vanishing curvature tensor (and only in such manifolds) the order of covariant differentiation is immaterial, so that in this respect covariant differentiation behaves like ordinary partial differentiation.* This enables us to give a more direct proof of

6. THEOREM (THE TEST CASE; SECOND VERSION). Let $(M, \langle \cdot, \cdot \rangle)$ be an n -dimensional Riemannian manifold for which the curvature tensor R is 0. Then M is locally isometric to \mathbb{R}^n with its usual Riemannian metric.

PROOF. As before, we assume we are in \mathbb{R}^n , and choose the standard coordinate system y^1, \dots, y^n around 0.

Step 1. We claim that we can find 1-forms $\eta = \sum \lambda_i dy^i$, with any desired initial value $\eta(0)$, satisfying

$$(*) \quad \lambda_{i;j} = 0 \quad i, j = 1, \dots, n.$$

To prove this, we begin by finding $\lambda_i(y, 0, \dots, 0)$, with the prescribed value for $y = 0$, and such that

$$(*)_1 \quad 0 = \lambda_{i;1}(y, 0, \dots, 0) = \frac{\partial \lambda_i(y, 0, \dots, 0)}{\partial y^1} - \sum_{v=1}^n \lambda_v(y, 0, \dots, 0) \Gamma_{1i}^v(y, 0, \dots, 0).$$

This just involves solving a set of ordinary differential equations, which is even linear, so that solutions exist for all y where the Γ 's are defined.

*At first sight, it might appear that this should always be the case, since covariant differentiation is the same as ordinary partial differentiation in a Riemannian normal coordinate system around p . However, the relation $\lambda^i_{;j} = \partial \lambda^i / \partial x^j$ holds only at p , so generally $\lambda^i_{;jk}(p) \neq \partial^2 \lambda^i / \partial x^j \partial x^k(p)$.

Next we find $\lambda_i(y_1, y, 0, \dots, 0)$, with the initial values $\lambda_i(y_1, 0, \dots, 0)$ just obtained, satisfying

$$\begin{aligned}
 (*_2) \quad 0 &= \lambda_{i;2}(y_1, y, 0, \dots, 0) \\
 &= \frac{\partial \lambda_i(y_1, y, 0, \dots, 0)}{\partial y^2} \\
 &\quad - \sum_{v=1}^n \lambda_v(y_1, y, 0, \dots, 0) \Gamma_{2i}^v(y_1, y, 0, \dots, 0).
 \end{aligned}$$

We continue in this way until we eventually obtain $\lambda_i(y_1, \dots, y_{n-1}, y)$ satisfying

$$(*_n) \quad 0 = \lambda_{i;n}(y_1, \dots, y_{n-1}, y).$$

We now claim that, in addition to the relation $\lambda_{i;1}(y, 0, \dots, 0) = 0$ given by $(*_1)$, we actually have

$$\lambda_{i;1}(y_1, y, 0, \dots, 0) = 0.$$

To see this, we first note that we have

$$\lambda_{i;21} = \lambda_{i;2;1} = \frac{\partial \lambda_{i;2}}{\partial y^1} - \sum_{v=1}^n \lambda_{v;2} \Gamma_{1i}^v - \sum_{v=1}^n \lambda_{i;v} \Gamma_{12}^v.$$

Since $0 = \lambda_{i;2}(y_1, y, 0, \dots, 0)$ by $(*_2)$, we obtain

$$\lambda_{i;21} = - \sum_{v=1}^n \lambda_{i;v} \Gamma_{12}^v \quad \text{at } (y_1, y, 0, \dots, 0).$$

Since $R = 0$, the Ricci identities then imply that

$$\lambda_{i;12} = \lambda_{i;21} = - \sum_{v=1}^n \lambda_{i;v} \Gamma_{12}^v \quad \text{at } (y_1, y, 0, \dots, 0),$$

i.e., that

$$\frac{\partial \lambda_{i;1}}{\partial y^2} - \sum_{v=1}^n \lambda_{v;1} \Gamma_{2i}^v - \sum_{v=1}^n \lambda_{1;v} \Gamma_{21}^v = - \sum_{v=1}^n \lambda_{1;v} \Gamma_{12}^v \quad \text{at } (y_1, y, 0, \dots, 0),$$

so that

$$\frac{\partial \lambda_{i;1}}{\partial y^2} - \sum_{v=1}^n \lambda_{v;1} \Gamma_{2i}^v = 0 \quad \text{at } (y_1, y, 0, \dots, 0).$$

Since we have the initial conditions $\lambda_{i;1}(y_1, 0, \dots, 0) = 0$, it is clear that the solution of this equation is just the desired one,

$$\lambda_{i;1}(y_1, y, 0, \dots, 0) = 0.$$

Proceeding in the same way, we next obtain

$$\lambda_{i;1}(y_1, y_2, y, 0, \dots, 0) = \lambda_{i;2}(y_1, y_2, y, 0, \dots, 0) = \lambda_{i;3}(y_1, y_2, y, 0, \dots, 0) = 0,$$

and, eventually,

$$0 = \lambda_{i;1} = \lambda_{i;2} = \dots = \lambda_{i;n} \quad \text{at } (y_1, \dots, y_{n-1}, y).$$

This completes the proof of the claim.

For $\alpha = 1, \dots, n$ we now choose $\eta^{(\alpha)} = \sum_i \lambda^{(\alpha)}_i dy^i$, so that

$$X_\alpha = (\lambda^{(\alpha)}_1(0), \dots, \lambda^{(\alpha)}_n(0))_0$$

are orthonormal with respect to $\langle \cdot, \cdot \rangle_0$.

Step 2. We claim that if $\lambda_{i;j} = 0$, then $\sum_i \lambda_i dy^i = dx$ for some function x . This is because we have

$$0 = \lambda_{i;j} = \frac{\partial \lambda_i}{\partial y^j} - \sum_{v=1}^n \lambda_v \Gamma_{ji}^v,$$

which shows that

$$\frac{\partial \lambda_i}{\partial y^j} = \frac{\partial \lambda_j}{\partial y^i}.$$

Now choose functions x^α with $\lambda^{(\alpha)}_i = \partial x^\alpha / \partial y^i$. As before, the x^α are a coordinate system in a neighborhood of 0.

Step 3. We claim that x is the desired coordinate system, i.e., that

$$\delta_{\mu\nu} = \sum_{i,j=1}^n g^{ij} \frac{\partial x^\mu}{\partial y^i} \frac{\partial x^\nu}{\partial y^j} = \sum_{i,j=1}^n g^{ij} \lambda^{(\mu)}_i \lambda^{(\nu)}_j.$$

As before, we just have to prove that the right side of this equation has all partial derivatives $\partial/\partial y^k$ equal to 0. But

$$\begin{aligned} \frac{\partial}{\partial y^k} \left(\sum_{i,j} g^{ij} \lambda^{(\mu)}_i \lambda^{(\nu)}_j \right) &= \left(\sum_{i,j} g^{ij} \lambda^{(\mu)}_i \lambda^{(\nu)}_j \right)_{;k} \\ &= \sum_{i,j} g^{ij}_{;k} \lambda^{(\mu)}_i \lambda^{(\nu)}_j + g^{ij} \lambda^{(\mu)}_{i;k} \lambda^{(\nu)}_j \\ &\quad + g^{ij} \lambda^{(\mu)}_i \lambda^{(\nu)}_{j;k} \\ &\quad \text{by Proposition 2} \\ &= 0 \text{ by Ricci's Lemma and equations (*). } \blacklozenge \end{aligned}$$

Comparing this proof of the Test Case with the first proof, we see that

Step 1 uses the *conditions* $R = 0$ to obtain the forms $\sum_i \lambda^{(\alpha)}_i dy^i$ satisfying (*). Instead of appealing to Theorem I.6-1, we essentially reprove this theorem; the Ricci identities make the proof almost as easy as the proof of Theorem I.6-0, the only complication being that the “mixed covariant derivatives” $\lambda_{i;12}$ depend on all $\lambda_{i;j}$, not just on $\lambda_{i;1}$.

Step 2, precisely the same as before, uses *symmetry of the Christoffel symbols*, $\Gamma_{ij}^k = \Gamma_{ji}^k$.

Step 3 uses the *definition of the Christoffel symbols* $[ij, k]$ to prove that the vectors $\partial/\partial x^\alpha$ are orthonormal. The proof is simpler because some of the calculations have been absorbed into the proof of Proposition 2, while the calculations using (**) on page 196 have been incorporated into Ricci's Lemma.

The absolute differential calculus turned out to be so useful (for many other applications besides the one just given) that it was soon exploited in the way all successful mathematical theories are—it was generalized. Notice that the

possibility of defining covariant derivatives depends only on the equation

$$(*) \quad \Gamma'^{\gamma}_{\alpha\beta} = \sum_{i,j,k} \Gamma^k_{ij} \frac{\partial x^i}{\partial x'^{\alpha}} \frac{\partial x^j}{\partial x'^{\beta}} \frac{\partial x'^{\gamma}}{\partial x^k} + \sum_{\mu=1}^n \frac{\partial^2 x^{\mu}}{\partial x'^{\alpha} \partial x'^{\beta}} \frac{\partial x'^{\gamma}}{\partial x^{\mu}};$$

it does not depend on the particular way that the Γ^k_{ij} are defined in terms of the g_{ij} . This observation suggests that we focus our attention on the transformation law (*) itself. Quantities which transform in this way are classically called *connections*. More precisely:

A **(classical) connection** on a manifold M is an assignment of n^3 numbers to each coordinate system, such that equation (*) holds between the n^3 numbers Γ^k_{ij} assigned to the coordinate system x and the n^3 numbers Γ'^k_{ij} assigned to the coordinate system x' .

Although this definition is exceedingly unappealing, classically it was motivated in the following way. If f is a function, then the quantities $\partial f / \partial x^i$ are the components of a tensor, but if λ^i are the components of a tensor, then the quantities $\partial \lambda^i / \partial x^j$ are not. If we attempt to construct a tensor by adding linear combinations of the λ^i , thus obtaining

$$\frac{\partial \lambda^i}{\partial x^j} + \sum_{\mu=1}^n \lambda^{\mu} \Gamma^i_{j\mu},$$

we find that these quantities are the components of a tensor provided that the Γ^k_{ij} transform according to (*).

Once we are given a connection (whatever in the world this connection may mean), we can imitate most of the work already done in this chapter for the special case where the Γ^k_{ij} are the Christoffel symbols, and in addition we can generalize other considerations from Riemannian geometry. What follows is a brief outline of this program.

We note first that, in contrast to the special case where the Γ^k_{ij} are the Christoffel symbols, a general connection need not satisfy $\Gamma^k_{ij} = \Gamma^k_{ji}$. However, it is easy to see that the quantities

$$T^k_{ij} = \Gamma^k_{ij} - \Gamma^k_{ji}$$

are the components of a *tensor* T , the **torsion tensor** of the connection. (In the next chapter, we will see the reason for the term “connection”, but no one seems

to have a good explanation for the term “torsion” in this case.) A connection Γ_{ij}^k is called **symmetric** if the torsion tensor is zero. In this case, $T_{ij}^k = 0$ for every coordinate system, so $\Gamma_{ij}^k = \Gamma_{ji}^k$ for every coordinate system. Conversely, if $\Gamma_{ij}^k = \Gamma_{ji}^k$ in a set of coordinate systems which cover M , then the connection is symmetric.

The following result gives at least a little geometric significance to symmetry of a connection.

7. PROPOSITION. The torsion tensor T of a connection satisfies $T(p) = 0$ if and only if there is a coordinate system around p with

$$\Gamma_{ij}^k(p) = 0 \quad \text{for all } i, j, k.$$

PROOF. If $\Gamma_{ij}^k(p) = 0$, then $T(p) = 0$, so $T'^k_{ij} = 0$ in any coordinate system x' , which means that $\Gamma'^\gamma_{\alpha\beta} = \Gamma'^\gamma_{\beta\alpha}$.

Conversely, suppose that $\Gamma_{ij}^k(p) = \Gamma_{ji}^k(p)$ for all i, j, k in a coordinate system x . Define x'^k by

$$x'^k(q) = [x^k(q) - x^k(p)] + \frac{1}{2} \sum_{i,j=1}^n \Gamma_{ij}^k(p) [x^i(q) - x^i(p)] \cdot [x^j(q) - x^j(p)].$$

Using $\Gamma_{ij}^k(p) = \Gamma_{ji}^k(p)$, we compute that

$$\begin{aligned} \frac{\partial x'^k}{\partial x^l} &= \delta_l^k + \sum_{i=1}^n \Gamma_{il}^k(p) [x^i - x^i(p)] \\ \frac{\partial x'^k}{\partial x^l}(p) &= \delta_l^k. \end{aligned}$$

This shows that x' is a coordinate system in a neighborhood of p . Moreover,

$$\frac{\partial^2 x'^k}{\partial x^k \partial x^l}(p) = \Gamma_{il}^k(p).$$

Substituting into (*), we see that $\Gamma'^\gamma_{\alpha\beta}(p) = 0$. ♦

Proposition 7 becomes more significant when we introduce the concept of geodesics. In our treatment of Riemannian metrics, we defined geodesics as

critical points for the energy function. For a general connection Γ_{ij}^k , we can simply define a **geodesic** as a path γ satisfying

$$\frac{d^2\gamma^k}{dt^2} + \sum_{i,j=1} \Gamma_{ij}^k \circ \gamma \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0;$$

a calculation shows this condition does not depend on the coordinate system. The basic theorems on differential equations show that geodesics through p are uniquely determined by their tangent vectors $\gamma'(0) \in M_p$; we can thus define $\exp: M_p \rightarrow M$ as before.* We can also introduce “Riemannian normal coordinates” at p ; we choose any basis X_1, \dots, X_n for M_p , define $\chi: M_p \rightarrow \mathbb{R}^n$ by $\chi(\sum_{i=1}^n a^i X_i) = (a^1, \dots, a^n)$, and let $x = \chi \circ \exp^{-1}$. As in Proposition 4-1, we note that the geodesic $\gamma^k(t) = \xi^k t$ satisfies

$$\sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \xi^i \xi^j = 0,$$

so that

$$\sum_{i,j=1}^n \Gamma_{ij}^k(p) \xi^i \xi^j = 0 \quad \text{for all } n\text{-tuples } (\xi^1, \dots, \xi^n).$$

This implies that

$$\Gamma_{ij}^k(p) + \Gamma_{ji}^k(p) = 0;$$

if we also have $T(p) = 0$, then we deduce that $\Gamma_{ij}^k(p) = 0$.

We define covariant derivatives of tensors and the curvature tensor R for a connection by the formulas on pages 210 and 214. Notice that Proposition 1 holds for a *symmetric* connection, while Proposition 2 holds for any connection. Naturally, Proposition 3 has no analogue for general connections. For non-symmetric connections, the comparison of mixed covariant derivatives becomes a little more complicated. Recall that for a function $f: M \rightarrow \mathbb{R}$ we have

$$f_{;ij} = \frac{\partial^2 f}{\partial x^i \partial x^j} - \sum_{v=1}^n \frac{\partial f}{\partial x^v} \Gamma_{ji}^v.$$

When the connection is not symmetric, we can express $f_{;ij} - f_{;ji}$ in terms of the torsion tensor, which is also involved in the new Ricci identities.

*Many global results about geodesics for a Riemannian metric do *not* hold for more general connections; see Chapter 8, Addendum 2.

8. PROPOSITION. For a connection Γ_{ij}^k , with curvature tensor R and torsion tensor T , we have

$$\begin{aligned} f_{;ij} - f_{;ji} &= \sum_{v=1}^n \frac{\partial f}{\partial x^v} T_{ij}^v \\ \lambda^i_{;jk} - \lambda^i_{;kj} &= - \sum_{l=1}^n \lambda^l R^i_{ljk} + \sum_{l=1}^n \lambda^i_{;l} T^l_{jk} \\ \lambda_{i;jk} - \lambda_{i;kj} &= \sum_{l=1}^n \lambda_l R^l_{ijk} + \sum_{l=1}^n \lambda_{i;l} T^l_{jk}. \end{aligned}$$

PROOF. Compute, compute. ♦

(For all these relations it is, of course, extremely important that, in the definitions, care is given to the order of the subscripts in the Γ 's.)

Finally, we wish to consider the properties of the curvature tensor which are given in Proposition 4-10. Two of these have no analogue for a general connection, since they involve a metric, but there is an additional relation, involving the covariant derivative, which holds for any connection.

9. PROPOSITION. The curvature tensor for any connection satisfies the following identities:

$$(1) \quad R^i_{jkl} = -R^i_{jlk}$$

(2) (Bianchi's first identity)

$$\begin{aligned} R^i_{jkl} + R^i_{klj} + R^i_{ljk} \\ = (T^i_{kl;j} + T^i_{lj;k} + T^i_{jk;l}) + \sum_{\mu=1}^n (T^{\mu}_{jk} T^i_{\mu l} + T^{\mu}_{kl} T^i_{\mu j} + T^{\mu}_{lj} T^i_{\mu k}) \end{aligned}$$

(3) (Bianchi's second identity)

$$\begin{aligned} (R^h_{ijk;l} + R^h_{ikl;j} + R^h_{ilj;k}) \\ + \sum_{\mu=1}^n (T^{\mu}_{jk} R^h_{i\mu l} + T^{\mu}_{kl} R^h_{i\mu j} + T^{\mu}_{lj} R^h_{i\mu k}) = 0. \end{aligned}$$

In particular, if the connection is symmetric, then we have the much simpler relations

$$(2') \quad R^i_{jkl} + R^i_{klj} + R^i_{ljk} = 0$$

$$(3') \quad R^h_{ijk;l} + R^h_{ikl;j} + R^h_{ilj;k} = 0.$$

Classically, (3') alone is known as "Bianchi's identity".

PROOF. Equation (1) follows immediately from the definition. In the case of a symmetric connection, equation (2') is also easy to verify (we have already done it in Proposition 4-10). It is even simpler to verify if we use Riemannian normal coordinates at p ; in this case the definition (page 214) gives

$$R^i_{jkl}(p) = \frac{\partial \Gamma^i_{lj}}{\partial x^k}(p) - \frac{\partial \Gamma^i_{kj}}{\partial x^l}(p),$$

which yields (2') at once. Using Proposition 1, for a symmetric connection, we also obtain

$$R^h_{ijk;l}(p) = \frac{\partial^2 \Gamma^h_{ki}}{\partial x^l \partial x^j}(p) - \frac{\partial^2 \Gamma^h_{ji}}{\partial x^l \partial x^k}(p),$$

which gives (3').

The proof of (2) and (3) in general is considerably more complicated. To begin with, notice that $T^i_{\mu l} = -T^i_{l\mu}$, so

$$\sum_{\mu} T^{\mu}_{jk} T^i_{\mu l} = \sum_{\mu} \Gamma^{\mu}_{jk} T^i_{\mu l} + \sum_{\mu} \Gamma^{\mu}_{kj} T^i_{l\mu}.$$

We also have

$$T^i_{jk;l} = \frac{\partial T^i_{jk}}{\partial x^l} + \sum_{\mu} \Gamma^i_{l\mu} T^{\mu}_{jk} - \sum_{\mu} \Gamma^{\mu}_{lj} T^i_{\mu k} - \sum_{\mu} \Gamma^{\mu}_{lk} T^i_{j\mu}.$$

From these equations we see that the right side of (2) equals

$$\left(\frac{\partial T^i_{jk}}{\partial x^l} + \sum_{\mu} T^{\mu}_{jk} \Gamma^i_{l\mu} \right) + \text{the two terms obtained by cyclically permuting } j, k, l.$$

Using the definition of T^i_{jk} , this is easily seen to equal the left side of (2).

To prove (3), we note first that (1) gives

$$\sum_{\mu} T^{\mu}_{jk} R^h_{i\mu l} = \sum_{\mu} \Gamma^{\mu}_{jk} R^h_{i\mu l} + \Gamma^{\mu}_{kj} R^h_{i l\mu}.$$

We also have

$$R^h_{ijk;l} = \frac{\partial R^h_{ijk}}{\partial x^l} + \sum_{\mu} R^{\mu}_{ijk} \Gamma^h_{l\mu} - \sum_{\mu} R^h_{\mu jk} \Gamma^{\mu}_{li} - \sum_{\mu} R^h_{i\mu k} \Gamma^{\mu}_{lj} - \sum_{\mu} R^h_{ij\mu} \Gamma^{\mu}_{lk}.$$

From these equations we see that the left side of (3) equals

$$\left(\frac{\partial R^h_{ijk}}{\partial x^l} + \sum_{\mu} R^{\mu}_{ijk} \Gamma^h_{l\mu} - \sum_{\mu} R^h_{\mu jk} \Gamma^{\mu}_{li} \right) + \text{the two terms obtained by cyclically permuting } j, k, l.$$

Plugging back into the definition, we find that this is zero. ♦

Believe it or not, the Bianchi identity will be useful later on, and crucial in the last chapter of Volume V. Even more surprising, in Chapter 7 we will present a derivation of the Bianchi identity which will make it seem like a natural result. With the present proof of the Bianchi identity we end our summary of the classical theory of connections. The presentation was made mainly as background for the succeeding chapters, in which the same results will begin to take on a more modern appearance.

CHAPTER 6

THE ∇ OPERATOR

The contents of this chapter really differ very little from those of the previous one, but everything will look quite different. The clean modern symbolism which gets introduced here is abandoned only in those parts of the chapter which compare the present treatment with that given previously. This refurbishment of the classical theory, due to Koszul, is effected by singling out for invariant treatment just one of the concepts introduced previously, and then defining the other concepts in terms of it. We will begin with a definition, and then compare it to the classical one.

A **(Koszul) connection** on a C^∞ manifold M is a function ∇ (read “dell”) which associates a C^∞ vector field $\nabla_X Y$ to any two C^∞ vector fields X and Y , and which satisfies

- (1) $\nabla_{X_1+X_2} Y = \nabla_{X_1} Y + \nabla_{X_2} Y$
- (2) $\nabla_X (Y_1 + Y_2) = \nabla_X Y_1 + \nabla_X Y_2$
- (3) $\nabla_{fX} Y = f \cdot \nabla_X Y$
- (4) $\nabla_X (fY) = f \cdot \nabla_X Y + X(f) \cdot Y.$

Notice that ∇ is assumed linear *over the C^∞ functions* in the argument X . By our standard theorem (I.4-2) this means that for any given vector field Y we can define

$$\nabla_{X_p} Y \in M_p$$

for every $X_p \in M_p$ so that

$$\nabla_X Y = p \mapsto \nabla_{X_p} Y.$$

Alternatively, one can define a Koszul connection to be a map ∇ which assigns a vector $\nabla_{X_p} Y \in M_p$ to every $X_p \in M_p$ and every C^∞ vector field Y , and which satisfies

- (1') $\nabla_{X_p+X'_p} Y = \nabla_{X_p} Y + \nabla_{X'_p} Y$
- (2') $\nabla_{X_p} (Y_1 + Y_2) = \nabla_{X_p} Y_1 + \nabla_{X_p} Y_2$

$$(3') \quad \nabla_{aX_p} Y = a \nabla_{X_p} Y \text{ for all } a \in \mathbb{R}$$

$$(4') \quad \nabla_{X_p}(fY) = f(p) \cdot \nabla_{X_p} Y + X_p(f) \cdot Y_p$$

$$(5') \quad \text{If } X \text{ and } Y \text{ are } C^\infty \text{ vector fields, then so is } p \mapsto \nabla_{X_p} Y.$$

We then define $\nabla_X Y$ by $\nabla_X Y(p) = \nabla_{X_p} Y$.

As one example of a Koszul connection, we take M to be \mathbb{R}^n and let $\nabla_{X_p} Y$ be the directional derivative of Y in the direction X_p (computed by taking the directional derivative of the component functions of Y). It is clear that properties (1')–(5') hold for this ∇ . However, the most important justification for the particular conditions required of a Koszul connection comes from a comparison with classical connections. If x^1, \dots, x^n is a coordinate system on M , and we define Γ_{ij}^k by

$$(*) \quad \nabla_{\frac{\partial}{\partial x^i}} \frac{\partial}{\partial x^j} = \sum_{k=1}^n \Gamma_{ij}^k \frac{\partial}{\partial x^k},$$

then from (1)–(4) it is an easy exercise to deduce that Γ_{ij}^k are the components of a (classical) connection; conversely, given a classical connection, we can use (*) and (1)–(4) to determine a well-defined ∇ . In the coordinate system x , if

$$X = \sum_{i=1}^n a^i \frac{\partial}{\partial x^i}, \quad Y = \sum_{j=1}^n \lambda^j \frac{\partial}{\partial x^j},$$

then

$$\nabla_X Y = \sum_{k=1}^n \left(\sum_{i=1}^n a^i \lambda^k_{;i} \right) \frac{\partial}{\partial x^k}.$$

For a given vector field Y we have a tensor ∇Y of type $\begin{pmatrix} 1 \\ 1 \end{pmatrix}$, that is, a collection of linear transformations $\nabla Y(p): M_p \rightarrow M_p$, given by

$$\nabla Y(p)(X_p) = \nabla_{X_p} Y \quad (= \nabla_X Y(p)).$$

Clearly

$$\nabla Y \left(\frac{\partial}{\partial x^i} \right) = \sum_{k=1}^n \lambda^k_{;i} \frac{\partial}{\partial x^k};$$

we can also write this as

$$\nabla Y = \sum_{i,k=1}^n \lambda^k_{;i} dx^i \otimes \frac{\partial}{\partial x^k},$$

which shows that ∇Y is the tensor classically described in terms of its components $\lambda^k_{;i}$.

The covariant derivatives of all other tensors are now going to be defined in terms of this covariant derivative, which we have made the cornerstone of our new definition of a connection (and *not* merely in terms of the Γ^k_{ij} which it determines). There are two completely different ways of doing this, each of which has its advantages. The first way is purely formal:

1. PROPOSITION. Let X be a C^∞ vector field on a C^∞ manifold M with a Koszul connection ∇ . Then there is a unique operator

$$A \mapsto \nabla_X A$$

from C^∞ tensor fields to C^∞ tensor fields, preserving the type $\binom{k}{l}$, such that

- (1) $\nabla_X f = X(f)$
- (2) $\nabla_X Y$ is the vector field given by the connection ∇
- (3) $A \mapsto \nabla_X A$ is linear over \mathbb{R}
- (4) $\nabla_X(A \otimes B) = \nabla_X A \otimes B + A \otimes \nabla_X B$
- (5) For any contraction C , we have $\nabla_X \circ C = C \circ \nabla_X$.

Moreover, each $\nabla_X A$ is linear *over the C^∞ functions* in the argument X , so for every tensor field A of type $\binom{k}{l}$ and every $X_p \in M_p$ we can define

$$\nabla_{X_p} A \in \mathcal{T}_l^k(M_p)$$

with

$$\begin{aligned} \nabla_{X_p + X'_p} A &= \nabla_{X_p} A + \nabla_{X'_p} A \\ \nabla_{aX_p} A &= a \nabla_{X_p} A. \end{aligned}$$

PROOF. Essentially, this is Problem I.5-15. If we define

$$\begin{aligned} Df &= X(f) \\ DY &= \nabla_X Y, \end{aligned}$$

then D does satisfy the condition

$$D(fY) = fDY + Df \cdot Y \quad \text{i.e.,} \quad D(f \otimes Y) = f \otimes DY + Df \otimes Y$$

which is assumed for this problem. Briefly, the proof that $D = \nabla$ can be extended uniquely is as follows. For a 1-form ω we want

$$\begin{aligned} X(\omega(Y)) &= D(\omega(Y)) = D(\text{contraction of } \omega \otimes Y) \\ &= \text{contraction of } [D\omega \otimes Y + \omega \otimes DY] \\ &= D\omega(Y) + \omega(DY) \\ &= D\omega(Y) + \omega(\nabla_X Y), \end{aligned}$$

so we want

$$(\nabla_X \omega)(Y) = D\omega(Y) = X(\omega(Y)) - \omega(\nabla_X Y) \quad \text{for all } Y.$$

Since any A is a sum of functions times tensor products of vector fields and 1-forms, conditions (3) and (4) determine $\nabla_X A$.

Following through the proof in detail, it is easily checked that $\nabla_X A$ is linear over the C^∞ functions in the argument X . ♦

In view of Proposition 1, for any tensor A of type $\binom{k}{l}$ we can define a new tensor ∇A of type $\binom{k+1}{l}$ by

$$\nabla A(p)(X_{1p}, \dots, X_{kp}, X_p) = \nabla_{X_p} A(X_{1p}, \dots, X_{kp}).$$

If $\omega = \sum_j \lambda_j dx^j$ is a tensor of type $\binom{1}{0}$, and we set

$$\nabla_{\frac{\partial}{\partial x^i}} \omega = \sum_{l=1}^n a_l dx^l,$$

then we have

$$\begin{aligned} \frac{\partial}{\partial x^i} \lambda_k &= \nabla_{\frac{\partial}{\partial x^i}} \left(\text{contraction of } \omega \otimes \frac{\partial}{\partial x^k} \right) \\ &= \text{contraction of } \left(\left[\nabla_{\frac{\partial}{\partial x^i}} \omega \right] \otimes \frac{\partial}{\partial x^k} + \omega \otimes \nabla_{\frac{\partial}{\partial x^i}} \frac{\partial}{\partial x^k} \right) \\ &= a_k + \sum_{\mu=1}^n \Gamma_{ik}^\mu \lambda_\mu, \end{aligned}$$

so we obtain

$$\begin{aligned} \nabla_{\frac{\partial}{\partial x^i}} \omega &= \sum_{k=1}^n \left(\frac{\partial \lambda_k}{\partial x^i} - \sum_{\mu=1}^n \Gamma_{ik}^\mu \lambda_\mu \right) dx^k \\ &= \sum_{k=1}^n \lambda_{k;i} dx^k. \end{aligned}$$

We can also write this as

$$\nabla \omega = \sum_{i,k=1}^n \lambda_{k;i} dx^k \otimes dx^i,$$

which shows that $\nabla\omega$ is the tensor classically described in terms of its components $\lambda_{k,i}$. Similarly, we easily see that if

$$A = \sum A_{i_1 \dots i_k}^{j_1 \dots j_l} dx^{i_1} \otimes \dots \otimes dx^{i_k} \otimes \frac{\partial}{\partial x^{j_1}} \otimes \dots \otimes \frac{\partial}{\partial x^{j_l}},$$

then

$$\nabla A = \sum A_{i_1 \dots i_k; h}^{j_1 \dots j_l} dx^{i_1} \otimes \dots \otimes dx^{i_k} \otimes dx^h \otimes \frac{\partial}{\partial x^{j_1}} \otimes \dots \otimes \frac{\partial}{\partial x^{j_l}}.$$

The uniqueness clause in Proposition 1 is precisely what accounts for its usefulness: all properties of ∇A should be derivable from properties (1)–(5), since these properties characterize ∇A . On the other hand, the proposition gives no idea what is going on geometrically. To obtain such a picture we introduce another extremely important concept.

First consider a curve $c: [a, b] \rightarrow M$. By a **vector field V along c** we mean a function V on $[a, b]$ with $V_t = V(t) \in M_{c(t)}$. In a coordinate system (x, U) we

can write

$$V_t = \sum_{i=1}^n v_i(t) \cdot \frac{\partial}{\partial x^i} \Big|_{c(t)}.$$

We call V a C^∞ vector field along c if the functions v^i are C^∞ on $[a, b]$; this is equivalent to saying that $t \mapsto V_t(f)$ is C^∞ for every C^∞ function f on M .

Now suppose that V is a C^∞ vector field on a neighborhood of $c([a, b])$. Then

$$t \mapsto \nabla_{\frac{dc}{dt}} V$$

is a C^∞ vector field along c . This vector field is called the **covariant derivative of V along c** ; we will denote it by the convenient symbolism

$$\frac{DV}{dt},$$

which involves all the classical ambiguities. We would like to generalize this covariant derivative along c to vector fields V which are themselves defined only along c .

2. PROPOSITION. There is precisely one operation $V \mapsto DV/dt$, from C^∞ vector fields V along c to C^∞ vector fields along c , with the following properties:

- (a) $\frac{D(V+W)}{dt} = \frac{DV}{dt} + \frac{DW}{dt}$
- (b) $\frac{D(fV)}{dt} = \frac{df}{dt}V + f\frac{DV}{dt}$ for $C^\infty f: [a, b] \rightarrow \mathbb{R}$
- (c) If $V_s = Y_{c(s)}$ for some C^∞ vector field Y defined in a neighborhood of $c(t)$, then

$$\frac{DV}{dt} = \nabla_{\frac{dc}{dt}} Y.$$

PROOF. If x is a coordinate system around $p = c(t_0)$ then for t sufficiently close to t_0 we can write

$$V(t) = \sum_{j=1}^n v^j(t) \cdot \frac{\partial}{\partial x^j} \Big|_{c(t)}$$

for unique functions v^j . If (a), (b), (c) are to hold, then we must have

$$\frac{DV}{dt} = \sum_{j=1}^n \frac{D}{dt} \left(v^j(t) \cdot \frac{\partial}{\partial x^j} \Big|_{c(t)} \right) \quad \text{by (a)}$$

$$= \sum_{j=1}^n \left\{ \frac{dv^j}{dt} \cdot \frac{\partial}{\partial x^j} \Big|_{c(t)} + v^j(t) \frac{D}{dt} \frac{\partial}{\partial x^j} \Big|_{c(t)} \right\} \quad \text{by (b)}$$

$$= \sum_{j=1}^n \left\{ \frac{dv^j}{dt} \cdot \frac{\partial}{\partial x^j} \Big|_{c(t)} + v^j(t) \nabla_{\frac{dc}{dt}} \frac{\partial}{\partial x^j} \right\} \quad \text{by (c)}$$

$$= \sum_{j=1}^n \left\{ \frac{dv^j}{dt} \cdot \frac{\partial}{\partial x^j} \Big|_{c(t)} + v^j(t) \sum_{i=1}^n \frac{dc^i}{dt} \nabla_{\frac{\partial}{\partial x^i}} \Big|_{c(t)} \frac{\partial}{\partial x^j} \right\}$$

and thus

$$\frac{DV}{dt} = \sum_{k=1}^n \left(\frac{dv^k}{dt} + \sum_{i,j=1}^n \Gamma_{ij}^k(c(t)) \frac{dc^i}{dt} v^j(t) \right) \frac{\partial}{\partial x^k} \Big|_{c(t)}$$

So there is at most one such operation. Conversely, it is easy to check that this formula does have the required properties. \blacklozenge

Remark. There are two things which should be noted about this Proposition, and the interest of the first tends to overshadow the significance of the second.

(1) The Proposition assigns a value to DV/dt even at points where $dc/dt = 0$. This value is not necessarily 0. In fact, if c is a constant curve, $c(t) = p$ for all t , then a vector field V along c is just a curve in M_p , and DV/dt is just the ordinary derivative of this vector-valued curve.

(2) When $dc/dt \neq 0$, so that c is an imbedding in a neighborhood of t , we can always write $V_s = Y_{c(s)}$ for some Y defined in a neighborhood of $c(t)$. But Y is not unique, so even now condition (c) does not by itself determine DV/dt —we also need conditions (a) and (b). This result is very similar to our basic principle for defining tensors (Theorem I.4-2): in the proof of that result we expressed all vectors in terms of the $\partial/\partial x^i$; in the present case we express all vector fields along c in terms of the $\partial/\partial x^i|_{c(t)}$.

We say that a vector field V along c is **parallel along c** (with respect to ∇) if $DV/dt = 0$ along c . When $M = \mathbb{R}^n$ and ∇ is just the directional derivative, we obtain the standard picture of a parallel vector field. In general, given a

curve $c: [a, b] \rightarrow M$, and a vector $V_a \in M_{c(a)}$, there is a unique vector field V along c which is parallel along c . This is because the equations

$$(*) \quad \frac{dv^k(t)}{dt} + \sum_{i,j=1}^n \frac{dc^i(t)}{dt} \Gamma_{ij}^k(c(t)) v^j(t) = 0$$

are linear differential equations with unique solutions v^j , defined on all of $[a, b]$, for given initial conditions; the desired vector field V is then

$$V_t = \sum_{j=1}^n v^j(t) \cdot \frac{\partial}{\partial x^j} \Big|_{c(t)}.$$

The vector $V_t \in M_{c(t)}$ is said to be obtained from V_a by **parallel translation along c** . It is clear from equations (*) that $(V+W)_t = V_t + W_t$ and $(\lambda \cdot V)_t = \lambda \cdot V_t$ for $\lambda \in \mathbb{R}$. We therefore obtain a linear transformation

$$\tau_t : M_{c(a)} \rightarrow M_{c(t)} \quad V_a \mapsto V_t.$$

Clearly, τ_t is one-one, for its inverse is just parallel translation along the reversed portion of c from t to a . Thus, along any curve c we obtain an isomorphism between any two tangent spaces $M_{c(t_1)}$ and $M_{c(t_2)}$; this possibility of comparing, or “connecting”, tangent spaces at different points gives rise to the term “connection”. It was invented by Levi-Civita, who used the equations (*) as the definition.

The parallel translation τ_t is defined in terms of ∇ , but we can also reverse the process.

3. PROPOSITION. Let c be a curve with $c(0) = p$ and $c'(0) = X_p$. Then

$$\nabla_{X_p} Y = \lim_{h \rightarrow 0} \frac{1}{h} (\tau_h^{-1} Y_{c(h)} - Y_p).$$

PROOF. Let V_1, \dots, V_n be parallel vector fields along c which are linearly independent at $c(0)$, and hence at all points of c . Set

$$Y(c(t)) = \sum_{i=1}^n \gamma^i(t) \cdot V_i(t).$$

Then

$$\begin{aligned} \lim_{h \rightarrow 0} \frac{1}{h} (\tau_h^{-1} Y_{c(h)} - Y_p) &= \lim_{h \rightarrow 0} \frac{1}{h} \left[\sum_{i=1}^n \gamma^i(h) \tau_h^{-1} V_i(h) - \gamma^i(0) V_i(0) \right] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} \left[\sum_{i=1}^n \gamma^i(h) V_i(0) - \gamma^i(0) V_i(0) \right] \\ &= \sum_{i=1}^n \lim_{h \rightarrow 0} \frac{\gamma^i(h) - \gamma^i(0)}{h} \cdot V_i(0) \\ &= \sum_{i=1}^n \frac{d\gamma^i}{dt}(0) V_i(0) = \frac{D}{dt} \Big|_{t=0} \sum_{i=1}^n \gamma^i(t) V_i(t) \\ &= \nabla_{X_p} Y. \quad \spadesuit \end{aligned}$$

Motivated by Proposition 3, we now define $\nabla_{X_p} A$ where A is any tensor field of type $\binom{k}{l}$. We have

$$A(q) \in \mathcal{T}_l^k(M_q) \quad \text{for all } q,$$

and the isomorphism

$$\tau_t: M_{c(0)} \rightarrow M_{c(t)}$$

gives rise to an isomorphism

$$\mathcal{T}_l^k(\tau_t): \mathcal{T}_l^k(M_{c(0)}) \rightarrow \mathcal{T}_l^k(M_{c(t)});$$

therefore we can define

$$\nabla_{X_p} A = \lim_{h \rightarrow 0} \frac{1}{h} ([\mathcal{T}_l^k(\tau_h)]^{-1} A(c(h)) - A(p)).$$

If we regard $A(q)$ as a function of k tangent vectors in M_q and l vectors in M_q^* , this means that for $v_1, \dots, v_k \in M_p$ and $\lambda_1, \dots, \lambda_l \in M_p^*$ we have

$$\begin{aligned} (\nabla_{X_p} A)(v_1, \dots, v_k, \lambda_1, \dots, \lambda_l) \\ = \lim_{h \rightarrow 0} \frac{1}{h} [A(c(h))(\tau_h v_1, \dots, \tau_h v_k, \tau_h^* \lambda_1, \dots, \tau_h^* \lambda_l) \\ - A(p)(v_1, \dots, v_k, \lambda_1, \dots, \lambda_l)]. \end{aligned}$$

4. PROPOSITION. This $\nabla_{X_p} A$ coincides with that given by Proposition 1.

PROOF. It suffices to prove properties (1)–(5) for the new $\nabla_{X_p} A$. This is left to the reader [the proof of (4) and (5) involves the usual trick which one uses in the proof of the product rule for derivatives]. ♦

[Note that without this result it would not be at all obvious that $\nabla_{X_p} A$ is linear in X_p .]

5. COROLLARY. Let A be a tensor field of type $\binom{k}{l}$. If Y_1, \dots, Y_k are vector fields, then

$$(\nabla_{X_p} A)(Y_{1p}, \dots, Y_{kp}) = \nabla_{X_p} (A(Y_1, \dots, Y_k)) - \sum_{i=1}^k A(Y_{1p}, \dots, \nabla_{X_p} Y_i, \dots, Y_{kp}).$$

PROOF. Use Proposition 1, noting that $A(Y_1, \dots, Y_k)$ can be obtained by applying k contractions to

$$A \otimes Y_1 \otimes \dots \otimes Y_k.$$

(It is also instructive to obtain a proof from the definition in terms of parallel translations.) ♦

Our definition of $\nabla_X A$ may be compared to the definition, in Problem I.5-14, of $L_X A$. In the latter case, the maps ϕ^*_h given by the vector field X play the roles of the parallel translations τ_h in the present instance. Notice that Problem I.5-15 can be used in both cases to formally extend the operation from vector fields to arbitrary tensors.

After these preliminaries, the further study of Koszul connections proceeds quite rapidly. We first define, for vector fields X and Y ,

$$T(X, Y) = \nabla_X Y - \nabla_Y X - [X, Y].$$

A simple calculation shows that T is *linear over the C^∞ functions*, so that it determines a tensor. Clearly this is just the classical torsion tensor; as usual, the invariant definition involves a bracket, which disappears in the expression in coordinates.

We now want to distinguish the connection determined by the Christoffel symbols for a metric. Suppose we are in a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$. We will call a connection **compatible with $\langle \cdot, \cdot \rangle$** if the parallel translations $\tau_t: M_{c(a)} \rightarrow M_{c(t)}$ along any curve $c: [a, b] \rightarrow M$ are isometries (with respect to $\langle \cdot, \cdot \rangle_{c(a)}$ and $\langle \cdot, \cdot \rangle_{c(t)}$).

6. LEMMA. A connection ∇ is compatible with a metric $\langle \cdot, \cdot \rangle$ if and only if it satisfies the following condition: If V and W are vector fields along any curve c , then

$$\frac{d}{dt} \langle V, W \rangle = \left\langle \frac{DV}{dt}, W \right\rangle + \left\langle V, \frac{DW}{dt} \right\rangle.$$

PROOF. Suppose ∇ satisfies this condition. Then if V is parallel along c we have

$$\frac{d}{dt} \langle V, V \rangle = 2 \left\langle \frac{DV}{dt}, V \right\rangle = 0,$$

so $\langle V, V \rangle$ is constant along c . Thus each τ_t is norm preserving, and hence an isometry.

Conversely, suppose ∇ is compatible with the metric. Choose parallel vector fields P_1, \dots, P_n along c which are orthonormal at one point of c , and hence at every point of c . Let

$$V_t = \sum_{i=1}^n v^i(t) P_{i_t}, \quad W_t = \sum_{j=1}^n w^j(t) P_{j_t}.$$

Then

$$\langle V, W \rangle = \sum_{i=1}^n v^i \cdot w^i,$$

and by Proposition 2 we have, remembering that $DP_i/dt = 0$,

$$\frac{DV}{dt} = \sum_{i=1}^n \frac{dv^i}{dt} P_i, \quad \frac{DW}{dt} = \sum_{j=1}^n \frac{dw^j}{dt} P_j.$$

So

$$\left\langle \frac{DV}{dt}, W \right\rangle + \left\langle V, \frac{DW}{dt} \right\rangle = \sum_{i=1}^n \left(\frac{dv^i}{dt} w^i + v^i \frac{dw^i}{dt} \right) = \frac{d}{dt} \langle V, W \rangle. \quad \spadesuit$$

7. COROLLARY. The connection ∇ is compatible with $\langle \cdot, \cdot \rangle$ if and only if

$$X_p \langle Y, Z \rangle = \langle \nabla_{X_p} Y, Z_p \rangle + \langle Y_p, \nabla_{X_p} Z \rangle$$

for all vector fields Y, Z and vectors $X_p \in M_p$.

PROOF. Apply the Lemma to a curve c with $c'(0) = X_p$. \spadesuit

8. LEMMA (FUNDAMENTAL LEMMA OF RIEMANNIAN GEOMETRY). On a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$ there is a unique symmetric connection compatible with $\langle \cdot, \cdot \rangle$.

PROOF. Suppose ∇ is compatible with $\langle \cdot, \cdot \rangle$. Choose a coordinate system (x, U) . By Corollary 7

$$(*) \quad \frac{\partial g_{jk}}{\partial x^i} = \frac{\partial}{\partial x^i} \left\langle \frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k} \right\rangle = \left\langle \nabla_{\frac{\partial}{\partial x^i}} \frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k} \right\rangle + \left\langle \frac{\partial}{\partial x^j}, \nabla_{\frac{\partial}{\partial x^i}} \frac{\partial}{\partial x^k} \right\rangle.$$

Cyclically permuting i, j, k , and using

$$\nabla_{\frac{\partial}{\partial x^i}} \frac{\partial}{\partial x^j} = \nabla_{\frac{\partial}{\partial x^j}} \frac{\partial}{\partial x^i} \quad (\text{from symmetry}),$$

we obtain

$$\sum_{l=1}^n \Gamma_{ij}^l g_{lk} = \left\langle \nabla_{\frac{\partial}{\partial x^i}} \frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k} \right\rangle = [ij, k],$$

which implies that

$$\Gamma_{ij}^l = \sum_{k=1}^n g^{kl} [ij, k].$$

Thus the Γ 's for ∇ must be the Christoffel symbols.

We know that the Christoffel symbols do indeed satisfy $(*)$, which shows that the equation in Corollary 7 does hold. (In fact, this equation is equivalent to Ricci's Lemma, 5-3.) \spadesuit

The unique connection of Lemma 8 obviously ought to be called the Christoffel connection for $\langle \cdot, \cdot \rangle$; instead, it is called the Levi-Civita connection* for $\langle \cdot, \cdot \rangle$! Naturally, Lemma 8 is more impressive before reading the proof than after. Nevertheless, it is still a very nice result. Perhaps its only defect is the restriction to *symmetric* connections; in Addendum 1 to this chapter we present some justification for this restriction. We have already given one interpretation of symmetry; but the following will be more useful for present purposes. For a C^∞ function $s: \mathbb{R}^2 \rightarrow M$ (a “parameterized surface” in M), we define a **vector field V along s** to be a function V with

$$V_{(x,y)} \in M_{s(x,y)}.$$

In particular, we have the vector fields

$$\frac{\partial s}{\partial x} = s_* \left(\frac{\partial}{\partial x} \right), \quad \frac{\partial s}{\partial y} = s_* \left(\frac{\partial}{\partial y} \right).$$

For any C^∞ vector field V along s , we define

$$\left(\frac{DV}{\partial x} \right)_{(x,y)} = \begin{array}{l} \text{covariant derivative along } c(t) = s(t, y) \\ \text{of } t \mapsto V_{(t,y), \text{ evaluated at } t = x,} \end{array}$$

and we define $DV/\partial y$ similarly.

8. PROPOSITION. If ∇ is symmetric, then

$$\frac{D}{\partial x} \frac{\partial s}{\partial y} = \frac{D}{\partial y} \frac{\partial s}{\partial x}.$$

PROOF. Express both sides in terms of a coordinate system and compute. ♦

*This is an historical mix-up, due to the fact that the collection of parallel translations determined by ∇ was called “Levi-Civita’s connection” for ∇ .

We are now ready to define the curvature tensor for a Koszul connection ∇ . If X, Y, Z are vector fields, we consider the vector field

$$R(X, Y)Z = \nabla_X(\nabla_Y Z) - \nabla_Y(\nabla_X Z) - \nabla_{[X, Y]}Z.$$

A straightforward computation shows that (because of the bracket term) R is *linear over the C^∞ functions* in all three variables, so it defines a tensor R , the **curvature tensor** of ∇ . Obviously, this definition is somehow related to the Ricci identity (Proposition 5-8)

$$(*) \quad \lambda^i{}_{;jk} - \lambda^i{}_{;kj} = - \sum_{l=1}^n \lambda^l R^i{}_{ljk} + \sum_{l=1}^n \lambda^i{}_{;l} T^l{}_{jk},$$

but at first sight we seem to be missing a term for the torsion. To see why this is so, recall that if

$$Z = \sum_{i=1}^n \lambda^i \frac{\partial}{\partial x^i},$$

then $\lambda^i{}_{;j}$ are the components of ∇Z , i.e.,

$$\nabla_{\frac{\partial}{\partial x^j}} Z = \sum_{i=1}^n \lambda^i{}_{;j} \frac{\partial}{\partial x^i}.$$

Now $\lambda^i{}_{;jk} = \lambda^i{}_{;j;k}$ are *not* the components of $\nabla_{\partial/\partial x^k}(\nabla_{\partial/\partial x^j} Z)$; rather they are the components of $\nabla(\nabla Z)$. So

$$\begin{aligned} \sum_{i=1}^n \lambda^i{}_{;jk} \frac{\partial}{\partial x^i} &= \nabla \nabla Z \left(\frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k} \right) \\ &= \left[\nabla_{\frac{\partial}{\partial x^k}} (\nabla Z) \right] \left(\frac{\partial}{\partial x^j} \right) \\ &= \nabla_{\frac{\partial}{\partial x^k}} \left(\nabla Z \left(\frac{\partial}{\partial x^j} \right) \right) - \nabla Z \left(\nabla_{\frac{\partial}{\partial x^k}} \frac{\partial}{\partial x^j} \right) \quad \text{by Corollary 5} \\ &= \nabla_{\frac{\partial}{\partial x^k}} \left(\nabla_{\frac{\partial}{\partial x^j}} Z \right) - \nabla \left(\nabla_{\frac{\partial}{\partial x^k}} \frac{\partial}{\partial x^j} \right) Z. \end{aligned}$$

Consequently,

$$\begin{aligned}
& \nabla_{\frac{\partial}{\partial x^j}} \left(\nabla_{\frac{\partial}{\partial x^k}} Z \right) - \nabla_{\frac{\partial}{\partial x^k}} \left(\nabla_{\frac{\partial}{\partial x^j}} Z \right) \\
&= \sum_{i=1}^n (\lambda^i{}_{;kj} - \lambda^i{}_{;jk}) \frac{\partial}{\partial x^i} + \nabla_{\left(\nabla_{\frac{\partial}{\partial x^j}} \frac{\partial}{\partial x^k} - \nabla_{\frac{\partial}{\partial x^k}} \frac{\partial}{\partial x^j} \right)} Z \\
&= \sum_{i=1}^n \left(\sum_{l=1}^n \lambda^l R^i{}_{ljk} - \sum_{l=1}^n \lambda^i{}_{;l} T^l_{jk} \right) \frac{\partial}{\partial x^i} + \nabla_{\left(\sum_{l=1}^n T^l_{jk} \frac{\partial}{\partial x^l} \right)} Z \quad \text{by } (*).
\end{aligned}$$

Since

$$\nabla_{\left(\sum_{l=1}^n T^l_{jk} \frac{\partial}{\partial x^l} \right)} Z = \sum_{l=1}^n T^l_{jk} \nabla_{\frac{\partial}{\partial x^l}} Z = \sum_{i,l=1}^n T^l_{jk} \lambda^i{}_{;l} \frac{\partial}{\partial x^i},$$

we obtain simply

$$\begin{aligned}
\nabla_{\frac{\partial}{\partial x^j}} \left(\nabla_{\frac{\partial}{\partial x^k}} Z \right) - \nabla_{\frac{\partial}{\partial x^k}} \left(\nabla_{\frac{\partial}{\partial x^j}} Z \right) &= \sum_{i=1}^n \left(\sum_{l=1}^n \lambda^l R^i{}_{ljk} \right) \frac{\partial}{\partial x^i} \\
&= R \left(\frac{\partial}{\partial x^j}, \frac{\partial}{\partial x^k} \right) Z,
\end{aligned}$$

so the definition does agree with the classical one. At the same time, it is clearly preferable, in that it does not involve the torsion.

[Classically, there is practically no way to even name the quantity

$$\nabla_{\frac{\partial}{\partial x^j}} \left(\nabla_{\frac{\partial}{\partial x^k}} Z \right),$$

since $\lambda^i{}_{;kj}$ is automatically interpreted as the components of the tensor $\nabla \nabla Z$. For a vector field $Y = \sum_i b^i \partial / \partial x^i$, we can write the components of

$$\nabla_{\frac{\partial}{\partial x^j}} (\nabla_Y Z) \quad \text{as} \quad \left(\sum_{l=1}^n \lambda^i{}_{;l} b^l \right)_{;j},$$

the summation over l making it clear that we are taking covariant derivatives of the tensor field with components $\mu^i = \sum_l \lambda^i{}_{;l} b^l$. However, for the special case

$$\nabla_{\frac{\partial}{\partial x^j}} \left(\nabla_{\frac{\partial}{\partial x^k}} Z \right),$$

the expression

$$\left(\sum_{l=1}^n \lambda^i{}_{;l} \delta^l_k \right)_{;j}$$

is about the best we can do.]

The following result will be our analogue of the Ricci identities.

9. **PROPOSITION.** Let $s: \mathbb{R}^2 \rightarrow M$ be a parameterized surface, and V a C^∞ vector field along s . Then

$$\frac{D}{\partial x} \frac{D}{\partial y} V - \frac{D}{\partial y} \frac{D}{\partial x} V = R \left(\frac{\partial s}{\partial x}, \frac{\partial s}{\partial y} \right) V.$$

PROOF. Compute in a coordinate system. \diamond

It should come as no surprise to learn that we can now prove the Test Case; it may be surprising, however, to see how simple the proof becomes.

10. **THEOREM (THE TEST CASE; THIRD VERSION).** Let $(M, \langle \cdot, \cdot \rangle)$ be an n -dimensional Riemannian manifold for which the curvature tensor R (for the Levi-Civita connection) is 0. Then M is locally isometric to \mathbb{R}^n with its usual Riemannian metric.

PROOF. We assume we are in \mathbb{R}^n , with y^1, \dots, y^n the standard coordinate system.

Step 1. We claim that we can find vector fields X , with arbitrary values $X(0) \in \mathbb{R}^n_0$, satisfying

$$\nabla_{\frac{\partial}{\partial y^i}} X = 0 \quad \text{for all } i,$$

and hence

$$\nabla_Z X = 0 \quad \text{for all } Z.$$

To do this we first choose $X(y, 0, \dots, 0)$, with the desired initial value, so that it is parallel along the y^1 -axis.

For each fixed y^1 , we then choose $X(y^1, y, 0, \dots, 0)$, with the values $X(y^1, 0, \dots, 0)$ just obtained, so that X is parallel along the curves $y \mapsto (y^1, y, 0, \dots, 0)$. The vector field X is now defined on the surface

Clearly $DX/\partial y^2$ is 0 along s , while $DX/\partial y^1$ is 0 along $\{s(y, 0)\}$. Now we have

$$\frac{D}{\partial y^1} \frac{D}{\partial y^2} X - \frac{D}{\partial y^2} \frac{D}{\partial y^1} X = R \left(\frac{\partial s}{\partial y^1}, \frac{\partial s}{\partial y^2} \right) X = 0,$$

so

$$\frac{D}{\partial y^2} \frac{D}{\partial y^1} X = 0.$$

This means that $DX/\partial y^1$ is parallel along the curves $y \mapsto s(y^1, y)$. Since $DX/\partial y^1$ is 0 at $s(y^1, 0)$, we have $DX/\partial y^1 = 0$ along s .

We can clearly continue in this way to obtain the desired X . Now choose X_1, \dots, X_n with this property so that $X_1(0), \dots, X_n(0)$ are orthonormal with respect to $\langle \cdot, \cdot \rangle_0$. Clearly, X_1, \dots, X_n are linearly independent in a neighborhood of 0.

Step 2. Since the connection ∇ associated with $\langle \cdot, \cdot \rangle$ is symmetric, we have

$$0 = \nabla_{X_i} X_j - \nabla_{X_j} X_i - [X_i, X_j].$$

But $\nabla_Z X_i = 0$ for all Z . So $[X_i, X_j] = 0$. This means that there is a coordinate system x^1, \dots, x^n with $X_i = \partial/\partial x^i$.

Step 3. We claim that x is the desired coordinate system, i.e., that the X_i are everywhere orthonormal. This is obvious, for they are orthonormal at 0 and parallel along any curve, and parallel translation preserves the inner product $\langle \cdot, \cdot \rangle$. ♦

This proof is completely analogous to the first two proofs of the Test Case, except that it is “dual” to them in the sense that we find the vector fields $\partial/\partial x^i$ instead of the 1-forms dx^i .

Step 1 uses the conditions $R = 0$ to obtain the parallel vector fields X_i , in a way completely analogous to, but simpler than, *Step 1* in the second version.

Step 2 now uses *symmetry of the connection* to prove that $[X_i, X_j] = 0$, a condition which is dual to exactness of the 1-forms obtained in the previous versions.

Step 3 uses the *definition of the Levi-Civita connection* to prove that the vectors X_i are everywhere orthonormal. As we have already pointed out, the fact that parallel translation preserves the inner product $\langle \cdot, \cdot \rangle$ is equivalent to Ricci’s Lemma, which we used in *Step 3* of the second version.

Notice that the proof shows that if we can find n everywhere linearly independent vector fields X_1, \dots, X_n , which are **parallel** (i.e., which satisfy $\nabla_Z X_i = 0$ for all Z), then the manifold is flat. Consequently, such vector fields generally *cannot* be found. This means that parallel translation of a vector along two different curves with the same end-points generally gives *different* results; for if X_p were the parallel translate of X_0 along both the curves shown below, we would clearly have both

$$\nabla_{\frac{\partial}{\partial x^1}} X(p) = 0 \quad \text{and} \quad \nabla_{\frac{\partial}{\partial x^2}} X(p) = 0.$$

This phenomenon can also be described by saying that parallel translation of a vector along a closed curve generally brings it back to a different vector. In Volume III we will see some more quantitative statements of this fact.

Our next two results are simply Proposition 5-9 and 4-10. They are reproved here in a spirit more in keeping with the present treatment of connections, but it is not hard to see that they are essentially the proofs given before. As a matter of notation, if we are given an expression $A(X, Y, Z)$, we will let $\mathfrak{S}A(X, Y, Z)$ denote the cyclic sum

$$\mathfrak{S}A(X, Y, Z) = A(X, Y, Z) + A(Y, Z, X) + A(Z, X, Y).$$

11. PROPOSITION. Let ∇ be a connection with torsion T and curvature R . Then for all vector fields X, Y, Z, W we have

$$(1) \quad R(X, Y)Z = -R(Y, X)Z$$

$$(2) \quad (\text{Bianchi's first identity})$$

$$\mathfrak{S}\{R(X, Y)Z\} = \mathfrak{S}\{(\nabla_X T)(Y, Z)\} + \mathfrak{S}\{T(T(X, Y)Z)\}$$

$$(3) \quad (\text{Bianchi's second identity})$$

$$\mathfrak{S}\{(\nabla_Z R)(X, Y, W)\} + \mathfrak{S}\{R(T(X, Y), Z)W\} = 0.$$

In particular, if $T = 0$, then

$$(2') \quad \mathfrak{S}\{R(X, Y)Z\} = 0$$

$$(3') \quad \mathfrak{S}\{(\nabla_Z R)(X, Y, W)\} = 0.$$

PROOF. (1) is clear from the definition.

To prove (2), we first note that

$$\begin{aligned} T(T(X, Y), Z) &= T(\nabla_X Y, Z) - T(\nabla_Y X, Z) - T([X, Y], Z) \\ &= T(\nabla_X Y, Z) + T(Z, \nabla_Y X) - T([X, Y], Z). \end{aligned}$$

We also have, by Corollary 5,

$$(\nabla_Z T)(X, Y) = \nabla_Z(T(X, Y)) - T(\nabla_Z X, Y) - T(X, \nabla_Z Y).$$

From these equations we obtain

$$\mathfrak{S}\{T(T(X, Y), Z)\} = -\mathfrak{S}\{(\nabla_Z T)(X, Y)\} + \mathfrak{S}\{\nabla_Z(T(X, Y)) - T([X, Y], Z)\}.$$

The second term on the right side equals

$$\mathfrak{S}\{\nabla_X(\nabla_Y Z) - \nabla_Y(\nabla_X Z) - \nabla_{[X, Y]}Z\} + \mathfrak{S}\{[[X, Y], Z]\} = \mathfrak{S}\{R(X, Y)Z\} + 0,$$

since the Jacobi identity states that $\mathfrak{S}\{[[X, Y], Z]\} = 0$.

To prove (3), we first use (1) to obtain

$$\begin{aligned} \mathfrak{S}\{R(T(X, Y), Z)W\} &= \mathfrak{S}\{R(\nabla_X Y, Z)W + R(Z, \nabla_Y X)W - R([X, Y], Z)W\} \\ &= \mathfrak{S}\{R(\nabla_Z X, Y)W + R(X, \nabla_Z Y)W\} - \mathfrak{S}\{R([X, Y], Z)W\}. \end{aligned}$$

By Corollary 5 we also have

$$\begin{aligned} (\nabla_Z R)(X, Y, W) &= \nabla_Z(R(X, Y)W) - R(X, Y)\nabla_Z W \\ &\quad - R(\nabla_Z X, Y)W - R(X, \nabla_Z Y)W. \end{aligned}$$

From these equations we have

$$\begin{aligned} \mathfrak{S}\{R(T(X, Y), Z)W\} &= -\mathfrak{S}\{(\nabla_Z R)(X, Y, W)\} \\ &\quad + \mathfrak{S}\{\nabla_Z(R(X, Y)W) - R(X, Y)\nabla_Z W \\ &\quad - R([X, Y], Z)W\}. \end{aligned}$$

Now

$$\begin{aligned} &\nabla_Z(R(X, Y)W) - R(X, Y)\nabla_Z W - R([X, Y], Z)W \\ &= \nabla_Z \nabla_X \nabla_Y W - \nabla_Z \nabla_Y \nabla_X W \quad \boxed{-\nabla_Z \nabla_{[X, Y]} W} \\ &\quad - \nabla_X \nabla_Y \nabla_Z W + \nabla_Y \nabla_X \nabla_Z W + \nabla_{[X, Y]} \nabla_Z W \\ &\quad \nabla_{[X, Y]} \nabla_Z W \quad + \quad \boxed{\nabla_Z \nabla_{[X, Y]} W} \\ &\quad + \nabla_{[[X, Y], Z]} W. \end{aligned}$$

Writing $[\nabla_X, \nabla_Y]$ for the operation $W \mapsto \nabla_X \nabla_Y W - \nabla_Y \nabla_X W$ (as on pg. I.155), we can write this as

$$\nabla_Z([\nabla_X, \nabla_Y]W) - [\nabla_X, \nabla_Y](\nabla_Z W) + \nabla_{[[X, Y], Z]} W.$$

The cyclic sum of these quantities is 0, because of the Jacobi identity

$$\mathfrak{S}\{[[X, Y], Z]\} = 0,$$

and the “Jacobi identity”

$$\mathfrak{S}\{[\nabla_Z, [\nabla_X, \nabla_Y]]W\} = 0$$

(recall that in any ring, if we define $[a, b] = ab - ba$, then $[,]$ satisfies the Jacobi identity). ♦

12. PROPOSITION. For the curvature tensor R of the Levi-Civita connection ∇ associated to a Riemannian metric \langle , \rangle we also have

- (1) $\langle R(X, Y)Z, W \rangle = -\langle R(X, Y)W, Z \rangle$
- (2) $\langle R(X, Y)Z, W \rangle = \langle R(Z, W)X, Y \rangle.$

PROOF. Equation (1) is equivalent to

$$\langle R(X, Y)Z, Z \rangle = 0 \quad \text{for all } X, Y, Z.$$

It suffices to prove this when $[X, Y] = 0$. In this case

$$\langle R(X, Y)Z, Z \rangle = \langle \nabla_X(\nabla_Y Z) - \nabla_Y(\nabla_X Z), Z \rangle,$$

so we must show that $\langle \nabla_X(\nabla_Y Z), Z \rangle$ is symmetric in X and Y .

Now $YX\langle Z, Z \rangle$ is symmetric in X and Y , since $[X, Y] = 0$. But

$$X\langle Z, Z \rangle = 2\langle \nabla_X Z, Z \rangle,$$

so

$$YX\langle Z, Z \rangle = 2\langle \nabla_Y \nabla_X Z, Z \rangle + 2\langle \nabla_X Z, \nabla_Y Z \rangle.$$

Since the right-most term is symmetric in X and Y , so is $\langle \nabla_Y \nabla_X Z, Z \rangle$.

Equation (2) follows from (1), Proposition 12, and Proposition 4-11. ♦

To complete our treatment of Koszul connections, we define a **geodesic** for ∇ to be a path $\gamma: [a, b] \rightarrow M$ with

$$\frac{D}{dt} \frac{d\gamma}{dt} = 0;$$

thus, the tangent vector $d\gamma/dt$ must be parallel along γ . In the coordinate system x we immediately obtain the equations for a geodesic,

$$\frac{d^2 \gamma^k}{dt^2} + \sum_{i,j=1}^n \Gamma_{ij}^k(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0.$$

The existence of a unique geodesic, with given initial vector $\gamma'(0) \in M_p$ follows immediately. Since parallel translation is an isomorphism, the tangent vector $d\gamma/dt$ of a geodesic γ is nowhere zero (except when γ is a constant path). If V is any vector field along γ , then we can write

$$V = f \frac{d\gamma}{dt} \quad f: [a, b] \rightarrow \mathbb{R},$$

and

$$\frac{DV}{dt} = \frac{df}{dt} \frac{d\gamma}{dt} + f \frac{D}{dt} \frac{d\gamma}{dt} = \frac{df}{dt} \frac{d\gamma}{dt}.$$

This is 0 only if f is linear. Consequently, a reparameterization $\bar{\gamma} = \gamma \circ p$ of γ is also a geodesic only if p is linear.*

We know that this result can be made more precise for the Levi-Civita connection ∇ associated to a metric $\langle \cdot, \cdot \rangle$, and the proof of the more precise result is now especially easy: We have

$$\frac{d}{dt} \left\langle \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle = 2 \left\langle \frac{D}{dt} \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle = 0,$$

so $\|d\gamma/dt\|$ is constant, i.e., γ is parameterized proportionally to arclength (Theorem I.9-12). The reader is invited to investigate how the proof of Gauss' Lemma (I.9-15) is simplified in the present set up. We will complete our study of the ∇ operator by providing the invariant description of the First Variation Formula promised so long ago.

13. THEOREM (FIRST VARIATION FORMULA). Let $\gamma: [a, b] \rightarrow M$ be a piecewise C^∞ path and $\alpha: (-\varepsilon, \varepsilon) \times [a, b] \rightarrow M$ a variation. Let

$$\begin{aligned} W_t &= \frac{\partial \alpha}{\partial u}(0, t), & \text{the "variation vector field"} \\ V_t &= \frac{d\gamma}{dt}, & \text{the "velocity vector of } \gamma \text{"} \\ A_t &= \frac{D}{dt} V_t, & \text{the "acceleration vector of } \gamma \text{"}. \end{aligned}$$

Also choose $a = t_0 < \cdots < t_N = b$ to include all discontinuity points of V , and set

$$\begin{aligned} \Delta_{t_i} V &= V(t_i^+) - V(t_i^-) & i = 1, \dots, N-1 \\ \Delta_{t_0} V &= V(t_0^+) \\ \Delta_{t_N} V &= -V(t_N^-). \end{aligned}$$

Then

$$\left. \frac{dE(\bar{\alpha}(u))}{du} \right|_{u=0} = - \int_a^b \langle W_t, A_t \rangle dt - \sum_{i=0}^N \langle W_{t_i}, \Delta_{t_i} V \rangle.$$

PROOF. We will give the proof when V has no discontinuities, leaving to the reader the simple auxiliary argument for the general case.

*Again we point out that certain global theorems about geodesics for Riemannian metrics do not generalize to arbitrary connections; see Chapter 8, Addendum 2.

From

$$\frac{\partial}{\partial u} \left\langle \frac{\partial \alpha}{\partial t}, \frac{\partial \alpha}{\partial t} \right\rangle = 2 \left\langle \frac{D}{\partial u} \frac{\partial \alpha}{\partial t}, \frac{\partial \alpha}{\partial t} \right\rangle$$

we obtain

$$\begin{aligned} \frac{dE(\bar{\alpha}(u))}{du} &= \frac{1}{2} \frac{d}{du} \int_a^b \left\langle \frac{\partial \alpha}{\partial t}, \frac{\partial \alpha}{\partial t} \right\rangle dt = \int_a^b \left\langle \frac{D}{\partial u} \frac{\partial \alpha}{\partial t}, \frac{\partial \alpha}{\partial t} \right\rangle dt \\ &= \int_a^b \left\langle \frac{D}{\partial t} \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial t} \right\rangle dt \quad \text{by Proposition 9.} \end{aligned}$$

Now the identity

$$\frac{\partial}{\partial t} \left\langle \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial t} \right\rangle = \left\langle \frac{D}{\partial t} \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial t} \right\rangle + \left\langle \frac{\partial \alpha}{\partial u}, \frac{D}{\partial t} \frac{\partial \alpha}{\partial t} \right\rangle$$

implies the following analogue of integration by parts:

$$\int_a^b \left\langle \frac{D}{\partial t} \frac{\partial \alpha}{\partial t}, \frac{\partial \alpha}{\partial t} \right\rangle dt = \left\langle \frac{\partial \alpha}{\partial u}, \frac{\partial \alpha}{\partial t} \right\rangle \Big|_{t=a}^{t=b} - \int_a^b \left\langle \frac{\partial \alpha}{\partial u}, \frac{D}{\partial t} \frac{\partial \alpha}{\partial t} \right\rangle dt.$$

Thus

$$\frac{dE(\bar{\alpha}(u))}{du} \Big|_{u=0} = - \int_a^b \langle W_t, A_t \rangle dt - \langle W(a), V(a) \rangle + \langle W(b), V(b) \rangle,$$

which is the desired formula. ♦

ADDENDUM 1

CONNECTIONS WITH THE SAME GEODESICS

Let ∇ and $\bar{\nabla}$ be two connections on M . We define

$$D(X, Y) = \bar{\nabla}_X Y - \nabla_X Y.$$

A simple computation shows that D is linear over the C^∞ functions in both arguments, so it determines a tensor D , the **difference tensor** of the two connections. In a coordinate system x we have

$$D = \sum \bar{\Gamma}_{ij}^k - \Gamma_{ij}^k \, dx^i \otimes dx^j \otimes \frac{\partial}{\partial x^k}.$$

As is well known, there is a unique way to write $D = S + A$ with S symmetric and A alternating, namely

$$S(X, Y) = \frac{1}{2}[D(X, Y) + D(Y, X)]$$

$$A(X, Y) = \frac{1}{2}[D(X, Y) - D(Y, X)].$$

Note that if \bar{T} and T are the torsion tensors of $\bar{\nabla}$ and ∇ , then

$$\begin{aligned} (*) \quad 2A(X, Y) &= \bar{\nabla}_X Y - \nabla_X Y - \bar{\nabla}_Y X + \nabla_Y X \\ &= \bar{T}(X, Y) + [X, Y] - T(X, Y) - [X, Y] \\ &= \bar{T}(X, Y) - T(X, Y), \end{aligned}$$

so $\bar{\nabla}$ and ∇ have the same torsion if and only if $A = 0$.

14. PROPOSITION. The following are equivalent:

- (a) The connections $\bar{\nabla}$ and ∇ have the same geodesics [with the same parameterizations]
- (b) $D(X, X) = 0$ for all X
- (c) $S = 0$.

PROOF. (a) \Rightarrow (b): Given $0 \neq X_p \in M$, let γ be the geodesic (for the connections $\bar{\nabla}$ and ∇) with $\gamma'(0) = X_p$. Let X be a vector field in a neighborhood of p which equals $d\gamma/dt$ along the part of γ in the neighborhood. Then

$$D(X_p, X_p) = \bar{\nabla}_{X_p} X - \nabla_{X_p} X = 0 + 0.$$

(b) \Rightarrow (a): Let γ be a geodesic for ∇ , and let X be a vector field which equals $d\gamma/dt$ along a portion of γ . Then

$$\bar{\nabla}_{X_p} X = D(X_p, X_p) + \nabla_{X_p} X = 0 + 0,$$

which shows that γ is a geodesic for $\bar{\nabla}$.

(b) \Leftrightarrow (c): $D(X, X) = 0 \Leftrightarrow S(X, X) = 0$. The latter condition implies that $S = 0$, for we have

$$\begin{aligned} 0 &= S(X + Y, X + Y) = S(X, X) + S(Y, Y) + S(X, Y) + S(Y, X) \\ &= 2S(X, Y). \quad \spadesuit \end{aligned}$$

15. COROLLARY. If the connections ∇ and $\bar{\nabla}$ have the same geodesics and the same torsion, then $\bar{\nabla} = \nabla$.

16. COROLLARY. For every connection $\bar{\nabla}$, there is a unique connection ∇ with the same geodesics and with torsion 0.

PROOF. Uniqueness follows from Corollary 16. For existence we define $\nabla_X Y = \bar{\nabla}_X Y - \frac{1}{2}\bar{T}(X, Y)$, checking easily that ∇ is a connection. Since \bar{T} is skew-symmetric, $D = \frac{1}{2}\bar{T}$ must simply be A , so $S = 0$, so ∇ and $\bar{\nabla}$ have the same geodesics. Also, $T = \bar{T} - 2A = 0$, so ∇ has torsion 0. \spadesuit

We thus see that if we divide all connections into equivalence classes, putting all connections with the same geodesics in the same class, then each class has exactly one connection with zero torsion. We can also say exactly how large each class is: If ∇ is a connection with torsion 0 and \bar{T} is a skew-symmetric tensor of type $\binom{2}{0}$, then there is a connection $\bar{\nabla}$ in the same class as ∇ , but with torsion \bar{T} , namely

$$\bar{\nabla}_X Y = \nabla_X Y + \frac{1}{2}\bar{T}(X, Y).$$

It is also of interest to inquire when two connections $\bar{\nabla}$ and ∇ have the same geodesics, with possibly *different* parameterizations. Such connections are called “projectively equivalent”, because in ordinary space a projective map is one that takes straight lines to straight lines.

17. PROPOSITION (H. WEYL; 1921). The following are equivalent:

- (a) The connections $\bar{\nabla}$ and ∇ have the same geodesics, with possibly different parameterizations.
- (b) For every X there is λ_X with $D(X, X) = \lambda_X \cdot X$.
- (c) There is a (unique) 1-form ω with $S(X, Y) = \omega(X)Y + \omega(Y)X$.

PROOF. (a) \Rightarrow (b): Given $X_p \in M$, let γ be the geodesic for the connection ∇ with $\gamma' = X_p$, and let $\bar{\gamma}$ be the reparameterization which makes it a geodesic for $\bar{\nabla}$. Let X be a vector field which equals $d\gamma/dt$ along γ and \bar{X} a vector field which equals $d\bar{\gamma}/dt$ along γ . Then along γ we have $X = f\bar{X}$ for some f . So

$$\begin{aligned} D(X_p, X_p) &= \bar{\nabla}_{X_p} X - \nabla_{X_p} X \\ &= \bar{\nabla}_{f(p)\bar{X}_p} f\bar{X} - 0 \\ &= f(p)[\bar{X}_p(f) \cdot \bar{X}_p + f(p)\bar{\nabla}_{\bar{X}_p} \bar{X}] \\ &= f(p)\bar{X}_p(f) \cdot \bar{X}_p = \bar{X}_p(f)X_p. \end{aligned}$$

(b) \Rightarrow (a): Let γ be a geodesic for ∇ , and let X be a vector field which equals $d\gamma/dt$ along γ . Then for $p = \gamma(t)$ we have

$$(1) \quad \bar{\nabla}_{X_p} X = D(X_p, X_p) + \nabla_{X_p} X = \lambda_{X_p} X_p = g(t)X_p, \quad \text{say.}$$

Let $f(t) = e^{G(t)} \neq 0$, where $G'(t) = g(t)$ so that

$$(2) \quad \frac{df}{dt} = g(t)f(t),$$

and let \bar{X} be a vector field such that

$$(3) \quad \bar{X}_{\gamma(t)} = \frac{1}{f(t)} X_{\gamma(t)} = \frac{1}{f(t)} \frac{d\gamma}{dt}.$$

Then

$$\begin{aligned} \bar{\nabla}_{\bar{X}_p} \bar{X} &= \frac{1}{f(t)} \bar{\nabla}_{X_p} \frac{1}{f} X \\ &= \frac{1}{f(t)} \left[X_p \left(\frac{1}{f} \right) X_p + \frac{1}{f(t)} \bar{\nabla}_{X_p} X \right] \\ &= \frac{1}{f(t)} \left[-\frac{df/dt}{f(t)^2} X_p + \frac{1}{f(t)} g(t) X_p \right] && \text{by (1)} \\ &= \frac{1}{f(t)} \left[-\frac{df/dt}{f(t)^2} X_p + \frac{df/dt}{f(t)^2} X_p \right] && \text{by (2)} \\ &= 0. \end{aligned}$$

Consequently, γ is a geodesic for \bar{V} if we reparameterize it as $\bar{\gamma} = \gamma \circ p^{-1}$, where p is chosen so that

$$\frac{d\gamma}{dt} = \bar{X}_{\bar{\gamma}(t)},$$

i.e., so that

$$(p^{-1})'(t) \frac{d\gamma}{dt} \Big|_{p^{-1}(t)} = \frac{1}{f(p^{-1}(t))} \frac{d\gamma}{dt} \Big|_{p^{-1}(t)} \quad \text{by (3).}$$

For this we need

$$\frac{1}{p'(p^{-1}(t))} = \frac{1}{f(p^{-1}(t))},$$

or simply $p'(s) = f(s) > 0$ (compare Problem I.9-27).

(c) \Rightarrow (b) is clear.

(b) \Rightarrow (c): We first establish the following algebraic

LEMMA. Let V be a vector space, and $S: V \times V \rightarrow V$ a symmetric bilinear map such that for each $v \in V$ there is $\lambda_v \in \mathbb{R}$ with

$$S(v, v) = \lambda_v v.$$

Then there is a unique $\phi \in V^*$ such that

$$S(v, w) = \phi(v)w + \phi(w)v.$$

PROOF. If ϕ exists, clearly $\phi(v) = \lambda_v/2$ for $v \neq 0$. Conversely, if this definition makes ϕ linear we will be done, for then

$$\begin{aligned} S(v, v) + S(w, w) + 2S(v, w) &= S(v + w, v + w) = \lambda_{v+w}(v + w) \\ &= (\lambda_v + \lambda_w)(v + w), \end{aligned}$$

so

$$2\phi(v)v + 2\phi(w)w + 2S(v, w) = 2\phi(v)v + 2\phi(w)w + 2\phi(v)w + 2\phi(w)v,$$

which yields

$$S(v, w) = \phi(v)w + \phi(w)v.$$

We prove that ϕ is linear as follows. From

$$\begin{aligned} \lambda_{v+w}(v + w) &= \lambda_v v + \lambda_w w + 2S(v, w) \\ \lambda_{v-w}(v - w) &= \lambda_v v + \lambda_w w - 2S(v, w) \end{aligned}$$

we obtain

$$(\lambda_{v+w} + \lambda_{v-w} - 2\lambda_v)v + (\lambda_{v+w} - \lambda_{v-w} - 2\lambda_w)w = 0.$$

For linearly independent v and w we thus have

$$\begin{aligned}\lambda_{v+w} + \lambda_{v-w} - 2\lambda_v &= 0 \\ \lambda_{v+w} - \lambda_{v-w} - 2\lambda_w &= 0,\end{aligned}$$

and hence $\lambda_{v+w} = \lambda_v + \lambda_w$. This is clearly also true if v and w are linearly dependent. Homogeneity is likewise trivial. **Q.E.D.**

When V is n -dimensional, we have the explicit formula

$$(*) \quad \phi(v) = \frac{1}{n+1} \text{ trace of } w \mapsto S(v, w),$$

which can be deduced as follows. Choose a basis v_1, \dots, v_n with $v = v_1$. Then

$$S(v_1, v_j) = \phi(v_1)v_j + \phi(v_j)\phi_1,$$

so

$$\text{trace of } w \mapsto S(v_1, w) = \sum_{j=1}^n j^{\text{th}} \text{ component of } \phi(v_1)v_j + \phi(v_j)v_1;$$

this component is $\phi(v_1)$ for $j \neq 1$, and $2\phi(v_1)$ for $j = 1$.

Formula $(*)$ clearly shows that

$$\omega(X) = \frac{1}{n+1} \text{ trace } Y \mapsto S(X, Y)$$

is the desired C^∞ 1-form on M . \blacklozenge

18. COROLLARY. The connections $\bar{\nabla}$ and ∇ have the same torsion and the same geodesics (suitably reparameterized) if and only if there is a (unique) 1-form ω with

$$D(X, Y) = \omega(X)Y + \omega(Y)X.$$

Note, by the way, that for any connection ∇ and any 1-form ω , the function

$$\bar{\nabla}_X Y = \nabla_X Y + \omega(X)Y + \omega(Y)X$$

always is a connection, with the same torsion as ∇ .

ADDENDUM 2

RIEMANN'S INVARIANT DEFINITION
OF THE CURVATURE TENSOR

In part C of Chapter 4 we presented an extract from Riemann's paper of 1861. Our use of "..." near the end was rather deceitful, because one of the omissions was by no means a minor one. In the deleted portion Riemann gives a result, which, although it plays no further role in our development of Riemannian geometry, is nevertheless extremely interesting, for it amounts to another invariant definition of the curvature tensor. We therefore give below an unabridged version of the second part of the extract, beginning with the last paragraph in the version in Chapter 4C. It will present greater difficulties of interpretation than any thing else we have read, and is followed immediately by an exposition in modern terms.

* * * * *

The functions g_{ij} must necessarily satisfy these equations whenever $\sum_{i,j} g_{ij} dy^i dy^j$ can be transformed into the form $\sum_i (dx^i)^2$: we denote the left side of this equation by

$$(ij,kl).$$

To make the nature of this equation more transparent, we form the expression

$$\delta\delta \sum g_{ij} dy^i dy^j - 2d\delta \sum g_{ij} dy^i \delta y^j + dd \sum g_{ij} \delta y^i \delta y^j,$$

the variations of the second order d^2 , $d\delta$, δ^2 being so determined that

$$\delta' \sum g_{ij} dy^i \delta y^j - \delta \sum g_{ij} dy^i \delta' y^j - d \sum g_{ij} \delta y^i \delta' y^j = 0$$

$$\delta' \sum g_{ij} dy^i dy^j - 2d \sum g_{ij} dy^i \delta' y^j = 0$$

$$\delta' \sum g_{ij} \delta y^i \delta y^j - 2\delta \sum g_{ij} \delta y^i \delta' y^j = 0,$$

δ' denoting an arbitrary variation. In this way the above expression becomes

$$(II) \quad = \sum (ij,kl)(dy^i \delta y^j - dy^j \delta y^i)(dy^k \delta y^l - dy^l \delta y^k).$$

Now from the formation of this expression it is immediately evident that a change of the independent variables changes it into a new form depending in

the same way on the $\sum g_{ij} dx^i dx^j$. And if the quantities g_{ij} are constant, all coefficients of the expression (II) turn out to be equal to 0. Thus if $\sum g_{ij} dy^i dy^j$ can be transformed into a similar expression with constant coefficients, it is necessary that expression (II) vanishes identically.

In the same way it turns out that if the expression (II) does not vanish, the expression

$$(III) \quad -\frac{1}{2} \frac{\sum (ij,kl)(dy^i \delta y^j - dy^j \delta y^i)(dy^k \delta y^l - dy^l \delta y^k)}{\sum g_{ij} dy^i dy^j \sum g_{ij} dy^i \delta y^j - \left(\sum g_{ij} dy^i \delta y^j\right)^2}$$

does not change if the independent variables are changed, and moreover remains unchanged if in place of the variations dy^i , δy^i , arbitrary independent linear expressions of them, $\alpha dy^i + \beta \delta y^i$, $\gamma dy^i + \delta y^i$ are substituted. Moreover, the maximum and minimum values of the function (III) of the same dy^i , δy^i depend neither on the form of the expression $\sum g_{ij} dy^i dy^j$ nor on the values of the variations dy^i , δy^i , whence from these values it can be determined when two expressions of this kind can be transformed into each other.

These interpretations can be illustrated by what one might call a geometrical interpretation, which, although it depends on unusual conceptions, it will nevertheless help, as one goes along, to have touched upon.

The expression $\sqrt{\sum g_{ij} dy^i dy^j}$ can be regarded as just the line element in a generalized space of n dimensions transcending our intuition. If in this space at the point (y^1, \dots, y^n) all shortest lines are drawn, in which the initial elements of variation of the y^i are $\alpha dy^1 + \beta \delta y^1 : \alpha dy^2 + \beta \delta y^2 : \dots : \alpha dy^n + \beta \delta y^n$, α and β denoting arbitrary quantities, these lines make up a surface which can be developed in the space of our common intuition. In this way the expression (III) will measure the curvature of this surface at the point (y^1, \dots, y^n) .

If we now return to the case $n = 3$, the expression (II) is a form of the second degree in

$$dy^2 \delta y^3 - dy^3 \delta y^2, \quad dy^3 \delta y^1 - dy^1 \delta y^3, \quad dy^1 \delta y^2 - dy^2 \delta y^1,$$

and in this case we obtain six equations, which the functions g_{ij} are required to satisfy if $\sum g_{ij} dy^i dy^j$ can be transformed into a form with constant coefficients. Given an acquaintance with the traditional methods, it is demonstrated without difficulty that these six conditions, when they are satisfied, suffice. It is to be observed nevertheless that only three of them are independent.

Riemann's description of the curvature tensor is particularly difficult to decipher because he is using classical notation from the calculus of variations. To state it in modern terms, consider a function $s: \mathbb{R}^2 \rightarrow M$, with $s(0) = p \in M$. This function s can be thought of as a "2-parameter variation of the point p ", and on M it gives rise to 2 vector fields,

$$\begin{aligned}\frac{\partial s}{\partial x} &= s_* \left(\frac{\partial}{\partial x} \right) \\ \frac{\partial s}{\partial y} &= s_* \left(\frac{\partial}{\partial y} \right).\end{aligned}$$

This notation involves the usual ambiguities, and in conformity with this, the function

$$(x, y) \mapsto \left\langle \frac{\partial s}{\partial x}(x, y), \frac{\partial s}{\partial y}(x, y) \right\rangle$$

on \mathbb{R}^2 will be denoted simply by

$$\left\langle \frac{\partial s}{\partial x}, \frac{\partial s}{\partial y} \right\rangle.$$

Riemann directs us to consider the expression

$$(A) \quad \frac{\partial^2}{\partial x^2} \left\langle \frac{\partial s}{\partial y}, \frac{\partial s}{\partial y} \right\rangle - 2 \frac{\partial^2}{\partial x \partial y} \left\langle \frac{\partial s}{\partial x}, \frac{\partial s}{\partial y} \right\rangle + \frac{\partial^2}{\partial y^2} \left\langle \frac{\partial s}{\partial x}, \frac{\partial s}{\partial x} \right\rangle.$$

If we let

$$X = \frac{\partial s}{\partial x}, \quad Y = \frac{\partial s}{\partial y},$$

then the value of this expression at $(x, y) = (0, 0)$ can be written

$$X_p(X(\langle Y, Y \rangle)) - 2X_p(Y(\langle X, Y \rangle)) + Y_p(Y(\langle X, X \rangle)),$$

or simply

$$(B) \quad [XX\langle Y, Y \rangle - 2XY\langle X, Y \rangle + YY\langle X, X \rangle](p).$$

On the other hand, to be certain that the expression (B) will equal (A) for some $s: \mathbb{R}^2 \rightarrow M$, we need to know that $[X, Y] = 0$. Riemann does not consider all $s: \mathbb{R}^2 \rightarrow M$, but only those with the following property: If $\sigma: \mathbb{R}^3 \rightarrow M$ is $\sigma(x, y, 0) = s(x, y)$, then

$$\left. \begin{aligned} \frac{\partial}{\partial z} \left\langle \frac{\partial \sigma}{\partial x}, \frac{\partial \sigma}{\partial y} \right\rangle - \left\langle \frac{\partial}{\partial y} \frac{\partial \sigma}{\partial x}, \frac{\partial \sigma}{\partial z} \right\rangle - \left\langle \frac{\partial}{\partial x} \frac{\partial \sigma}{\partial y}, \frac{\partial \sigma}{\partial z} \right\rangle &= 0 \\ \frac{\partial}{\partial z} \left\langle \frac{\partial \sigma}{\partial x}, \frac{\partial \sigma}{\partial x} \right\rangle - 2 \frac{\partial}{\partial x} \left\langle \frac{\partial \sigma}{\partial x}, \frac{\partial \sigma}{\partial z} \right\rangle &= 0 \\ \frac{\partial}{\partial z} \left\langle \frac{\partial \sigma}{\partial y}, \frac{\partial \sigma}{\partial y} \right\rangle - 2 \frac{\partial}{\partial y} \left\langle \frac{\partial \sigma}{\partial y}, \frac{\partial \sigma}{\partial z} \right\rangle &= 0 \end{aligned} \right\} \quad \text{at } (0, 0, 0).$$

Riemann claims that if $s: \mathbb{R}^2 \rightarrow M$ has this property, then the value of (A) at $(x, y) = (0, 0)$ is $-2\langle R(X_p, Y_p)Y_p, X_p \rangle$. (To account for the factor of -2 recall that Riemann's (ij, kl) equals $R_{ijkl}/2 = -R_{ijkl}/2$, and note that Riemann has $(dy^i \wedge dy^j) \otimes (dy^k \wedge dy^l)$ instead of $dy^i \otimes dy^j \otimes dy^k \otimes dy^l$.) This assertion can be rephrased as follows.

19. THEOREM (RIEMANN). For any linearly independent vectors $X_p, Y_p \in M_p$ there are vector fields X, Y extending them such that

(a) $[X, Y] = 0$

(b) For every vector field Z with $[X, Z](p) = [Y, Z](p) = 0$ we have

$$\left. \begin{array}{l} (1) \quad Z\langle X, Y \rangle - Y\langle X, Z \rangle - X\langle Y, Z \rangle = 0 \\ (2) \quad Z\langle X, X \rangle - 2X\langle X, Z \rangle = 0 \\ (3) \quad Z\langle Y, Y \rangle - 2Y\langle Y, Z \rangle = 0 \end{array} \right\} \quad \text{at } p.$$

For any such vector fields X and Y we have

$$-2\langle R(X_p, Y_p)Y_p, X_p \rangle = [XX\langle Y, Y \rangle - 2XY\langle X, Y \rangle + YY\langle X, X \rangle](p).$$

PROOF. Using Corollary 7, we see that equation (2) is equivalent to

$$2\langle \nabla_Z X, X \rangle - 2\langle \nabla_X X, Z \rangle - 2\langle X, \nabla_X Z \rangle = 0 \quad \text{at } p$$

and hence to

$$\langle \nabla_X X, Z \rangle = 0 \quad \text{at } p,$$

since $\nabla_Z X(p) - \nabla_X Z(p) = [X, Z](p) = 0$. Thus equation (2) is equivalent to

$$(2') \quad \nabla_X X(p) = 0.$$

Similarly, (3) is equivalent to

$$(3') \quad \nabla_Y Y(p) = 0.$$

Finally, (1) is equivalent to the equality, at p ,

$$\langle \nabla_Z X, Y \rangle + \langle X, \nabla_Z Y \rangle - \langle \nabla_Y X, Z \rangle - \langle X, \nabla_Y Z \rangle - \langle \nabla_X Y, Z \rangle - \langle Y, \nabla_X Z \rangle = 0,$$

and hence to

$$\langle \nabla_X Y + \nabla_Y X, Z \rangle = 0 \quad \text{at } p.$$

This is equivalent to

$$0 = \nabla_X Y(p) + \nabla_Y X(p) = 2\nabla_X Y(p), \quad \text{since } \nabla_X Y - \nabla_Y X = [X, Y] = 0,$$

so (1) is equivalent to

$$(1') \quad \nabla_X Y(p) = \nabla_Y X(p) = 0.$$

We can obtain such vector fields X and Y , with given values $X_p, Y_p \in M_p$, by mapping \mathbb{R}^2 into M in such a way that the x and y axes go into two geodesics in M with $s_*(\partial/\partial y)$ parallel along the image of the x -axis and $s_*(\partial/\partial x)$ parallel along the image of the y -axis.

Now for such vector fields we have

$$\begin{aligned} XX\langle Y, Y \rangle(p) &= 2X\langle \nabla_X Y, Y \rangle(p) = 2\langle \nabla_X \nabla_X Y, Y \rangle(p) + 2\langle \nabla_X Y, \nabla_X Y \rangle(p) \\ &= 2\langle \nabla_X \nabla_X Y, Y \rangle(p) \\ YY\langle X, X \rangle(p) &= 2\langle \nabla_Y \nabla_Y X, X \rangle(p) \\ -2XY\langle X, Y \rangle(p) &= -2X(\langle \nabla_Y X, Y \rangle + \langle X, \nabla_Y Y \rangle)(p) \\ &= -2\langle \nabla_X \nabla_Y X, Y \rangle(p) - 2\langle \nabla_Y X, \nabla_X Y \rangle(p) \\ &\quad - 2\langle \nabla_X X, \nabla_Y Y \rangle(p) - 2\langle X, \nabla_X \nabla_Y Y \rangle(p) \\ &= -2\langle \nabla_X \nabla_Y X, Y \rangle(p) - 2\langle X, \nabla_X \nabla_Y Y \rangle(p). \end{aligned}$$

So the sum is

$$\begin{aligned} &2[\langle \nabla_X \nabla_X Y, Y \rangle - \langle \nabla_X \nabla_Y X, Y \rangle](p) + 2[\langle \nabla_Y \nabla_Y X, X \rangle - \langle \nabla_X \nabla_Y Y, X \rangle](p) \\ &= 0 + 2[\langle \nabla_Y \nabla_X Y, X \rangle - \langle \nabla_X \nabla_Y Y, X \rangle](p) \\ &\quad \text{since } \nabla_Y X - \nabla_X Y = [X, Y] = 0 \text{ everywhere} \\ &= 2\langle R(Y_p, X_p)Y_p, X_p \rangle \\ &= -2\langle R(X_p, Y_p)Y_p, X_p \rangle. \quad \spadesuit \end{aligned}$$

CHAPTER 7

THE REPÈRE MOBILE (THE MOVING FRAME)

The previous chapter betrayed the historical development which we have been following, for the ∇ operator did not appear until very late in the game, around 1954.* In the meantime, Élie Cartan had elaborated a completely different theory, the method of the repère mobile. Despite the fact that this theory was invented soon after the Ricci calculus, some of its features are most easily understood by referring to the ∇ operator which historically came so much later.

Roughly speaking, the relationship between the results of Chapter 5 and those of Chapter 6 can be characterized as follows. When working with ∇ operators we express results in terms of arbitrary vector fields, while in the classical theory we always use the vector fields $X_i = \partial/\partial x^i$ given by a coordinate system (x, U) . At each point $p \in U$, these vector fields provide us with an ordered basis

$$(X_1(p), \dots, X_n(p)) \quad \text{for } M_p.$$

In general, an ordered basis (v_1, \dots, v_n) for a vector space V will also be called a **frame** in V . Now the vector fields X_i may be used to determine a function

$$p \mapsto (X_1(p), \dots, X_n(p)),$$

whose values are frames in the various tangent spaces M_p ; such a function is called a **moving frame**. Conversely, every moving frame $p \mapsto F_p$ determines vector fields X_1, \dots, X_n by $F_p = (X_1(p), \dots, X_n(p))$. Consequently, as a matter of convenience we will not distinguish between everywhere linearly independent vector fields X_1, \dots, X_n , and the moving frame they determine. In É. Cartan's theory, the basic idea, whose ramifications turn out to be extremely significant, is to express everything in terms of an arbitrary moving frame X_1, \dots, X_n , and not just in terms of the "natural moving frame" $X_i = \partial/\partial x^i$ given by a coordinate system x .

Notice that a moving frame X_1, \dots, X_n need not be the natural frame for any coordinate system, since we need not have $[X_i, X_j] = 0$. Also, a moving frame

*Nomizu, *Invariant affine connections on homogeneous spaces*, Amer. J. Math. **76** (1954), 33–65.

may exist on a region which cannot even be included in a coordinate system. For example, there is a moving frame X_1, X_2 on the whole torus. On a Riemannian

manifold $(M, \langle \cdot, \cdot \rangle)$ we define an **orthonormal** moving frame X_1, \dots, X_n to be one such that each $(X_1(p), \dots, X_n(p))$ is an orthonormal frame for M_p . The frame illustrated above, on the torus, is an example. An arbitrary moving frame X_1, \dots, X_n gives rise to an orthonormal moving frame if we apply the Gram-Schmidt orthonormalization process to it (Problem I.9-11).

Given a moving frame X_1, \dots, X_n on (an open subset U of) M , we now ask if it is possible to describe quantitatively just how the frame is moving. As a guide, we first consider a moving frame X_1, \dots, X_n in \mathbb{R}^n . In this case, we can, with a little abuse of notation, consider each X_i as an \mathbb{R}^n -valued function $X_i: \mathbb{R}^n \rightarrow \mathbb{R}^n$. If we consider the identity map as an \mathbb{R}^n -valued function $P: \mathbb{R}^n \rightarrow \mathbb{R}^n$, then the \mathbb{R}^n -valued 1-form dP is just

$$dP(X_a) = X.$$

Consequently, if we introduce 1-forms θ^i by

$$(I) \quad dP = \sum_{i=1}^n \theta^i \cdot X_i \quad \text{i.e.,} \quad dP(X_a) = \sum_{i=1}^n \theta^i(X_a) \cdot X_i(a) \in \mathbb{R}^n,$$

then θ^i are just the “dual forms” to the X_i , that is, $\theta^i(X_j) = \delta_j^i$. We also introduce 1-forms ω_j^i by

$$(II) \quad dX_j = \sum_{i=1}^n \omega_j^i \cdot X_i.$$

Clearly $\omega_j^i(X_a)$ is the X_i component of $dX_j(X_a)$. Since $dX_j(X_a)$ is just the directional derivative of X_j in the direction X_a , we can interpret $\omega_j^i(X_a)$ as the *rate at which X_j rotates toward $X_i(a)$ as we move along a curve with tangent vector X_a .*

Now it is not possible to find a moving frame with arbitrary θ^i and ω_j^i ; certain integrability conditions must be satisfied:

1. PROPOSITION. The 1-forms θ^i and ω_j^i for a moving frame X_1, \dots, X_n in \mathbb{R}^n satisfy the **structural equations of Euclidean space**:

$$\begin{aligned} d\theta^i &= \sum_k \theta^k \wedge \omega_k^i = - \sum_k \omega_k^i \wedge \theta^k \\ d\omega_j^i &= - \sum_k \omega_k^i \wedge \omega_j^k. \end{aligned}$$

PROOF. Noting that the equation $dP = \sum \theta^i \cdot X_i$ can also be written $dP = \sum_i \theta^i \wedge X_i$ (for the \mathbb{R}^n -valued 0-form X_i), we have

$$\begin{aligned} 0 = d^2P &= d\left(\sum_i \theta^i \wedge X_i\right) = \sum_i d\theta^i \wedge X_i - \sum_k \theta^k \wedge dX_k \\ &= \sum_i d\theta^i X_i - \sum_k \theta^k \wedge \sum_i \omega_k^i X_i \quad \text{by (II).} \end{aligned}$$

Setting the coefficient of each X_i equal to 0, we obtain the first structural equation.

We also have

$$\begin{aligned} 0 = d^2X_j &= \sum_i d\omega_j^i X_i - \sum_k \omega_j^k \wedge dX_k \\ &= \sum_i d\omega_j^i X_i - \sum_k \omega_j^k \wedge \sum_i \omega_k^i X_i, \end{aligned}$$

from which we immediately deduce the second structural equation. ♦

The structural equations can be written much more compactly if we use slightly modified matrix notation. Henceforth, we will write matrices as $A = (A_j^i)$, and define

$$(A \cdot B)_j^i = \sum_k A_k^i B_j^k,$$

so that our new A_k^i corresponds to the old A_{ik} . If $\mathbf{v} = (v_1, \dots, v_n)$ is an ordered n -tuple of vectors, and we define

$$w_j = \sum_i A_j^i v_i,$$

then the n -tuple $\mathbf{w} = (w_1, \dots, w_n)$ will be denoted by $\mathbf{v} \cdot A$. We put the A on the right because we have

$$\begin{aligned} [\mathbf{v} \cdot (A \cdot B)]_j &= \sum_i (A \cdot B)_j^i v_i = \sum_i \sum_k A_k^i B_j^k v_i \\ &= \sum_k B_j^k \left(\sum_i A_k^i v_i \right) = \sum_k B_j^k (\mathbf{v} \cdot A)_k \\ &= [(\mathbf{v} \cdot A) \cdot B]_j, \end{aligned}$$

which we can write simply as*

$$\mathbf{v} \cdot (AB) = (\mathbf{v} \cdot A) \cdot B.$$

Naturally, if $\mathbf{X} = (X_1, \dots, X_n)$ is an n -tuple of vector fields on a manifold M , and $A = (A_j^i)$ is a matrix of functions (or a matrix-valued function, whichever way you prefer to look at it), then $\mathbf{X} \cdot A$ denotes the n -tuple of vector fields $(\mathbf{X} \cdot A)_j = \sum_i A_j^i X_i$.

We extend this notation to forms in the natural way. If $\omega = (\omega_j^i)$ and $\eta = (\eta_j^i)$ are matrices of forms, of degree k and l , respectively, then $\omega \wedge \eta$ is the matrix of $(k + l)$ -forms

$$(\omega \wedge \eta)_j^i = \sum_k \omega_k^i \wedge \eta_j^k.$$

If θ denotes the column vector of l -forms $\theta^1, \dots, \theta^n$, then $\omega \wedge \theta$ is the column vector of $(k + l)$ -forms

$$(\omega \wedge \theta)^i = \sum_j \omega_j^i \wedge \theta^j.$$

With these conventions we can write the structural equations of Euclidean space as

$$\begin{aligned} d\theta &= -\omega \wedge \theta \\ d\omega &= -\omega \wedge \omega. \end{aligned}$$

Henceforth, we will use this notation whenever convenient; for a while the reader may feel more secure rewriting things in standard form. Our very next result justifies our characterization of the structural equations as “integrability conditions”.

*We express this by saying that the $n \times n$ matrices **act on the right** on the set of all n -tuples of vectors of V . On the other hand, suppose we choose a *fixed* basis v_1, \dots, v_n for V , and then define $A \cdot v$ for $v \in V$ by defining $A \cdot v_j = \sum_i A_j^i v_i$ and extending by linearity. In this case we will have $(A \cdot B) \cdot v = A \cdot (B \cdot v)$; so we say that the $n \times n$ matrices **act on the left** on V .

2. PROPOSITION. Let $\omega = (\omega_j^i)$ be a matrix of 1-forms on \mathbb{R}^n which satisfy the second structural equations

$$d\omega = -\omega \wedge \omega \quad \text{i.e.,} \quad d\omega_j^i = -\sum_k \omega_k^i \wedge \omega_j^k.$$

Then,

(1) In a neighborhood of 0 there is a matrix $A = (A_j^i)$ of functions, with arbitrary initial condition $A(0)$, such that

$$dA = -\omega \wedge A \quad \text{i.e.,} \quad dA_j^i = -\sum_k \omega_k^i A_j^k.$$

(2) In a neighborhood of 0 there is a moving frame X_1, \dots, X_n with arbitrary initial conditions $X_1(0), \dots, X_n(0)$, so that the dual 1-forms θ^i satisfy the first structural equation

$$d\theta = -\omega \wedge \theta \quad \text{i.e.,} \quad d\theta^i = -\sum_k \omega_k^i \wedge \theta^k.$$

PROOF. (1) Let y^1, \dots, y^n be the standard coordinate system on \mathbb{R}^n , and let y^1, \dots, y^n, z_j^i be the standard coordinate system on \mathbb{R}^{n+n^2} . Let Z be the matrix of functions $Z = (z_j^i)$ and consider the matrix of 1-forms

$$(*) \quad \Lambda = dZ + (\omega \wedge Z).$$

We have

$$\begin{aligned} d\Lambda &= d\omega \wedge Z - \omega \wedge dZ \\ &= -(\omega \wedge \omega) \wedge Z - \omega \wedge [\Lambda - (\omega \wedge Z)] \quad \text{by } (*) \text{ and the hypothesis} \\ &= -\omega \wedge \Lambda. \end{aligned}$$

By Proposition I.7-14, the n -dimensional distribution

$$\Delta_p = \bigcap_{i,j=1}^n \ker \Lambda_j^i(p)$$

in \mathbb{R}^{n+n^2} is integrable. Since $\Delta_{(0,z_0)} = (y^1, \dots, y^n)$ -plane, the integral manifold though any point $(0, z_0)$ is locally the graph of a function $p \mapsto A(p) \in \mathbb{R}^{n^2}$ with

$A(0) = z_0$. Since $dZ + (\omega \wedge Z) = 0$ on this graph, we conclude, as in the proof of Theorem I.10-17, that

$$(**) \quad dA = -\omega \wedge A.$$

(2) Choose A to be non-singular at 0, and define 1-forms θ^i by

$$\theta^i = \sum_j A_j^i dy^j,$$

which we can write simply as

$$\theta = A \wedge dy.$$

Then

$$\begin{aligned} d\theta &= dA \wedge dy \\ &= -\omega \wedge A \wedge dy \quad \text{by } (**) \\ &= -\omega \wedge \theta. \end{aligned}$$

So we just define the moving frame X_1, \dots, X_n by $\theta^i(X_j) = \delta_j^i$. ♦

For orthonormal moving frames we have one more relation:

3. PROPOSITION. The forms ω_j^i for an orthonormal moving frame X_1, \dots, X_n in \mathbb{R}^n satisfy

$$\omega_j^i = -\omega_i^j,$$

i.e., the matrix ω is skew-symmetric.

PROOF. We have

$$0 = d(\langle X_i, X_j \rangle) = \langle dX_i, X_j \rangle + \langle X_i, dX_j \rangle.$$

Here $\langle dX_i, X_j \rangle(X_a)$ means $\langle dX_i(X_a), X_j(a) \rangle$. Since the X_i are orthogonal, clearly $\langle dX_i, X_j \rangle(X_a)$ is just the X_j component of $dX_i(X_a)$. This means that $\langle dX_i, X_j \rangle = \omega_j^i$. ♦

Now consider a moving frame X_1, \dots, X_n on a manifold M . We can still define the **dual 1-forms** θ^i by $\theta^i(X_j) = \delta_j^i$; equation (I) can now be rewritten as $X_q = \sum_i \theta^i(X_q) \cdot X_i(q)$ for any $X_q \in M_q$, or simply $dP = \sum_i \theta^i \cdot X_i$, where “ dP ” denotes the identity map of a tangent space into itself. We cannot use equation (II) to define the forms ω_j^i , since “ dX_i ” makes no sense on a general manifold. However, Propositions 1 and 3 suggest a way of defining these forms on a Riemannian manifold.

4. PROPOSITION. Let X_1, \dots, X_n be a moving frame on a manifold M , and let θ^i be the dual 1-forms. Then there exist unique 1-forms ω_j^i such that

$$\begin{aligned} \text{(a)} \quad & \omega_j^i = -\omega_i^j \\ \text{(b)} \quad & d\theta^i = \sum_k \theta^k \wedge \omega_k^i. \end{aligned}$$

PROOF. Suppose ω_j^i satisfy (a) and (b). There are unique functions a_{jk}^i and b_{jk}^i with

$$\begin{aligned} \omega_j^i &= \sum_k a_{jk}^i \theta^k, \\ d\theta^i &= \frac{1}{2} \sum_{j,k} b_{jk}^i \theta^j \wedge \theta^k, \quad b_{jk}^i = -b_{kj}^i. \end{aligned}$$

Then (a) is equivalent to

$$\text{(a')} \quad a_{ik}^j = -a_{jk}^i,$$

while (b) gives

$$\frac{1}{2} \sum_{j,k} b_{jk}^i \theta^j \wedge \theta^k = d\theta^i = \sum_j \theta^j \wedge \omega_j^i = \sum_{j,k} a_{jk}^i \theta^j \wedge \theta^k,$$

and hence

$$\text{(b')} \quad a_{jk}^i - a_{kj}^i = b_{jk}^i.$$

Cyclically permuting i, j, k , we obtain from (a') and (b')

$$a_{jk}^i = \frac{1}{2}(b_{jk}^i + b_{ki}^j - b_{ij}^k).$$

This proves uniqueness.

Now suppose we define ω_j^i by

$$\omega_j^i = \sum_k a_{jk}^i \theta^k,$$

where the a_{jk}^i are as defined above, and hence satisfy (b'). It is easy to check that equation (a') holds, and hence that equation (a) holds. Moreover, from equation (b') we have

$$\omega_j^i(X_k) - \omega_k^i(X_j) = a_{jk}^i - a_{kj}^i = b_{jk}^i;$$

it follows that

$$\begin{aligned}
 \sum_l \theta^l \wedge \omega_l^i(X_j, X_k) &= \sum_l \theta^l(X_j) \omega_l^i(X_k) - \theta^l(X_k) \omega_l^i(X_j) \\
 &= \sum_l \delta_j^l \omega_l^i(X_k) - \delta_k^l \omega_l^i(X_j) \\
 &= \omega_j^i(X_k) - \omega_k^i(X_j) \\
 &= b_{jk}^i,
 \end{aligned}$$

which is equivalent to equation (b). ♦

Although we have used Proposition 3 to motivate Proposition 4, the latter result seems to involve neither a Riemannian metric nor an orthonormal moving frame. However the two are, in a sense, really there, since there is a unique Riemannian metric on the domain of the moving frame X_1, \dots, X_n which makes it an orthonormal moving frame. Naturally, if we are already given a Riemannian metric $\langle \cdot, \cdot \rangle$ on M , then we will expect the 1-forms ω_j^i to have some significance for this metric only when the moving frame is orthonormal with respect to it.

Let us therefore consider an *orthonormal* moving frame X_1, \dots, X_n on a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$. The unique 1-forms ω_j^i given by Proposition 4 are called the **connection forms** for the moving frame X_1, \dots, X_n . They satisfy $\omega_j^i = -\omega_i^j$ and the first structural equation, by their very definition. On the other hand, there is no reason to expect them to satisfy the second structural equation. Recognizing this, we define a matrix of 2-forms $\Omega = (\Omega_j^i)$ by

$$d\omega = -\omega \wedge \omega + \Omega \quad \text{i.e.,} \quad d\omega_j^i = - \sum_k \omega_k^i \wedge \omega_j^k + \Omega_j^i.$$

The 2-forms Ω_j^i are called the **curvature forms** for the orthonormal moving frame X_1, \dots, X_n . The names “connection forms” and “curvature forms” are explained by the very next theorem. Let us set

$$\begin{aligned}
 \nabla_{X_i} X_j &= \sum_{k=1}^n \Gamma_{ij}^k X_k \\
 R(X_i, X_j) X_k &= \sum_{l=1}^n \mathbf{R}_{kij}^l X_l,
 \end{aligned}$$

where ∇ is the Levi-Civita connection for $\langle \cdot, \cdot \rangle$, and R is its curvature tensor. We use bold letters $\mathbf{\Gamma}$ and \mathbf{R} to remind ourselves that these are not components with respect to a coordinate system; thus, for example, we do *not* necessarily have $\mathbf{\Gamma}_{ij}^k = \mathbf{\Gamma}_{ji}^k$ (but we clearly do have $\mathbf{R}_{kij}^l = \mathbf{R}_{kji}^l$).

5. THEOREM. Let X_1, \dots, X_n be an *orthonormal* moving frame on a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$, and let $\theta^i, \omega_j^i, \Omega_j^i$ be the dual forms, connection forms, and curvature forms for this moving frame. Then we have the **structural equations of $(M, \langle \cdot, \cdot \rangle)$** :

$$\begin{aligned} d\theta^i &= - \sum_k \omega_k^i \wedge \theta^k & d\theta &= -\omega \wedge \theta \\ d\omega_j^i &= - \sum_k \omega_k^i \wedge \omega_j^k + \Omega_j^i & d\omega &= -\omega \wedge \omega + \Omega, \end{aligned}$$

where

$$\omega_j^i = \sum_k \Gamma_{kj}^i \theta^k, \quad \Omega_j^i = \frac{1}{2} \sum_{k,l} \mathbf{R}_{jkl}^i \theta^k \wedge \theta^l = \sum_{k < l} \mathbf{R}_{jkl}^i \theta^k \wedge \theta^l.$$

PROOF. By the uniqueness part of Proposition 4, we can prove the first structural equation by showing that if we define $\omega_j^i = \sum_k \Gamma_{kj}^i \theta^k$, then the ω_j^i do satisfy conditions (a) and (b) of that proposition. Now by Corollary 6-7 we have

$$\begin{aligned} 0 &= X_k \langle X_i, X_j \rangle = \langle \nabla_{X_k} X_i, X_j \rangle + \langle X_i, \nabla_{X_k} X_j \rangle \\ &= \Gamma_{ki}^j + \Gamma_{kj}^i; \end{aligned}$$

this immediately implies that $\omega_j^i = -\omega_i^j$, which is condition (a).

As in the proof of Proposition 4, we have

$$\sum_l \theta^l \wedge \omega_l^i(X_j, X_k) = \omega_j^i(X_k) - \omega_k^i(X_j),$$

while we also have

$$\begin{aligned} d\theta^i(X_j, X_k) &= X_j(\theta^i(X_k)) - X_k(\theta^i(X_j)) - \theta^i([X_j, X_k]) \\ &\quad \text{by Theorem I.7-13} \\ &= 0 - 0 - \theta^i(\nabla_{X_j} X_k - \nabla_{X_k} X_j) \\ &= \Gamma_{jk}^i - \Gamma_{kj}^i \\ &= \omega_j^i(X_k) - \omega_k^i(X_j); \end{aligned}$$

this proves condition (b).

For the second structural equation we expand

$$\sum_i \mathbf{R}_{jkl}^i X_i = R(X_k, X_l)X_j = \nabla_{X_k} \nabla_{X_l} X_j - \nabla_{X_l} \nabla_{X_k} X_j - \nabla_{[X_k, X_l]} X_j$$

to obtain

$$\mathbf{R}^i_{jkl} = \sum_{\mu} (\Gamma^i_{k\mu} \Gamma^{\mu}_{lj} - \Gamma^i_{l\mu} \Gamma^{\mu}_{kj}) + X_k(\Gamma^i_{lj}) - X_l(\Gamma^i_{kj}) - \theta^i(\nabla_{[X_k, X_l]} X_j).$$

Comparing with

$$\begin{aligned} \left[d\omega_j^i + \sum_{\mu} \omega_{\mu}^i \wedge \omega_j^{\mu} \right] (X_k, X_l) &= X_k(\omega_j^i(X_l)) - X_l(\omega_j^i(X_k)) - \omega_j^i([X_k, X_l]) \\ &\quad + \sum_{\mu} [\omega_{\mu}^i(X_k) \omega_j^{\mu}(X_l) - \omega_{\mu}^i(X_l) \omega_j^{\mu}(X_k)], \end{aligned}$$

we see that this does indeed equal $\mathbf{R}^i_{jkl} = \Omega_j^i(X_k, X_l)$. ♦

Notice that the results of Theorem 5 can also be written

$$\begin{aligned} \nabla_{X_k} X_j &= \sum_i \omega_j^i(X_k) X_i \\ R(X_k, X_l) X_j &= \sum_i \Omega_j^i(X_k, X_l) X_i. \end{aligned}$$

If we did not already have the ∇ operator and its curvature tensor, then we could, and É. Cartan did, use these equations to *define* R . Since the θ^i , hence the ω_j^i , and finally the Ω_j^i , all depend on the moving frame, it is then necessary to check that the resulting definition of R depends only on the values of X_j, X_k, X_l at a given point. We save until the end of the chapter some remarks about what is involved in that. At the moment, we would like to point out that we are already in a position to prove the test case, and thus begin to justify the epithet “structural equations”.

6. THEOREM (THE TEST CASE; FOURTH VERSION). Let $(M, \langle \cdot, \cdot \rangle)$ be an n -dimensional Riemannian manifold for which the curvature tensor R is 0. Then M is locally isometric to \mathbb{R}^n with its usual Riemannian metric.

PROOF. Let Y_1, \dots, Y_n be an orthonormal moving frame around $p \in M$, and let θ^i and ω_j^i be its dual forms and connection forms. By assumption, we have

$$d\omega_j^i = - \sum_k \omega_k^i \wedge \omega_j^k.$$

Step 1. By Proposition 2, in a neighborhood of p there is a matrix $A = (A_j^i)$ of functions with $A(p)$ orthogonal and

$$(*) \quad dA = -\omega \wedge A.$$

Let $B = A^{-1}$ and define 1-forms $\phi^i = \sum_j B_j^i \theta^j$, which we can also write as

$$\theta = A \wedge \phi.$$

Step 2. We have

$$\begin{aligned} A \wedge d\phi &= d\theta - (dA \wedge \phi) \\ &= -\omega \wedge \theta + (\omega \wedge A \wedge \phi) && \text{by } (*) \text{ and the first structural equation} \\ &= -\omega \wedge A \wedge \phi + (\omega \wedge A \wedge \phi) && \text{by definition of } \theta \\ &= 0. \end{aligned}$$

So $d\phi = 0$, and consequently there are functions x^i with $\phi^i = dx^i$.

Step 3. We claim that x^1, \dots, x^n is the desired coordinate system, i.e., that the natural frame $\partial/\partial x^1, \dots, \partial/\partial x^n$ is orthonormal. To prove this, we first note that the 1-forms ϕ^i satisfy $\phi^i(Y_j) = B_j^i$, so

$$\frac{\partial}{\partial x^j} = \sum_i A_j^i Y_i.$$

Since the Y_j are orthonormal, it suffices to prove that (A_j^i) is always an orthogonal matrix. This is a consequence of $(*)$ and the fact that $\omega = (\omega_j^i)$ is skew-symmetric. The argument for this conclusion has already been given on page 36: if t denotes the transpose, we note that $A \cdot A^t$ satisfies the differential equation

$$\begin{aligned} d(A \cdot A^t) &= -(\omega \wedge A \cdot A^t) - (A \cdot (\omega \wedge A)^t) && \text{by } (*) \\ &= -(\omega \wedge A \cdot A^t) - (A \cdot A^t \wedge \omega^t) \\ &= -\omega \wedge (A \cdot A^t) + (A \cdot A^t) \wedge \omega, \end{aligned}$$

with the initial condition $A \cdot A^t(0) = I$. By uniqueness, the solution is $A \cdot A^t = I$ everywhere. ♦

We leave it to the reader to correlate the three *Steps* in this proof with those in previous sections. Note that the first structural equation involves the symmetry of the connection, as shown by the proof of Theorem 5, and that skew-symmetry of ω is equivalent to the definition of the Christoffel symbols, since it is the condition which determines the ω_j^i in Proposition 4.

In contrast to previous chapters, in this one we are going to give more than one proof of the Test Case. Although the proof just given is a natural use of the structural equations as integrability conditions, it does not illustrate the fundamental principle to be used in the method of the repère mobile, which is *to choose the moving frame most suitable to the particular problem*. When we return to the study of surfaces in 3-space, or submanifolds of Riemannian manifolds in general, we will see many instances of this principle. In our present setup there is one especially important moving frame, the investigation of which will take some time.

Let X_{1p}, \dots, X_{np} be an orthonormal frame at M_p . In a sufficiently small neighborhood of p we can define a moving frame X_1, \dots, X_n by choosing $X_i(q)$ to be the parallel translate of X_{ip} along the unique geodesic from p to q . The

moving frame X_1, \dots, X_n is said to be **adapted** to the frame X_{1p}, \dots, X_{np} . In order to explore the properties of this moving frame, it is convenient to introduce the map

$$\Phi: \mathbb{R} \times M_p \rightarrow M$$

defined by

$$\Phi(t, X_p) = \exp(tX_p)$$

(actually, of course, Φ is usually not defined on all of $\mathbb{R} \times M_p$, but we will continue to write $\Phi: \mathbb{R} \times M_p \rightarrow M$ for convenience). On M_p we introduce the coordinate system t^1, \dots, t^n by $t^i(\sum_j a^j X_{jp}) = a^i$, and we use t for the standard coordinate system on \mathbb{R} ; we then let (t, t^1, \dots, t^n) denote the obvious

coordinate system on $\mathbb{R} \times M_p$. We now begin to describe the dual forms θ^i and the connection forms ω_j^i in terms of their pull-backs to $\mathbb{R} \times M_p$.

7. PROPOSITION. When we write $\Phi^*\theta^i$ and $\Phi^*\omega_j^i$ in terms of dt^1, \dots, dt^n and dt , we have

$$\begin{aligned}\Phi^*\theta^i &= t^i dt + \bar{\theta}^i \\ \Phi^*\omega_j^i &= \bar{\omega}_j^i,\end{aligned}$$

where $\bar{\theta}^i$ and $\bar{\omega}_j^i$ are 1-forms which do *not* involve dt .

PROOF. We can always write

$$\begin{aligned}\Phi^*\theta^i &= f_i dt + \bar{\theta}^i \\ \Phi^*\omega_j^i &= g_{ij} dt + \bar{\omega}_j^i;\end{aligned}$$

it is only necessary to identify the f_i and g_{ij} . To do this, we fix a^1, \dots, a^n and consider the geodesic

$$\gamma(s) = \exp\left(s \sum_i a^i X_{ip}\right), \quad s \in (-\varepsilon, \varepsilon).$$

This can be written as $\gamma = \Phi \circ c$, where $c: (-\varepsilon, \varepsilon) \rightarrow \mathbb{R} \times M_p$ is $c(s) = (s, \sum_i a^i X_{ip})$. So

$$\begin{aligned}\gamma^*\theta^i(s) &= c^*\Phi^*\theta^i(s) = f_i(s, a^1, \dots, a^n) dt \\ \gamma^*\omega_j^i(s) &= c^*\Phi^*\omega_j^i(s) = g_{ij}(s, a^1, \dots, a^n) dt.\end{aligned}$$

On the other hand,

$$\gamma^*\theta^i \left(\frac{d}{dt} \Big|_s \right) = \theta^i \left(\frac{d\gamma}{dt} \Big|_s \right) = \theta^i \left(\sum_k a^k X_k(\gamma(s)) \right) = a^i,$$

which shows that $f_i = t^i$. Also

$$\gamma^*\omega_j^i \left(\frac{d}{dt} \Big|_s \right) = \omega_j^i \left(\sum_k a^k X_k(\gamma(s)) \right) = \sum_k \Gamma_{kj}^i a^k;$$

this sum vanishes, because X_j is parallel along γ , which means that

$$0 = \nabla_{\sum_k a^k X_k} X_j = \sum_k a^k \nabla_{X_k} X_j = \sum_k a^k \sum_i \Gamma_{kj}^i X_i. \quad \spadesuit$$

In our next result we will look at “partial derivatives” of the $\bar{\theta}^i$ and $\bar{\omega}_j^i$. If we are given an expression

$$\bar{\theta}^i = \sum_{j=1}^n g_j dt^j,$$

then we will use the symbol

$$\frac{\partial \bar{\theta}^i}{\partial t} \quad \text{for} \quad \sum_{j=1}^n \frac{\partial g_j}{\partial t} dt^j$$

and we will use similar symbols for the $\bar{\omega}_j^i$ [this definition depends on the particular coordinate system (t, t^1, \dots, t^n)]. Note that in

$$d\bar{\theta}^i = \sum_{j=1}^n \left(\frac{\partial g_j}{\partial t} dt + \sum_k \frac{\partial g_j}{\partial t^k} dt^k \right) \wedge dt^j,$$

the terms involving dt are precisely

$$dt \wedge \frac{\partial \bar{\theta}^i}{\partial t}.$$

8. PROPOSITION. We have the following “structural equations in polar coordinates”:

$$\begin{aligned} \frac{\partial \bar{\theta}^i}{\partial t} &= dt^i + \sum_k t^k \bar{\omega}_k^i & \bar{\theta}^i(0, X) &= 0 \quad \text{for all } X \in M_p \\ \frac{\partial \bar{\omega}_j^i}{\partial t} &= \sum_{k,l} (\mathbf{R}^i_{jkl} \circ \Phi) t^i \bar{\theta}^l & \bar{\omega}_j^i(0, X) &= 0 \quad \text{for all } X \in M_p \end{aligned}$$

PROOF. By Proposition 7 we have

$$\begin{aligned} (1) \quad \Phi^*(d\theta^i) &= d(\Phi^*\theta^i) = dt^i \wedge dt + dt \wedge \frac{\partial \bar{\theta}^i}{\partial t} + \text{terms not involving } dt \\ (2) \quad \Phi^*(d\omega_j^i) &= d(\Phi^*\omega_j^i) = dt \wedge \frac{\partial \bar{\omega}_j^i}{\partial t} + \text{terms not involving } dt. \end{aligned}$$

On the other hand, by the structural equations (Theorem 5) and Proposition 7 again, we have

$$(3) \quad \begin{aligned} \Phi^*(d\theta^i) &= - \sum_k \Phi^* \omega_k^i \wedge \Phi^* \theta^k \\ &= - \sum_k \bar{\omega}_k^i \wedge (t^k dt + \bar{\theta}^k) \end{aligned}$$

$$(4) \quad \begin{aligned} \Phi^*(d\omega_j^i) &= - \sum_k \Phi^* \omega_k^i \wedge \Phi^* \omega_j^k + \frac{1}{2} \Phi^* \left(\sum_{k,l} \mathbf{R}^i_{jkl} \theta^k \wedge \theta^l \right) \\ &= - \sum_k \bar{\omega}_k^i \wedge \bar{\omega}_j^k + \frac{1}{2} \sum_{k,l} (\mathbf{R}^i_{jkl} \circ \Phi) (t^k dt + \bar{\theta}^k) \wedge (t^l dt + \bar{\theta}^l). \end{aligned}$$

Comparing the coefficients of dt in (1) and (3) we obtain

$$dt^i - \frac{\partial \bar{\theta}^i}{\partial t} = - \sum_k t^k \bar{\omega}_k^i,$$

which gives us the first equation in the theorem. Similarly, from (2) and (4) we obtain

$$dt \wedge \frac{\partial \bar{\omega}_j^i}{\partial t} = \frac{1}{2} \sum_{k,l} (\mathbf{R}^i_{jkl} \circ \Phi) [dt \wedge (t^k \bar{\theta}^l - t^l \bar{\theta}^k)];$$

together with the relation $\mathbf{R}^i_{jkl} = -\mathbf{R}^i_{jlk}$, this gives the second equation.

Since $\Phi(0, X) = p$ for all $X \in M_p$, we have $\Phi_{*(0,X)} = 0$, which gives the “initial conditions”

$$\bar{\theta}^i(0, X) = 0, \quad \bar{\omega}_j^i(0, X) = 0. \quad \blacklozenge$$

9. COROLLARY. The forms $\bar{\theta}^i$ satisfy the second order differential equation

$$\frac{\partial^2 \bar{\theta}^i}{\partial t^2} = \sum_{j,k,l} (\mathbf{R}^i_{jkl} \circ \Phi) t^j t^k \bar{\theta}^l$$

with the initial conditions

$$\begin{aligned} \bar{\theta}^i(0, X) &= 0 \\ \frac{\partial \bar{\theta}^i}{\partial t}(0, X) &= dt^i. \end{aligned}$$

PROOF. Differentiate the first equation in Proposition 8 and substitute in from the second. \blacklozenge

It should not be hard to see that for all $X \in M_p$ we have

$$(*) \quad \Phi_* \left(\frac{\partial}{\partial t^j} \Big|_{(1, X)} \right) = \exp_* \left(\frac{\partial}{\partial t^j} \Big|_X \right);$$

in this equation $\partial/\partial t^j$ denotes a tangent vector in $\mathbb{R} \times M_p$ as well as one in M_p , since we are using the same symbol t^j for a coordinate function on $\mathbb{R} \times M_p$ as on M_p . We have also written Φ_* instead of $\Phi_*(1, X)$, etc. Equation (*) shows that θ is determined by \exp_* and $\bar{\theta}^i(1, X)$. This makes Corollary 9 particularly significant, since it determines $\bar{\theta}^i(1, X)$ in terms of the functions $\mathbf{R}^i_{jkl} \circ \Phi$. As a first illustration of this point, we bore ourselves to tears by twice again proving

10. THEOREM (THE TEST CASE; FIFTH VERSION). Let $(M, \langle \cdot, \cdot \rangle)$ be an n -dimensional Riemannian manifold for which the curvature tensor R is 0. Then M is locally isometric to \mathbb{R}^n with its usual Riemannian metric.

PROOF. *Step 1.* Let X_1, \dots, X_n be the moving frame adapted to an orthonormal frame X_{1p}, \dots, X_{np} for M_p . From Proposition 8 we have

$$\frac{\partial \bar{\omega}_j^i}{\partial t} = 0, \quad \bar{\omega}_j^i(0, X) = 0,$$

which shows that $\bar{\omega}_j^i = 0$. This implies that $\omega_j^i = 0$, since (*) shows that Φ_* is a diffeomorphism at $(1, X)$ and

$$\bar{\omega}_j^i = \Phi^* \omega_j^i = \omega_j^i \circ \Phi_*.$$

Step 2. Since $\omega_j^i = 0$, the first structural equation shows that $d\theta^i = 0$. So

$$\begin{aligned} 0 &= d\theta^i(X_j, X_k) = X_j(\theta^i(X_k)) - X_k(\theta^i(X_j)) - \theta^i([X_j, X_k]) \\ &= -\theta^i([X_j, X_k]). \end{aligned}$$

Thus $[X_j, X_k] = 0$ for all j, k , so there is a coordinate system x^1, \dots, x^n with $X_i = \partial/\partial x^i$.

Step 3. This is the desired coordinate system, since the X_i are obtained from the X_{ip} by parallel translation, and are consequently everywhere orthonormal. ♦

In this proof it is still possible to separate the argument into the standard three steps. But in the next proof everything happens at once.

11. THEOREM (THE TEST CASE; SIXTH VERSION). Let $(M, \langle \cdot, \cdot \rangle)$ be an n -dimensional Riemannian manifold for which the curvature tensor R is 0. Then M is locally isometric to \mathbb{R}^n with its usual Riemannian metric.

PROOF. Let X_1, \dots, X_n be the moving frame adapted to an orthonormal frame X_{1p}, \dots, X_{np} for M_p . From Corollary 9 we have

$$\frac{\partial^2 \bar{\theta}^i}{\partial t^2} = 0, \quad \bar{\theta}^i(0, X) = 0, \quad \frac{\partial \bar{\theta}^i}{\partial t}(0, X) = dt^i,$$

which implies that

$$\bar{\theta}^i(t, X) = t dt^i, \quad \text{in particular } \bar{\theta}^i(1, X) = dt^i.$$

So

$$\begin{aligned} \delta_j^i &= \bar{\theta}^i(1, X) \left(\frac{\partial}{\partial t^j} \Big|_{(1, X)} \right) = \Phi^* \theta^i \left(\frac{\partial}{\partial t^j} \Big|_{(1, X)} \right) \quad [\text{for convenience we do not write } \Phi^* \theta^i(1, X)] \\ &= \theta^i \left(\exp_* \left(\frac{\partial}{\partial t^j} \Big|_X \right) \right) \quad \text{by (*).} \end{aligned}$$

This shows that the value of the vector field X_j at $\exp X$ is

$$X_j(\exp X) = \exp_* \left(\frac{\partial}{\partial t^j} \Big|_X \right).$$

Now the vector fields $\partial/\partial t^j$ on M_p are orthonormal with respect to the usual Riemannian metric $\langle \cdot, \cdot \rangle$ on M_p , so this equation shows that $\exp: (M_p, \langle \cdot, \cdot \rangle) \rightarrow (M, \langle \cdot, \cdot \rangle)$ is an isometry. ♦

Readers may sort out for themselves the vestigial forms in which the three *Steps* appear in this last proof. One thing does seem worth pointing out explicitly. In the two closely related proofs of Theorems 10 and 11 we use the device of expressing the integrability conditions $R = 0$ in terms of the map Φ . This is roughly equivalent to the method outlined in Problem I.6-8, where we solve a system of partial differential equations in \mathbb{R}^n by reducing them to ordinary equations along lines through the origin.

The proof of Theorem 11, similar to the previous proof as it may be, is particularly important to us, for the methods used may be generalized to arbitrary Riemannian manifolds $(M, \langle \cdot, \cdot \rangle)$. To do this we introduce 1-forms $\bar{\theta}^i$ on M_p

by $\bar{\bar{\theta}}^i(X) = \bar{\theta}^i(1, X)$. More precisely, if $X \in M_p$ and $v_X \in (M_p)_X$, then we have a tangent vector

$$(0, v_X) \in (\mathbb{R} \times M_p)_{(1, X)}$$

(recall that the tangent space of the product of two manifolds is isomorphic to the direct sum of the tangent spaces of the manifolds), so we may define

$$\bar{\bar{\theta}}^i(v_X) \quad [= \bar{\bar{\theta}}^i(X)(v_X)] \quad = \bar{\theta}^i(1, X)((0, v_X)).$$

In particular, we have (leaving out the arguments for $\bar{\theta}^i$ and $\bar{\bar{\theta}}^i$)

$$(**) \quad \bar{\bar{\theta}}^i \left(\frac{\partial}{\partial t^j} \Big|_X \right) = \bar{\theta}^i \left(\frac{\partial}{\partial t^j} \Big|_{(1, X)} \right).$$

Now define a tensor $\langle \ , \ \rangle$ of type $\binom{2}{0}$ on M_p by

$$\langle \ , \ \rangle = \sum_{i=1}^n \bar{\bar{\theta}}^i \otimes \bar{\theta}^i.$$

12. THEOREM. The map $\exp: (M_p, \langle \ , \ \rangle) \rightarrow (M, \langle \ , \ \rangle)$ is an isometry (in a neighborhood of $0 \in M_p$ on which \exp is a diffeomorphism).

PROOF. Since

$$\left\langle \sum_{j=1}^n a^j X_j, \sum_{j=1}^n b^j X_j \right\rangle = \sum_{i=1}^n a^i b^i = \sum_{i=1}^n \theta^i \left(\sum_{j=1}^n a^j X_j \right) \cdot \theta^i \left(\sum_{j=1}^n b^j X_j \right),$$

we have $\langle \ , \ \rangle = \sum_i \theta^i \otimes \theta^i$. On the other hand, we also have

$$\begin{aligned} \left\langle \frac{\partial}{\partial t^j} \Big|_X, \frac{\partial}{\partial t^k} \Big|_X \right\rangle &= \sum_{i=1}^n \bar{\bar{\theta}}^i \left(\frac{\partial}{\partial t^j} \Big|_X \right) \bar{\theta}^i \left(\frac{\partial}{\partial t^k} \Big|_X \right) \\ &= \sum_{i=1}^n \bar{\theta}^i \left(\frac{\partial}{\partial t^j} \Big|_{(1, X)} \right) \bar{\theta}^i \left(\frac{\partial}{\partial t^k} \Big|_{(1, X)} \right) \quad \text{by } (**) \\ &= \sum_{i=1}^n \theta^i \left(\exp_* \left(\frac{\partial}{\partial t^j} \Big|_X \right) \right) \cdot \theta^i \left(\exp_* \left(\frac{\partial}{\partial t^k} \Big|_X \right) \right), \end{aligned}$$

which means that

$$\langle \ , \ \rangle = \exp^* \left(\sum_i \theta^i \otimes \theta^i \right) = \exp^* \langle \ , \ \rangle. \quad \blacklozenge$$

Recall (page 194) that for a 2-dimensional subspace $W \subset M_q$ of the tangent space of a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$ we define the sectional curvature $K(W)$ as

$$K(W) = \frac{\langle R(A, B)B, A \rangle}{\|A, B\|^2}, \quad A, B \text{ a basis for } W.$$

Let $p \in M$ be some fixed point. For every $X \in M_p$ and 2-dimensional subspace $V \subset M_p$, we will let $L(X, V)$ be the sectional curvature $K(W)$, where $W \subset M_{\exp X}$ is the parallel translate of V along the geodesic $t \mapsto \exp tX$.

13. COROLLARY (THE CURVATURE DETERMINES THE METRIC).

Let M and M' be two Riemannian manifolds, and $T: M_p \rightarrow M'_{p'}$, an isometry for some $p \in M$ and $p' \in M'$. Suppose that $L(X, V) = L'(T(X), T(V))$ for all 2-dimensional subspaces $V \subset M_p$ and all sufficiently small X . Then there is an isometry from some neighborhood of $p \in M$ to a neighborhood of $p' \in M'$.

PROOF. Choose an orthonormal frame $X_{1p}, \dots, X_{np} \in M_p$, let X_1, \dots, X_n be the adapted moving frame in M , and let X'_1, \dots, X'_n be the moving frame in M' adapted to $T(X_{1p}), \dots, T(X_{np})$. Let $\Phi: \mathbb{R} \times M_p \rightarrow M$ and $\Phi': \mathbb{R} \times M'_{p'} \rightarrow M'$ be as defined previously, let $\bar{\theta}^i$ and $\bar{\theta}'^i$ be the corresponding forms on $\mathbb{R} \times M_p$ and $\mathbb{R} \times M'_{p'}$, and let $S: \mathbb{R} \times M_p \rightarrow \mathbb{R} \times M'_{p'}$ be $S(a, X) = (a, T(X))$. From the definition of \mathbf{R}^i_{jkl} before Theorem 5 we see that

$$\mathbf{R}^i_{jkl} = \langle R(X_k, X_l)X_j, X_i \rangle.$$

The hypotheses of the theorem therefore imply that

$$\mathbf{R}^i_{jij} \circ \Phi = \mathbf{R}'^i_{jij} \circ (\Phi' \circ S) \quad \text{for all } i, j.$$

From Proposition 4-12 we deduce that

$$\mathbf{R}^i_{jkl} \circ \Phi = \mathbf{R}'^i_{jkl} \circ (\Phi' \circ S) \quad \text{for all } i, j, k, l.$$

Now Corollary 9 (and the uniqueness of solutions of differential equations with given initial conditions) implies that

$$\bar{\theta}^i = \bar{\theta}'^i \circ S,$$

and therefore that

$$\bar{\bar{\theta}}^i = \bar{\bar{\theta}}'^i \circ T.$$

This means that T is an isometry of $(M_p, \langle \cdot, \cdot \rangle)$ and $(M'_{p'}, \langle \cdot, \cdot \rangle')$. The result then follows from Theorem 12. ♦

This corollary is the main assertion made by Riemann in his Habilitation lecture. We have proved a purely local result, but global results have also been obtained; see Ambrose, *Parallel translation of Riemannian curvature*, Annals of Math. **64** (1956), 337–363.

The result of Corollary 13 is perhaps not what the reader may have understood by the assertion that “the curvature determines the metric”, for it involves the parallel translation in the manifold, and not merely the curvature. Notice, however, that any rigorous statement about curvature determining the metric must involve a map $f: M \rightarrow M'$, so that we know what it means to compare curvature in M with curvature in M' ; in our case the map f is $\exp_{p'} \circ (\exp_p)^{-1}$. In this connection the following rather different question has always seemed to me the more interesting one. Suppose we have a diffeomorphism $f: M \rightarrow M'$ such that for every 2-dimensional $V \in M_q$ we have $K(V) = K'(f_*(V))$; then is f an isometry? It is easy to see that as stated this is *not* true, because *any* diffeomorphism $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ satisfies the hypothesis (when \mathbb{R}^n has its usual Riemannian metric), but not necessarily the conclusion. It is also easy to obtain other examples. Consider the sphere $S^n \subset \mathbb{R}^{n+1}$ of radius a , with the induced Riemannian metric. For $n = 2$, we know that $K(S^2_p) = K(p) = 1/a^2$. If $n > 2$ and \mathcal{O} is a neighborhood of 0 in a 2-dimensional subspace $V \subset M_p$, then $\exp(\mathcal{O})$ is isometric to a portion of S^2 , so we have $K(V) = 1/a^2$ for all such V . Consequently, once again any diffeomorphism $f: S^n \rightarrow S^n$ satisfies the hypothesis of our question, but not necessarily the conclusion. As we shall see in Addendum 2, there are also examples where all $K(V)$ are the same negative number.

In addition to these rather special counterexamples, it is simple to construct infinitely many other 2-dimensional examples. If we have a 2-dimensional manifold M such that the sets $K = \text{constant}$ give a foliation of M , then we can choose

$f: M \rightarrow M$ to be *any* diffeomorphism which keeps each folium fixed as a set. There are also specific classical examples of 2-manifolds M, M' which are not isometric under any map, but for which there is a diffeomorphism $f: M \rightarrow M'$

with $K'(f(p)) = K(p)$ [see pg. III.166]. Perhaps these examples are responsible for the fact that the higher dimensional cases remained unsettled for so long. Though it might be natural to assume that this case is even more hopeless, just the opposite is true: when $n > 2$, a diffeomorphism which preserves sectional curvatures is, *roughly speaking*, an isometry, except for the special counterexamples mentioned in the previous paragraph. For details the reader is referred to R. S. Kulkarni, *Curvature and Metric*, Annals of Math. **91** (1970), 311–331.

Before we proceed further with the study of moving frames, we pause to note that in the 2-dimensional case, Corollary 9 (and Corollary 13 which depends on it) have really been available to us since Chapter 3. Recall that we chose polar coordinates (ρ, ϕ) on M_p , and used them to introduce polar coordinates $(r, \varphi) = (\rho, \phi) \circ \exp^{-1}$ on a neighborhood of p [see page 136]. If we write

$$\langle \cdot, \cdot \rangle = dr \otimes dr + G d\phi \otimes d\phi,$$

and define g on \mathbb{R}^2 by

$$g = G \circ \exp \circ (\rho, \phi)^{-1},$$

then we have the following formulas (collected together on page 145):

$$\begin{aligned} \sqrt{g}(0, \phi) &= 0 \\ \frac{\partial \sqrt{g}}{\partial \rho}(0, \phi) &= 1 \\ \frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) &= -\sqrt{g}(\rho, \phi) \cdot K(\exp(\rho, \phi)). \end{aligned}$$

These equations are easily seen to be equivalent to the equations in Corollary 9, and can be used the same way. For example, if $K = 0$ in a neighborhood of p , then

$$\frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) = 0;$$

together with the initial conditions, this shows that $\sqrt{g} = \rho$, so

$$\langle \cdot, \cdot \rangle = dr \otimes dr + r^2 d\phi \otimes d\phi,$$

which is exactly the expression in polar coordinates for the usual Riemannian metric on \mathbb{R}^2 . Even the n -dimensional Test Case could be proved in this way, by considering $\exp(V)$ for various 2-dimensional $V \subset M_p$. However, the equations of Corollary 9 are generally most useful in higher dimensions. As an exercise in using them, Addendum 1 derives the form of the metric in an n -dimensional manifold of constant curvature.

Everything which we have done so far in this chapter has involved the Levi-Civita connection associated to a metric $\langle \cdot, \cdot \rangle$; moreover, we immediately interpreted the connection and curvature forms in terms of concepts defined in previous chapters. But the method of the repère mobile is meant to treat arbitrary connections, and was used to define the curvature tensor before the ∇ operator had been invented. For the remainder of this chapter we will be concerned with this independent development of the theory of connections. We want to describe any connection in terms of “connection forms” ω_j^i , but we do not necessarily want the matrix $\omega = (\omega_j^i)$ to be skew-symmetric, so we do not have Proposition 4 to guide us. We do want to have the equations

$$\nabla_{X_k} X_j = \sum_i \omega_j^i(X_k) X_i,$$

which are a consequence of Theorem 5; these equations can also be written

$$\nabla X_j = \sum_i \omega_j^i \cdot X_i.$$

For convenience, we let $\mathbf{X} = (X_1, \dots, X_n)$ and abbreviate this equation as

$$\nabla \mathbf{X} = \mathbf{X} \cdot \omega \quad (\text{recall the notation introduced on page 261ff}).$$

Now consider another moving frame $\mathbf{X}' = \mathbf{X} \cdot a$. We want to have

$$\begin{aligned} \sum_i \omega_j'^i X'_i &= \nabla X'_j = \nabla \left(\sum_l a_j^l X_l \right) \\ &= \sum_l da_j^l X_l + \sum_l a_j^l \nabla X_l \quad \begin{array}{l} [\text{recall the formula for } \nabla_X fY \\ \text{and note that } X(f) = df(X)]. \end{array} \end{aligned}$$

Using our matrix notation, this means that we want

$$\begin{aligned} \mathbf{X}' \cdot \omega' &= \nabla \mathbf{X}' = \nabla(\mathbf{X} \cdot a) \\ &= \mathbf{X} \cdot da + \nabla \mathbf{X} \cdot a \\ &= \mathbf{X} \cdot da + \mathbf{X} \cdot (\omega \cdot a), \end{aligned}$$

so we want

$$\mathbf{X} \cdot (a\omega') = (\mathbf{X} \cdot a)\omega' = \mathbf{X}' \cdot \omega' = \mathbf{X} \cdot (da + \omega a)$$

for all moving frames \mathbf{X} . Thus we want the condition

$$(*) \quad \omega' = a^{-1} da + a^{-1} \omega a.$$

Hence we are led to the following definition:*

A **(Cartan) connection** on a manifold M is an assignment of a matrix $\omega = (\omega_j^i)$ of 1-forms to every moving frame \mathbf{X} such that equation (*) holds between the 1-forms ω_j^i assigned to the moving frame \mathbf{X} and the 1-forms $\omega_j'^i$ assigned to the moving frame $\mathbf{X}' = \mathbf{X} \cdot a$.

Given a Cartan connection, and a moving frame $\mathbf{X} = X_1, \dots, X_n$, the 1-forms ω_j^i which are assigned to \mathbf{X} are called the **connection forms** for \mathbf{X} , and we define the **dual forms** θ^i by $\theta^i(X_j) = \delta_j^i$. From these forms we can define all the tensors which arise in Chapters 5 and 6. What follows is an outline of such a development of the theory of Cartan connections, independently of previous considerations.

We begin with a simple observation about the consistency of the transformation laws (*). Suppose $\mathbf{X}'' = \mathbf{X}' \cdot b = (\mathbf{X} \cdot a) \cdot b = \mathbf{X} \cdot (ab)$ is another moving frame, and that ω', ω'' satisfy

$$\begin{aligned}\omega' &= a^{-1} da + a^{-1} \omega a \\ \omega'' &= b^{-1} db + b^{-1} \omega' b.\end{aligned}$$

Then

$$\begin{aligned}\omega'' &= b^{-1} db + b^{-1} (a^{-1} da + a^{-1} \omega a) b \\ &= [b^{-1} a^{-1} (da) b + b^{-1} a^{-1} a (db)] + b^{-1} a^{-1} \omega ab \\ &= (ab)^{-1} d(ab) + (ab)^{-1} \omega ab.\end{aligned}$$

This shows that if we are given connection forms for a certain set of moving frames whose domains cover M , and the various pairs of connection forms all satisfy (*), then there is a unique Cartan connection that assigns these forms to these particular moving frames. In view of this remark, it is very easy to determine a connection from a Riemannian metric.

14. PROPOSITION. On a Riemannian manifold $(M, \langle \ , \ \rangle)$ there is a unique Cartan connection with the property that the connection forms ω_j^i for any

*We are using the term "Cartan connection" as a convenient label, but the reader should be warned that in the literature this term is used for a different concept.

orthonormal moving frame X satisfy

$$\begin{aligned}\omega_j^i &= -\omega_i^j \\ d\theta^i &= \sum_k \theta^k \wedge \omega_k^i.\end{aligned}$$

PROOF. We already know, by Proposition 4, that for any moving frame there are unique 1-forms ω_j^i with this property. We just have to check that if \mathbf{X} and $\mathbf{X}' = \mathbf{X} \cdot a$ are orthonormal moving frames, then

$$\omega' = a^{-1} da + a^{-1} \omega a.$$

In view of uniqueness, we just have to show that if the forms ω_j^i satisfy the conditions of the theorem, and the forms ω'^i_j are defined by this formula, then they satisfy the same conditions,

$$\begin{aligned}\text{(a)} \quad \omega'^i_j &= -\omega'^j_i \\ \text{(b)} \quad d\theta'^i &= -\sum_k \omega'^i_k \wedge \theta'^k.\end{aligned}$$

Since \mathbf{X} and \mathbf{X}' are orthonormal, the matrix a is everywhere orthogonal, $a \cdot a^t = I$, where t denotes the transpose. So if 0 denotes the zero matrix we have

$$0 = da \cdot a^t + a \cdot da^t,$$

or

$$da^t = -a^{-1} \cdot da \cdot a^t = -a^t \cdot da \cdot a^t.$$

Consequently,

$$\begin{aligned}\text{(1)} \quad (a^{-1} da)^t &= (a^t da)^t = da^t \cdot a = -a^t \cdot da \cdot a^t \cdot a = -a^t \cdot da = -a^{-1} da \\ \text{(2)} \quad (a^{-1} \omega a)^t &= (a^t \omega a)^t = a^t \omega^t a = -a^t \omega a = -a^{-1} \omega a.\end{aligned}$$

Clearly (1) and (2) imply (a).

To prove (b), we first note that

$$\theta'^i(X_j) = \theta'^i \left(\sum_k (a^{-1})^k_j X'_k \right) = (a^{-1})^i_j = \sum_k (a^{-1})^i_k \theta^k(X_j),$$

so $\theta'^i = \sum_k (a^{-1})^i_k \theta^k$, or

$$\theta' = a^{-1} \cdot \theta.$$

Consequently,*

$$(3) \quad \begin{aligned} d\theta' &= (-a^{-1} \cdot da \cdot a^{-1}) \wedge \theta + a^{-1} d\theta \\ &= -a^{-1} da \wedge a^{-1} \theta - (a^{-1} \omega \wedge \theta). \end{aligned}$$

On the other hand,

$$(4) \quad \begin{aligned} \omega' \wedge \theta' &= (a^{-1} da + a^{-1} \omega a) \wedge (a^{-1} \theta) \\ &= a^{-1} da \wedge a^{-1} \theta + (a^{-1} \omega \wedge \theta). \end{aligned}$$

Clearly (3) and (4) imply (b). ♦

When we pass from the particular connection of Proposition 14 to a general Cartan connection, both structural equations need correction terms. If ω_j^i are the connection forms for a moving frame \mathbf{X} , with dual forms θ^i , we define 2-forms Θ^i and Ω_j^i by

$$\begin{aligned} d\theta &= -\omega \wedge \theta + \Theta & \text{i.e.,} & \quad d\theta^i = -\sum_k \omega_k^i \wedge \theta^k + \Theta^i \\ d\omega &= -\omega \wedge \omega + \Omega & \text{i.e.,} & \quad d\omega_j^i = -\sum_k \omega_k^i \wedge \omega_j^k + \Omega_j^i. \end{aligned}$$

We call the Θ^i and Ω_j^i the **torsion forms** and **curvature forms** for the moving frame X . We now compute the transformation formulas for these forms.

15. PROPOSITION. If Θ'^i and $\Omega_j'^i$ are the torsion and connection forms for another moving frame $\mathbf{X}' = \mathbf{X} \cdot a$, then

$$\begin{aligned} \Theta' &= a^{-1} \cdot \Theta \\ \Omega' &= a^{-1} \Omega a. \end{aligned}$$

*To compute $d(a^{-1})$ we differentiate $a \cdot a^{-1} = I$ to obtain

$$\begin{aligned} da \cdot a^{-1} + a \cdot d(a^{-1}) &= 0, \\ d(a^{-1}) &= -a^{-1} \cdot da \cdot a^{-1}. \end{aligned}$$

PROOF. We have

$$\begin{aligned}
 (1) \quad & \omega' = a^{-1} da + a^{-1} \omega a \\
 (2) \quad & d\theta = -\omega \wedge \theta + \Theta \\
 (3) \quad & d\theta' = -\omega' \wedge \theta' + \Theta' \\
 (4) \quad & d\omega = -\omega \wedge \omega + \Omega \\
 (5) \quad & d\omega' = -\omega' \wedge \omega' + \Omega'
 \end{aligned}$$

and, as in the proof of Proposition 14,

$$\begin{aligned}
 (6) \quad & \theta' = a^{-1} \theta \\
 (7) \quad & d\theta' = -a^{-1} da \wedge a^{-1} \theta + a^{-1} d\theta.
 \end{aligned}$$

So

$$(8) \quad d\theta' = -a^{-1} da \wedge a^{-1} \theta + a^{-1} (-\omega \wedge \theta + \Theta) \quad \text{by (2), (7).}$$

We also have

$$\begin{aligned}
 (9) \quad d\theta' &= -\omega' \wedge \theta' + \Theta' && \text{by (3)} \\
 &= -(a^{-1} da + a^{-1} \omega a) \wedge a^{-1} \theta + \Theta' && \text{by (1), (6)} \\
 &= -a^{-1} da \wedge a^{-1} \theta - a^{-1} (\omega \wedge \theta) + \Theta'.
 \end{aligned}$$

Comparison of (8) and (9) gives $a^{-1} \Theta = \Theta'$.

From (1) we obtain

$$\begin{aligned}
 (10) \quad d\omega' &= [-a^{-1} da a^{-1} \wedge da] + (-a^{-1} da a^{-1}) \wedge \omega a \\
 &\quad + a^{-1} d\omega a - a^{-1} \omega \wedge da \\
 &= [-a^{-1} da a^{-1} \wedge da] + (-a^{-1} da a^{-1}) \wedge \omega a \\
 &\quad + a^{-1} (-\omega \wedge \omega + \Omega) a - a^{-1} \omega \wedge da \quad \text{by (4).}
 \end{aligned}$$

We also have

$$\begin{aligned}
 (11) \quad d\omega' &= -\omega' \wedge \omega' + \Omega' \quad \text{by (5)} \\
 &= -(a^{-1} da + a^{-1} \omega a) \wedge (a^{-1} da + a^{-1} \omega a) + \Omega' \quad \text{by (1)} \\
 &= -(a^{-1} da \wedge a^{-1} da) - (a^{-1} da a^{-1} \wedge \omega a) - (a^{-1} \omega \wedge da) \\
 &\quad - (a^{-1} \omega \wedge \omega a) + \Omega'.
 \end{aligned}$$

Comparison of (10) and (11) gives $a^{-1} \Omega a = \Omega'$. ♦

The three relations

$$(1) \omega' = a^{-1} da + a^{-1} \omega a$$

$$(2) \Theta' = a^{-1} \Theta$$

$$(3) \Omega' = a^{-1} \Omega a$$

are precisely what enable us to define

$$(1) \nabla Y \text{ for vector fields } Y$$

$$(2) T(X, Y) \text{ for tangent vectors } X, Y$$

$$(3) R(X, Y)Z \text{ for tangent vectors } X, Y, Z.$$

We essentially know this already for the ∇ operator, which we consider first. Given a moving frame $\mathbf{X} = (X_1, \dots, X_n)$ with connection forms ω_j^i , we define

$$\nabla \mathbf{X} = \mathbf{X} \cdot \omega \quad [\text{i.e., } \nabla X_j = \sum_i \omega_j^i X_i \quad \text{or} \quad \nabla_X X_j = \sum_i \omega_j^i(X) X_i]$$

and extend this to arbitrary vector fields $Y = \sum_j b^j X_j$ by defining

$$\nabla \cdot \left(\sum_j b^j X_j \right) = \sum_j db^j \cdot X_j + b^j \nabla X_j.$$

For another moving frame $\mathbf{X}' = \mathbf{X} \cdot a$ with connection forms $\omega_j'^i$ we have

$$\begin{aligned} \nabla \mathbf{X}' &= \mathbf{X}' \cdot \omega' = (\mathbf{X} \cdot a) \cdot \omega' = (\mathbf{X} \cdot a) \cdot [a^{-1} da + a^{-1} \omega a] \\ &= \mathbf{X} \cdot [a \cdot (a^{-1} da + a^{-1} \omega a)] \\ &= \mathbf{X} \cdot da + \mathbf{X} \cdot (\omega \cdot a) = \mathbf{X} \cdot da + (\mathbf{X} \cdot \omega) \cdot a \\ &= \mathbf{X} \cdot da + \nabla \mathbf{X} \cdot a, \end{aligned}$$

which shows that the definition in terms of the two moving frames are consistent [this equation becomes

$$\begin{aligned} \nabla \left(\sum_j a_j^i X_j \right) &= \sum_i da_j^i \cdot X_i + \sum_k \left(\sum_i \omega_i^k a_j^i \right) X_k \\ &= \sum_i da_j^i X_i + \sum_i a_j^i \nabla X_i. \end{aligned}$$

when written out].

We next define

$$T(X_j, X_k) = \sum_i \Theta^i(X_j, X_k) \cdot X_i$$

and extend to arbitrary tangent vectors $X = \sum_j b^j X_j, Y = \sum_k c^k X_k$ by linearity,

$$T(X, Y) = \sum_{j,k} b^j c^k T(X_j, X_k).$$

For the moving frame $\mathbf{X}' = \mathbf{X} \cdot a$ we have

$$\begin{aligned} T(X'_\mu, X'_\nu) &= \sum_\rho \Theta'^\rho(X'_\mu, X'_\nu) X'_\rho \\ &= \sum_\rho \sum_l (a^{-1})^\rho_l \Theta^l \left(\sum_j a^j_\mu X_j, \sum_k a^k_\nu X_k \right) \sum_i a^i_\rho X_i \\ &= \sum_{j,k} a^j_\mu a^k_\nu \sum_i \Theta^i(X_j, X_k) X_i \\ &= \sum_{j,k} a^j_\mu a^k_\nu T(X_j, X_k), \end{aligned}$$

so the definitions in terms of the two moving frames are consistent. The tensor T is clearly alternating, since the Θ^i are 2-forms.

Finally, we define

$$R(X_k, X_l) X_j = \sum_i \Omega^i_j(X_k, X_l) X_i$$

and extend by linearity. For the moving frame $\mathbf{X}' = \mathbf{X} \cdot a$ we have

$$\begin{aligned} R(X'_\mu, X'_\nu) X'_\lambda &= \sum_\rho \Omega'^\rho_\lambda(X'_\mu, X'_\nu) X'_\rho \\ &= \sum_\rho \sum_{j,m} (a^{-1})^\rho_m \Omega^m_j a^j_\lambda \left(\sum_k a^k_\mu X_k, \sum_l a^l_\nu X_l \right) \sum_i a^i_\rho X_i \\ &= \sum_{j,k,l} a^k_\mu a^l_\nu a^j_\lambda \Omega^i_j(X_k, X_l) X_i, \end{aligned}$$

which again shows consistency. Clearly R is skew-symmetric in the first two arguments, since the Ω^i_j are 2-forms.

If we now define

$$\begin{aligned}\nabla_{X_k} X_j &= \sum_{i=1}^n \Gamma_{kj}^i X_i \\ T(X_j, X_k) &= \sum_{i=1}^n \mathbf{T}_{jk}^i X_i \\ R(X_k, X_l) X_j &= \sum_{i=1}^n \mathbf{R}_{jkl}^i X_i,\end{aligned}$$

then we have

$$\begin{aligned}\Gamma_{jk}^i &= \omega_j^i(X_k) \quad \text{or} \quad \omega_j^i = \sum_k \Gamma_{kj}^i \theta^k \\ \mathbf{T}_{jk}^i &= \Theta^i(X_j, X_k) \quad \text{or} \quad \Theta^i = \frac{1}{2} \sum_{j,k} \mathbf{T}_{jk}^i \theta^j \wedge \theta^k \\ \mathbf{R}_{jkl}^i &= \Omega_j^i(X_k, X_l) \quad \text{or} \quad \Omega_j^i = \frac{1}{2} \sum_{k,l} \mathbf{R}_{jkl}^i \theta^k \wedge \theta^l.\end{aligned}$$

Consequently, the “structural equations”

$$\begin{aligned}d\theta^i &= - \sum_k \omega_k^i \wedge \theta^k + \Theta^i = - \sum_k \omega_k^i \wedge \theta^k + \frac{1}{2} \sum_{j,k} \mathbf{T}_{jk}^i \theta^j \wedge \theta^k \\ d\omega_j^i &= - \sum_k \omega_k^i \wedge \omega_j^k + \Omega_j^i = - \sum_k \omega_k^i \wedge \omega_j^k + \frac{1}{2} \sum_{k,l} \mathbf{R}_{jkl}^i \theta^k \wedge \theta^l \\ \omega_j^i &= \sum_k \Gamma_{kj}^i \theta^k\end{aligned}$$

are purely a matter of definition. However, one can now easily reverse the computations in the proof of Theorem 5 to show that

$$\begin{aligned}T(X, Y) &= \nabla_X Y - \nabla_Y X - [X, Y] \\ R(X, Y) Z &= \nabla_X (\nabla_Y Z) - \nabla_Y (\nabla_X Z) - \nabla_{[X, Y]} Z,\end{aligned}$$

thus verifying that T and R are the torsion and curvature tensors for ∇ as defined previously. We leave this computation to the reader, as well as the task of deriving the general form of the structural equations in polar coordinates.

Even though the structural equations are merely definitions in this approach, we can derive new relations from them.

16. THEOREM. We have the following relations between θ , ω , Θ , and Ω :

(1) (Bianchi's first identity)

$$d\Theta + \omega \wedge \Theta = \Omega \wedge \theta$$

(2) (Bianchi's second identity)

$$d\Omega + (\omega \wedge \Omega) - (\Omega \wedge \omega) = 0.$$

(Notice that $\omega \wedge \Omega$ and $\Omega \wedge \omega$ are not equal up to sign, because Ω and ω are both matrices of forms and the order of matrix multiplication plays a role.)

PROOF. We have

$$\begin{aligned} 0 &= d(d\theta) = d(-\omega \wedge \theta + \Theta) \\ &= -d\omega \wedge \theta + (\omega \wedge d\theta) + d\Theta \\ &= -(-\omega \wedge \omega + \Omega) \wedge \theta + [\omega \wedge (-\omega \wedge \theta + \Theta)] + d\Theta \\ &= -\Omega \wedge \theta + \omega \wedge \Theta + d\Theta. \end{aligned}$$

Similarly,

$$\begin{aligned} 0 &= d(d\omega) = d(-\omega \wedge \omega + \Omega) \\ &= -d\omega \wedge \omega + (\omega \wedge d\omega) + d\Omega \\ &= -(-\omega \wedge \omega + \Omega) \wedge \omega + [\omega \wedge (-\omega \wedge \omega + \Omega)] + d\Omega \\ &= -\Omega \wedge \omega + (\omega \wedge \Omega) + d\Omega. \quad \spadesuit \end{aligned}$$

It takes quite a bit of calculation to convince oneself that the equations in Theorem 16 really are the Bianchi identities. This calculation is left to those readers who have more endurance than the author; we will merely consider the special case of the first Bianchi identity for a connection without torsion. In this case $\Theta = 0$, so the identity is just $\Omega \wedge \theta = 0$. Thus we have

$$0 = (\Omega \wedge \theta)^i = \sum_j \Omega_j^i \wedge \theta^j = \frac{1}{2} \sum_{j,k,l} \mathbf{R}^i_{jkl} \theta^k \wedge \theta^l \wedge \theta^j.$$

Applying this to (X_k, X_l, X_j) we obtain the familiar formula

$$\begin{aligned} 0 &= \frac{1}{2} \{ \mathbf{R}^i_{jkl} - \mathbf{R}^i_{jlk} + \mathbf{R}^i_{ljk} - \mathbf{R}^i_{lkj} + \mathbf{R}^i_{klj} - \mathbf{R}^i_{kjl} \} \\ &= \mathbf{R}^i_{jkl} + \mathbf{R}^i_{klj} + \mathbf{R}^i_{ljk}, \end{aligned}$$

(and thereby see why cyclic permutations of the indices should be involved). It turns out that taking the exterior derivative of the Bianchi identities does not give us any new relations, which indicates that these identities are the only general ones we should expect to find.

To complete the present chapter we also derive the relations satisfied by the curvature tensor for the Levi-Civita connection.

17. THEOREM. Let $(M, \langle \cdot, \cdot \rangle)$ be a Riemannian manifold, and consider the unique Cartan connection of Proposition 14. Then for every orthonormal moving frame we have

$$(1) \quad \Omega_j^i = -\Omega_i^j.$$

Consequently, the curvature tensor R satisfies

$$(2) \quad \langle R(X, Y)Z, W \rangle = -\langle R(X, Y)W, Z \rangle$$

$$(3) \quad \langle R(X, Y)Z, W \rangle = \langle R(Z, W)X, Y \rangle.$$

PROOF. Equation (1) is immediate from the fact that $\omega_j^i = -\omega_i^j$ (by assumption) and the second structural equation,

$$d\omega_j^i = -\sum_k \omega_k^i \wedge \omega_j^k + \Omega_j^i.$$

Since

$$\begin{aligned} \langle R(X_k, X_l)X_j, X_i \rangle &= \left\langle \sum_{\mu} \mathbf{R}^{\mu}_{jkl} X_{\mu}, X_i \right\rangle \\ &= \mathbf{R}^i_{jkl} = \Omega_j^i(X_k, X_l), \end{aligned}$$

equation (1) implies (2). Then, as before, (3) follows from Proposition 4-11. ❖

ADDENDUM 1

MANIFOLDS OF CONSTANT CURVATURE

A Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$ has **constant curvature** K_0 if for all $p \in M$, and all 2-dimensional $V \subset M_p$ we have $K(V) = K_0$. If M is 2-dimensional, this just means that $K(p) = K_0$ for all $p \in M$. In this case, we can easily find the form of the metric $\langle \cdot, \cdot \rangle$ from the considerations on page 145. We use geodesic polar coordinates $(r, \varphi) = (\rho, \phi) \circ \exp^{-1}$ so that the metric is

$$\langle \cdot, \cdot \rangle = dr \otimes dr + G d\varphi \otimes d\varphi.$$

If g on \mathbb{R}^2 is defined by $g = G \circ \exp \circ (\rho, \phi)^{-1}$, then we have seen that

$$\begin{aligned}\sqrt{g}(0, \phi) &= 0 \\ \frac{\partial \sqrt{g}}{\partial \rho}(0, \phi) &= 1 \\ \frac{\partial^2 \sqrt{g}}{\partial \rho^2}(\rho, \phi) &= -K_0 \sqrt{g}(\rho, \phi).\end{aligned}$$

The general solution of the last equation is

$$\begin{aligned}\sqrt{g}(\rho, \phi) &= c_1 \sin \sqrt{K_0} \rho + c_2 \cos \sqrt{K_0} \rho & K_0 > 0 \\ \sqrt{g}(\rho, \phi) &= c_1 \sinh \sqrt{-K_0} \rho + c_2 \cosh \sqrt{-K_0} \rho & K_0 < 0.\end{aligned}$$

Taking into account the initial conditions, we find that

$$\sqrt{g} = \frac{s(\sqrt{|K_0|} \rho)}{\sqrt{|K_0|}},$$

where

$$s \text{ denotes } \begin{cases} \sin & \text{whenever we are dealing with } K_0 > 0 \\ \sinh & \text{''} & K_0 < 0. \end{cases}$$

It follows that the metric is given by

$$\langle \cdot, \cdot \rangle = dr \otimes dr + \frac{s^2(\sqrt{|K_0|} r)}{\sqrt{|K_0|}} d\varphi \otimes d\varphi.$$

To obtain the analogous results in the n -dimensional case, we will return to the equations of Corollary 9. However, we will need a preliminary result,

which applies to spaces of constant curvature as a special case. A point p in an n -dimensional Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$ is called **isotropic** if the sectional curvatures $K(V)$ for all 2-dimensional $V \subset M_p$ have the same value K_0 ; this means that for all $X, Y \in M_p$ we have

$$\langle R(X, Y)Y, X \rangle = K_0 \cdot \|X, Y\|^2,$$

where $\|X, Y\|$ is the area of the parallelogram spanned by X and Y . Applying the formula on pg. I.308 (to the subspace of M_p spanned by X and Y), we can write this equation as

$$\langle R(X, Y)Y, X \rangle = K_0[\langle X, X \rangle \langle Y, Y \rangle - \langle X, Y \rangle^2].$$

18. LEMMA. If $p \in M$ is isotropic, with all sectional curvatures equal to K_0 , then for all $X, Y, Z, W \in M_p$ we have

$$\langle R(X, Y)Z, W \rangle = K_0[\langle X, W \rangle \langle Y, Z \rangle - \langle X, Z \rangle \langle Y, W \rangle].$$

PROOF. Denote the right side of this equation by $\mathcal{R}(X, Y, Z, W)$. By hypothesis, $\langle R(X, Y)Y, X \rangle = \mathcal{R}(X, Y, Y, X)$. It is easy to check that \mathcal{R} has properties (1)–(3), and hence (4), of Proposition 4-11. The desired result now follows from Proposition 4-12. ♦

Although not necessary for our calculations, the following consequence of this Lemma is a standard result, and is pertinent to the topic of constant curvature manifolds.

19. THEOREM (SCHUR). If M is a connected Riemannian manifold of dimension $n \geq 3$ and all points of M are isotropic, then M has constant curvature.

PROOF. By Lemma 18 we have, in a coordinate system x ,

$$R_{hijk} = K[g_{hj}g_{ik} - g_{hk}g_{ij}]$$

for some function K on M . Equivalently,

$$R^h_{ijk} = K(\delta_j^h g_{ik} - \delta_k^h g_{ij}).$$

Consequently, Ricci's Lemma (Proposition 5-3) and the relation $\delta_{j;l}^h = 0$ imply that

$$R^h_{ijk;l} = \frac{\partial K}{\partial x^l}(\delta_j^h g_{ik} - \delta_k^h g_{ij}).$$

From Bianchi's identity (Proposition 5-9(3')) we then obtain

$$0 = \frac{\partial K}{\partial x^l} (\delta_j^h g_{ik} - \delta_k^h g_{ij}) + \frac{\partial K}{\partial x^j} (\delta_k^h g_{il} - \delta_l^h g_{ik}) + \frac{\partial K}{\partial x^k} (\delta_l^h g_{ij} - \delta_j^h g_{il}).$$

In this identity set $h = k$ and sum over k , to obtain

$$\begin{aligned} 0 &= \frac{\partial K}{\partial x^l} (g_{ij} - n g_{ij}) + \frac{\partial K}{\partial x^j} (n g_{il} - g_{il}) + \frac{\partial K}{\partial x^l} g_{ij} - \frac{\partial K}{\partial x^j} g_{il} \\ &= (n - 2) \cdot \left[\frac{\partial K}{\partial x^j} g_{il} - \frac{\partial K}{\partial x^l} g_{ij} \right]. \end{aligned}$$

Since $n \geq 3$ we have

$$\frac{\partial K}{\partial x^j} g_{il} = \frac{\partial K}{\partial x^l} g_{ij}.$$

Hence

$$\delta_l^m \frac{\partial K}{\partial x^j} = \sum_i g^{mi} g_{il} \frac{\partial K}{\partial x^j} = \sum_i g^{mi} g_{ij} \frac{\partial K}{\partial x^l} = \delta_j^m \frac{\partial K}{\partial x^l}.$$

Choosing $m = j \neq l$, we obtain $\partial K / \partial x^l = 0$, for all l . So K is constant. ♦

To obtain the metric in a space of constant curvature K_0 , we now consider the equations of Corollary 9. By Lemma 18 we have

$$\mathbf{R}^i_{jkl} = \langle R(X_k, X_l)X_j, X_i \rangle = K_0[\delta_{ki}\delta_{lj} - \delta_{kj}\delta_{li}],$$

which implies that

$$\mathbf{R}^i_{jij} = -\mathbf{R}^i_{jji} = K_0 \quad (j \neq i); \quad \text{all other } \mathbf{R}^i_{jkl} = 0.$$

So our equations become

$$(*) \quad \frac{\partial^2 \bar{\theta}^i}{\partial t^2} = -K_0 \sum_k t^k (t^k \bar{\theta}^i - t^i \bar{\theta}^k).$$

To solve even these simplified equations requires quite a bit of trickiness. We first use the equations in Proposition 8 to obtain

$$\frac{\partial \left(\sum_i t^i \bar{\theta}^i \right)}{\partial t} = \sum_i t^i dt^i + \sum_{i,k} t^k t^i \bar{\omega}_k^i,$$

and thus

$$\frac{\partial \left(\sum_i t^i \bar{\theta}^i \right)}{\partial t} = \sum_i t^i dt^i, \quad \text{using skew-symmetry of the } \bar{\omega}_k^i = \Phi^* \omega_k^i.$$

Since $\sum_i t^i \bar{\theta}^i(0, X) = 0$, we have

$$\sum_i t^i \theta^i = t \sum_i t^i dt^i,$$

and hence

$$(**) \quad \left(\sum_i t^i \bar{\theta}^i \right)^2 = \sum_{i,j} t^i t^j \bar{\theta}^i \bar{\theta}^j = t^2 \sum_{i,j} t^i t^j dt^i dt^j = t^2 \left(\sum_i t^i dt^i \right)^2.$$

We next obtain equations for the quantities $t^i \bar{\theta}^j - t^j \bar{\theta}^i$. By (*) we have

$$\begin{aligned} \frac{\partial^2 (t^i \bar{\theta}^j - t^j \bar{\theta}^i)}{\partial t^2} &= -K_0 \sum_{k=1}^n t^k t^i (t^k \bar{\theta}^j - t^j \bar{\theta}^k) + t^k t^j (t^k \bar{\theta}^i - t^i \bar{\theta}^k) \\ &= -K_0 \sum_{k=1}^n (t^k)^2 (t^i \bar{\theta}^j - t^j \bar{\theta}^i) \\ &= -K_0 \rho^2 (t^i \bar{\theta}^j - t^j \bar{\theta}^i), \end{aligned}$$

where we have set

$$\rho = \sqrt{\sum_{k=1}^n (t^k)^2}.$$

Together with the initial conditions

$$\begin{aligned} (t^i \bar{\theta}^j - t^j \bar{\theta}^i)(0, X) &= 0 \\ \frac{\partial (t^i \bar{\theta}^j - t^j \bar{\theta}^i)}{\partial t}(0, X) &= t^i dt^j - t^j dt^i, \end{aligned}$$

we obtain

$$t^i \bar{\theta}^j - t^j \bar{\theta}^i = \frac{s(\rho \sqrt{|K_0|} t)}{\rho \sqrt{|K_0|}} (t^i dt^j - t^j dt^i).$$

Recall that for a form η , we use η^2 to denote the quadratic function $X \mapsto \eta(X) \cdot \eta(X)$. Summing the squares of the equations just derived, we now obtain

$$\begin{aligned}
& \frac{s^2(\rho\sqrt{|K_0|}t)}{\rho^2|K_0|} \sum_{i < j} (t^i dt^j - t^j dt^i)^2 \\
&= \frac{1}{2} \frac{s^2(\rho\sqrt{|K_0|}t)}{\rho^2|K_0|} \sum_{i,j} (t^i dt^j - t^j dt^i)^2 \\
&= \frac{1}{2} \sum_{i,j} (t^i \bar{\theta}^j - t^j \bar{\theta}^i)^2 = \frac{1}{2} \left[\sum_{i,j} (t^i)^2 (\bar{\theta}^j)^2 + (t^j)^2 (\bar{\theta}^i)^2 - 2t^i t^j \bar{\theta}^i \bar{\theta}^j \right] \\
&= \sum_{i,j} (t^i)^2 (\bar{\theta}^j)^2 - t^2 \sum_{i,j} t^i t^j dt^i dt^j \quad \text{by (**)} \\
&= \rho^2 \sum_{k=1}^n (\bar{\theta}^k)^2 - t^2 \left(\sum_k t^k dt^k \right)^2.
\end{aligned}$$

Since $\exp: (M_p, \sum_k \bar{\theta}^k \otimes \bar{\theta}^k) \rightarrow (M, \langle \cdot, \cdot \rangle)$ is an isometry, and $\bar{\theta}$ is the value of $\bar{\theta}^i$ when $t = 1$, the expression for $\| \cdot \|^2$ in normal coordinates is obtained by seeing what $\sum_k (\bar{\theta}^k)^2$ becomes when we set $t = 1$ and $t^k = x^k$ in the above equation. We let r denote what ρ becomes when we perform this substitution; that is, we let

$$r = \sqrt{\sum_{k=1}^n (x^k)^2}.$$

We then obtain

$$\| \cdot \|^2 = \frac{1}{r^2} \left\{ \left(\sum_k x^k dx^k \right)^2 + \frac{s^2(\sqrt{|K_0|}r)}{|K_0|r^2} \cdot \sum_{i < j} (x^i dx^j - x^j dx^i)^2 \right\}.$$

Notice that we have

$$\left(\sum_k x^k dx^k \right)^2 = r^2 \left[\sum_k (dx^k)^2 \right] - \sum_{i < j} (x^i dx^j - x^j dx^i)^2;$$

consequently, we can write

$$\| \|^2 = \sum_k (dx^k)^2 - \left[\frac{|K_0|r^2 - s^2(\sqrt{|K_0|}r)}{|K_0|r^4} \right] \sum_{i < j} (x^i dx^j - x^j dx^i)^2.$$

From the Taylor series for \sin it is easy to see that the coefficient of the sum $\sum_{i < j} (x^i dx^j - x^j dx^i)^2$ is C^∞ (in fact it is analytic). This formula thus gives a direct verification of Riemann's assertion about the form of $\| \|^2$ in normal coordinates (page 168). On the other hand, this form of the metric is *not* the one which Riemann mentioned in his lecture (page 159). We will consider this metric in Addendum 2.

ADDENDUM 2

CONFORMALLY EQUIVALENT MANIFOLDS

In a vector space V with a positive definite inner product $\langle \cdot, \cdot \rangle$ we define the **angle** $\angle(v, w)$ between two non-zero vectors $v, w \in V$ by

$$\angle(v, w) = \arccos \frac{\langle v, w \rangle}{\|v\| \cdot \|w\|}.$$

It is easy to say when two metrics give the same angle measurements.

20. LEMMA. Let $\langle \cdot, \cdot \rangle_1$ and $\langle \cdot, \cdot \rangle_2$ be two positive definite inner products on V . Then $\angle_1(v, w) = \angle_2(v, w)$ for all non-zero $v, w \in V$ if and only if there is a number $c > 0$ with $\langle \cdot, \cdot \rangle_2 = c \cdot \langle \cdot, \cdot \rangle_1$.

PROOF. If $\langle \cdot, \cdot \rangle_2 = c \cdot \langle \cdot, \cdot \rangle_1$, then clearly $\angle_2(v, w) = \angle_1(v, w)$ for all $v, w \neq 0$.

Conversely, suppose $\angle_2(v, w) = \angle_1(v, w)$ for all $v, w \neq 0$. Let v_1, \dots, v_n be an orthonormal basis for V with respect to $\langle \cdot, \cdot \rangle_1$. Then for $i \neq j$ we have

$$\angle_2(v_i, v_j) = \angle_1(v_i, v_j) = 0,$$

so $\langle v_i, v_j \rangle_2 = 0$. Define c_i by $\langle v_i, v_i \rangle_2 = c_i$. Then

$$\begin{aligned} \angle_1(v_i, v_i + v_j) &= \frac{\langle v_i, v_i + v_j \rangle_1}{\sqrt{\langle v_i, v_i \rangle_1} \sqrt{\langle v_i + v_j, v_i + v_j \rangle_1}} = \frac{1}{\sqrt{2}}, \\ \angle_2(v_i, v_i + v_j) &= \frac{\langle v_i, v_i + v_j \rangle_2}{\sqrt{\langle v_i, v_i \rangle_2} \sqrt{\langle v_i + v_j, v_i + v_j \rangle_2}} = \frac{c_i}{\sqrt{c_i} \sqrt{c_i + c_j}}. \end{aligned}$$

It follows that $c_i = c_j$. ♦

Now a diffeomorphism $f: (M_1, \langle \cdot, \cdot \rangle_1) \rightarrow (M_2, \langle \cdot, \cdot \rangle_2)$ between Riemannian manifolds is called **conformal** if each f_{*p} is angle preserving, and the two

Riemannian manifolds are then called **conformally equivalent**. By Lemma 20, a diffeomorphism f is conformal if and only if

$$\langle \cdot, \cdot \rangle_1 = \lambda f^* \langle \cdot, \cdot \rangle_2$$

for some positive function $\lambda: M_1 \rightarrow \mathbb{R}$. In particular, if a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$ is conformal to \mathbb{R}^n with its usual Riemannian metric, then around each point $p \in M$ we can choose a coordinate system x such that $g_{ij} = \lambda \delta_{ij}$ for some positive function $\lambda: M \rightarrow \mathbb{R}$. Such a coordinate system x is called **isothermal**.

In 1822 Gauss showed that isothermal coordinates can be found at any point of an arbitrary surface. His proof depends on a trick that works only for analytic (C^ω) manifolds, and uses a little knowledge of complex function theory. It is presented in Addendum 1 to Chapter 9 of Volume IV, together with a (much more involved) proof that works in the C^∞ case. For $n > 2$ it is not true that every n -manifold is locally conformally equivalent to \mathbb{R}^n . But certain important n -dimensional Riemannian manifolds are. In fact, in his lecture, Riemann states that on a manifold of constant curvature K_0 there is a coordinate system x with

$$\| \cdot \| = \frac{\sqrt{\sum_{i=1}^n (dx^i)^2}}{1 + \frac{K_0}{4} \sum_i (x^i)^2},$$

or equivalently

$$\langle \cdot, \cdot \rangle = \sum_{i=1}^n \frac{dx^i \otimes dx^i}{\left[1 + \frac{K_0}{4} \sum_i (x^i)^2\right]^2}.$$

Thus, x is an isothermal coordinate system.

It wasn't very hard for Riemann to guess this, because there is a very standard coordinate system for S^n which gives this metric (with $K_0 = 1$). We consider S^n as the sphere of radius 1 around the point $(0, \dots, 0, 1)$, so that S^n is tangent to $\mathbb{R}^n = \mathbb{R}^n \times \{0\} \subset \mathbb{R}^{n+1}$. Let $*$ be the "north pole", $* = (0, \dots, 0, 2) \in S^n$. The **stereographic projection**

$$\sigma: S^n - \{*\} \rightarrow \mathbb{R}^n$$

is defined geometrically as follows: for any $p \neq *$ in S^n , we let $\sigma(p)$ be the

point where the line between p and $*$ intersects \mathbb{R}^n . It is easy to check (see the

plane section on the right of the diagram) that

$$(1) \quad \sigma(p) = \left(\frac{2p^1}{2 - p^{n+1}}, \dots, \frac{2p^n}{2 - p^{n+1}} \right)$$

and that $f = \sigma^{-1}$ is given by

$$(2) \quad \sigma^{-1}(y) = f(y) = \left(\frac{y^1}{1 + \frac{1}{4} \sum (y^i)^2}, \dots, \frac{y^n}{1 + \frac{1}{4} \sum (y^i)^2}, \frac{\frac{1}{2} \sum (y^i)^2}{1 + \frac{1}{4} \sum (y^i)^2} \right).$$

If y^1, \dots, y^n denotes the standard coordinate system on \mathbb{R}^n , then the $x^i = y^i \circ \sigma$ give a coordinate system on $S^n - \{*\}$.

Let $i: S^n \rightarrow \mathbb{R}^{n+1}$ be the inclusion map, and $\langle \cdot, \cdot \rangle = \sum_{i=1}^{n+1} dz^i \otimes dz^i$ the usual Riemannian metric on \mathbb{R}^{n+1} , so that $i^* \langle \cdot, \cdot \rangle$ is the usual Riemannian metric on S^n . We find the expression

$$i^* \langle \cdot, \cdot \rangle = \sum_{i,j=1}^n g_{ij} dx^i \otimes dx^j$$

for $i^* \langle \cdot, \cdot \rangle$ by writing

$$\begin{aligned} \sum_{i,j=1}^n (g_{ij} \circ f) dy^i \otimes dy^j &= f^* \left(\sum_{i,j=1}^n g_{ij} dx^i \otimes dx^j \right) \\ &= f^* i^* \langle \cdot, \cdot \rangle = f^* \langle \cdot, \cdot \rangle \\ &= f^* \sum_{i=1}^{n+1} dz^i \otimes dz^i = \sum_{i=1}^{n+1} df^i \otimes df^i \\ &= \sum_{i=1}^{n+1} \sum_{j,k=1}^n \frac{\partial f^i}{\partial y^j} \frac{\partial f^i}{\partial y^k} dy^j \otimes dy^k, \end{aligned}$$

and computing the $\partial f^i / \partial y^j$ from (2). A forbidding looking computation finally coalesces into

$$\sum_{i,j=1}^n (g_{ij} \circ f) dy^i \otimes dy^j = \sum_{i=1}^n \frac{dy^i \otimes dy^i}{\left[1 + \frac{1}{4} \sum_i (y^i)^2\right]^2},$$

so that the expression for the metric $i^*\langle \ , \ \rangle$ is

$$\sum_{i=1}^n \frac{dx^i \otimes dx^i}{\left[1 + \frac{1}{4} \sum_i (x^i)^2\right]^2}.$$

(A neater way of deriving this formula is presented in Volume IV, Chapter 7.) If we were dealing with a sphere of curvature K_0 , the factor $1/4$ would be replaced by $K_0/4$.

Of course, we still have to check that this formula gives a metric of constant curvature K_0 when $K_0 < 0$. We will consider, more generally, all metrics on (a subset of) \mathbb{R}^n which have the standard coordinate system as isothermal coordinates, and determine just which of these have constant curvature.

Thus, we consider metrics on (a subset of) \mathbb{R}^n of the form

$$g_{ij} = \frac{\delta_{ij}}{F^2} \quad F \text{ nowhere } 0.$$

Then $g^{ij} = \delta^{ij} F^2$. We also have

$$\frac{\partial g_{ij}}{\partial x^k} = \frac{-2\delta_{ij}}{F^3} \frac{\partial F}{\partial x^k} = \frac{-2\delta_{ij}}{F^2} \frac{\partial \log F}{\partial x^k}.$$

Setting $\log F = f$, and using the formulas on pp. I.326 and I.328, we obtain

$$\Gamma_{ii}^i = \frac{-\partial f}{\partial x^i}, \quad \Gamma_{jj}^j = \frac{\partial f}{\partial x^j}, \quad \Gamma_{ij}^i = \Gamma_{ji}^j = \frac{-\partial f}{\partial x^j} \quad (i \neq j); \quad \text{all other } \Gamma_{jk}^i = 0.$$

From the formula on page 214 we obtain

$$R^i_{jij} = -R^i_{jji} = \frac{\partial^2 f}{\partial x^j \partial x^j} + \frac{\partial^2 f}{\partial x^i \partial x^i} - \sum_{r \neq i,j} \left(\frac{\partial f}{\partial x^r} \right)^2 \quad i \neq j$$

$$R^i_{jjl} = \frac{-\partial^2 f}{\partial x^i \partial x^l} - \frac{\partial f}{\partial x^i} \frac{\partial f}{\partial x^l} \quad i, j, l \text{ distinct}$$

$$R^i_{jil} = \frac{\partial^2 f}{\partial x^j \partial x^l} + \frac{\partial f}{\partial x^j} \frac{\partial f}{\partial x^l} \quad i, j, l \text{ distinct}$$

$$\text{all other } R^i_{jkl} = 0.$$

Now by Lemma 18, the metric has constant curvature K_0 if and only if

$$R_{ijkl} = K_0(g_{ik}g_{jl} - g_{il}g_{jk}),$$

or equivalently

$$\begin{aligned} R^i_{jkl} &= K_0(\delta_k^i g_{jl} - \delta_l^i g_{jk}) \\ &= \frac{K_0}{F^2}(\delta_k^i \delta_{jl} - \delta_l^i \delta_{jk}), \end{aligned}$$

and hence

$$R^i_{jij} = -R^i_{jji} = \frac{K_0}{F^2} \quad (j \neq i); \quad \text{all other } R^i_{jkl} = 0.$$

So the metric has constant curvature K_0 if and only if

$$\begin{aligned} \frac{\partial^2 f}{\partial x^j \partial x^l} + \frac{\partial f}{\partial x^j} \frac{\partial f}{\partial x^l} &= 0 & j \neq l \\ \frac{\partial^2 f}{\partial x^i \partial x^i} + \frac{\partial^2 f}{\partial x^j \partial x^j} - \sum_{r \neq i, j} \left(\frac{\partial f}{\partial x^r} \right)^2 &= \frac{K_0}{F^2} & i \neq j. \end{aligned}$$

Since

$$\frac{\partial^2 f}{\partial x^j \partial x^l} + \frac{\partial f}{\partial x^j} \frac{\partial f}{\partial x^l} = \frac{1}{F} \frac{\partial^2 f}{\partial x^j \partial x^l} \quad \text{for all } j, l,$$

these equations hold if and only if

$$(1) \quad \frac{\partial^2 F}{\partial x^j \partial x^l} = 0 \quad j \neq l$$

$$(2) \quad F \cdot \left(\frac{\partial^2 F}{\partial x^i \partial x^i} + \frac{\partial^2 F}{\partial x^j \partial x^j} \right) = K_0 + \sum_{r=1}^n \left(\frac{\partial F}{\partial x^r} \right)^2 \quad i \neq j.$$

Equation (1) implies that $F = G_1 + \cdots + G_n$, where G_j depends only on x^j . Using equation (2) for i, l and then for j, l , we obtain

$$\frac{\partial^2 G_i}{\partial x^i \partial x^i} = \frac{\partial^2 G_j}{\partial x^j \partial x^j}.$$

So we must have

$$G_i = cx_i^2 + b_i x_i + a_i,$$

for some c . From (2) we then obtain

$$K_0 = \sum_{r=1}^n (4a_r c - b_r^2).$$

There are two important special cases. If we choose $c = K_0/4$, $b_i = 0$, $a_i = 1/n$ we obtain the metric $\langle \cdot, \cdot \rangle = \sum g_{ij} dx^i \otimes dx^j$ which Riemann mentions, with

$$g_{ij} = \frac{\delta_{ij}}{\left[1 + \frac{K_0}{4} \sum_i (x^i)^2\right]^2}.$$

Notice that for $K_0 < 0$, this metric is defined only on

$$M = \left\{ a \in \mathbb{R}^n : \sum_{i=1}^n (a^i)^2 < -4/K_0 \right\}.$$

Nevertheless, $(M, \langle \cdot, \cdot \rangle)$ is complete. To see this, we compute that the curve γ defined by

$$\begin{aligned} \gamma^1(t) &= 2 \frac{\sinh \frac{\sqrt{|K_0|} t}{2}}{\sqrt{|K_0|} \cosh \frac{\sqrt{|K_0|} t}{2}} \\ \gamma^i(t) &= 0, \quad i > 1 \end{aligned}$$

is a geodesic through 0, parameterized by arclength, and defined for all t . Since the metric $\langle \cdot, \cdot \rangle$ is radially symmetric around 0, there are geodesics through 0 in all directions, which are defined for all t .

When $K_0 > 0$, the same metric is defined on all of \mathbb{R}^n , but it is *not* complete, since it is isometric to the n -sphere of radius $\sqrt{K_0}$ with a point deleted. Some theorems from Chapters 7 and 8 of Volume IV will throw more light on these matters.

The other important case occurs when $c = a_i = 0$ and $b_i = \delta_{in}$, so that the metric is

$$\sum_{i=1}^n \frac{dx^i \otimes dx^i}{(x^n)^2},$$

with constant curvature $K_0 = -1$. The 2-dimensional case, in particular, gives the nicest example of a non-Euclidean geometry (see Problem I.9-41).

ADDENDUM 3

É. CARTAN'S TREATMENT
OF NORMAL COORDINATES

In this Addendum we use moving frames to prove Riemann's claims about the form of the metric in normal coordinates, and in fact obtain stronger results; a special case of our result is represented by the form of the metric for spaces of constant curvature which we found in Addendum 1. Throughout, we will be working with a moving frame X_1, \dots, X_n adapted to an orthonormal basis X_{1p}, \dots, X_{np} for M_p ; the forms $\theta^i, \bar{\theta}^i$ are as defined previously, and x^1, \dots, x^n denotes the Riemannian normal coordinate system determined by X_{1p}, \dots, X_{np} .

21. PROPOSITION. The quadratic form $\| \|^2 - \sum_i (dx^i)^2$ can be written as a quadratic form in the differentials $x^r dx^s - x^s dx^r$.

PROOF. Consider the functions A_{jk}^i on $\mathbb{R} \times M_p$ which satisfy the equations

$$(1) \quad \begin{cases} \frac{\partial^2 A_{jk}^i}{\partial t^2} = \sum_r (\mathbf{R}_{rjk}^i \circ \Phi) t t^r + \sum_{r,s,l} (\mathbf{R}_{rsl}^i \circ \Phi) A_{jk}^l t^r t^s \\ A_{jk}^i(0, X) = 0 \\ \frac{\partial A_{jk}^i}{\partial t}(0, X) = 0. \end{cases}$$

We claim that

$$(2) \quad \bar{\theta}^i = t dt^i + \sum_{j,k} A_{jk}^i t^j dt^k.$$

To prove this, we simply note that if we *define* $\bar{\theta}^i$ by this formula, then an easy calculation shows that the $\bar{\theta}^i$ satisfy the equations and initial conditions of Corollary 9; since the solutions are unique, the result follows.

Now note, by skew-symmetry of \mathbf{R}_{jkl}^i in the last two indices, that $A_{jk}^i + A_{kj}^i$ satisfies a *linear* second order differential equation, with initial conditions

$$\begin{aligned} (A_{jk}^i + A_{kj}^i)(0, X) &= 0 \\ \frac{\partial}{\partial t}(A_{jk}^i + A_{kj}^i)(0, X) &= 0. \end{aligned}$$

It follows that

$$(3) \quad A_{jk}^i = -A_{kj}^i.$$

[The motivation for this proof is the following. The equations in Proposition 8 clearly imply that $\bar{\theta}^i - t \, dt^i = 0$ at $(t, 0)$. This means (by Lemma I.3-2) that we can write $\bar{\theta}^i$ as in (2). Then the equations in Corollary 9 imply that the A_{jk}^i satisfy (1).]

Next consider the functions B_{sjk}^r which satisfy the equations

$$(4) \quad \left\{ \begin{array}{l} \frac{\partial^2 B_{sjk}^r}{\partial t^2} = (\mathbf{R}_{sjk}^r \circ \Phi)t + \sum_{\mu, l} \mathbf{R}_{s\mu l}^i A_{jk}^l t^\mu \\ B_{sjk}^r(0, X) = 0 \\ \frac{\partial B_{sjk}^r}{\partial t}(0, X) = 0. \end{array} \right.$$

We claim that

$$(5) \quad A_{jk}^r = \sum_s B_{sjk}^r t^s.$$

This is proved by checking that if we define A_{jk}^r by (5), then equations (4) imply equations (1).

Using the skew-symmetry of \mathbf{R}_{sjk}^r in j and k and the skew-symmetry of A_{jk}^l in j and k [equation (3)], we easily see that

$$(6) \quad B_{sjk}^r = -B_{skj}^r.$$

Also, using skew-symmetry of \mathbf{R}_{sjk}^r in r and s , we see that

$$(7) \quad B_{sjk}^r = -B_{rjk}^s.$$

We know that the expression for $\| \|^2 = \sum_i (\theta^i)^2$ in the Riemannian normal coordinate system x^1, \dots, x^n is what $\sum_i (\bar{\theta}^i)^2$ becomes when we set $t = 1$ and $t^i = x^i$. So by (2) we have

$$\| \|^2 = \sum_i (dx^i)^2 + \sum_i \left(\sum_{j, k} A_{jk}^i x^j dx^k \right)^2 + \sum_r \left(\sum_{j, k} A_{jk}^r dx^r x^j dx^k \right).$$

Now (3) implies that the first triple sum is a quadratic form in the $x^r dx^s - x^s dx^r$. The second triple sum can be written

$$\sum_{r,s,l,j} B'_{sjk} x^s dx^r x^j dx^k;$$

using (6) and (7), we see that this can also be written as a quadratic form in the $x^r dx^s - x^s dx^r$. ♦

For further developments, see É. Cartan's *Leçons sur la Géométrie des Espaces de Riemann*, pp. 242ff.

CHAPTER 8

CONNECTIONS IN PRINCIPAL BUNDLES

The method of moving frames turns out to be surprisingly powerful, but it leads us to a definition of a connection which does not have the “invariance” property of the Koszul definition (although it is a big improvement over the classical definition, simply because the transformation law can be stated so much more elegantly). At the same time, we should note a certain deficiency in our proofs of the Test Case. We certainly have enough of them (six so far), and they use the integrability conditions $R = 0$ in many different ways. In the first proof we use the classical integrability theorem, and in the second and third proofs we essentially reprove this theorem. In the fourth proof we use the differential form version of the Frobenius Theorem, and in the fifth and sixth proofs we use the proof of the integrability theorem outlined in Problem I.6-8. However, in all this time we have never used the distribution formulation of the Frobenius Integrability Theorem (I.6-5), although this is the most geometric version of all.

These two phenomena will eventually turn out to be closely related, but for the present we will concentrate on the first problem. The main step in the solution of this problem was accomplished by Ehresmann* in 1950. With the advantages of hindsight we can reconstruct the solution in a way that makes it seem natural and almost obvious.

It will be helpful to begin by reconsidering the classical and modern definitions of vector fields. As we pointed out long ago, the snazziest modern definition of tangent vectors is essentially the same as the classical definition, as n -tuples of numbers which “transform” according to certain rules. On the other hand, the modern definition of a vector field represents a definite improvement over the classical definition. Instead of dealing with n -tuples of functions transforming according to certain rules, we make the set of tangent vectors into a new manifold, the tangent bundle, and define vector fields to be sections of this vector bundle. The idea behind the modern treatment of connections is to ob-

* Ehresmann, *Les connexions infinitesimales dans un espace fibre differentiable*, Colloque de Topologie, Bruxelles (1950), 29–55.

tain a bundle whose sections are just the moving frames on M . To do this, we will imitate the construction of the tangent bundle in a rather straightforward way.

Recall that a **frame** u for M_p is just an ordered basis $u = (u_1, \dots, u_n)$ for M_p . Let $F(M)$ denote the set of all frames u for all tangent spaces M_p . We call $F(M)$ the **bundle of frames** of M , and define $\pi: F(M) \rightarrow M$ to be the map which takes a basis u for M_p to $\pi(u) = p$. If (x, U) is a coordinate system on M and $p \in U$, then every frame $u = (u_1, \dots, u_n)$ for M_p can be written uniquely as

$$u_j = \sum_{i=1}^n x_j^i(u) \frac{\partial}{\partial x^i} \Big|_{\pi(u)}.$$

The matrix $(x_j^i(u))$ is non-singular, and any non-singular matrix can occur, so the map

$$u \mapsto (x^i(\pi(u)), x_j^i(u)) \in \mathbb{R}^n \times \text{GL}(n, \mathbb{R})$$

is a one-one map $x_\#$ from $\pi^{-1}(U)$ onto $x(U) \times \text{GL}(n, \mathbb{R})$. It is easy to see that if (y, V) is another coordinate system, then $y_\# \circ (x_\#)^{-1}$ is C^∞ , from $x_\#(\pi^{-1}(U \cap V))$ to $y_\#(\pi^{-1}(U \cap V))$. This means that we can make $F(M)$ into a C^∞ manifold in such a way that each $x_\#$ is a diffeomorphism; with this C^∞ structure on $F(M)$, the map π is clearly C^∞ . Notice, finally, that we have a C^∞ map $F(M) \times \text{GL}(n, \mathbb{R}) \rightarrow F(M)$, given by $(u, A) \mapsto u \cdot A$, where $(u \cdot A)_i = \sum_j A_i^j u_j$; we have $u \cdot A = u$ only when $A = I$, and the set of all $u \cdot A$ for $A \in \text{GL}(n, \mathbb{R})$ is just $\pi^{-1}(\pi(u))$.

Although we have called $F(M)$ the “bundle of frames”, it is clearly not a vector bundle; each fibre $\pi^{-1}(p)$ is diffeomorphic to $\text{GL}(n, \mathbb{R})$, rather than to some \mathbb{R}^N . However, $F(M)$ is another special sort of “bundle” which we will now define.

Let M be a C^∞ manifold, and G a Lie group. A (C^∞) **principal bundle over M , with group G** , is a triple (P, π, \cdot) where

- (1) P is a C^∞ manifold (the **total space** of the principal bundle)
- (2) $\pi: P \rightarrow M$ is a C^∞ map (the **projection map** of the bundle) onto M (the **base space** of the principal bundle), satisfying

$$\pi(u \cdot a) = \pi(u) \quad \text{for all } u \in P \text{ and } a \in G$$

- (3) the map \cdot (the **action** of G) is a C^∞ map $(u, a) \mapsto u \cdot a$ from $P \times G$ to P with

$$u \cdot (ab) = (u \cdot a) \cdot b \quad \text{for all } u \in P \text{ and } a, b \in G$$

such that the following “local triviality” condition holds:

For each $p \in M$ there is a neighborhood U of p and a diffeomorphism $t: \pi^{-1}(U) \rightarrow U \times G$ of the form

$$t(u) = (\pi(u), \phi(u))$$

where ϕ satisfies $\phi(u \cdot a) = \phi(u)a$ [the latter product being the product in G].

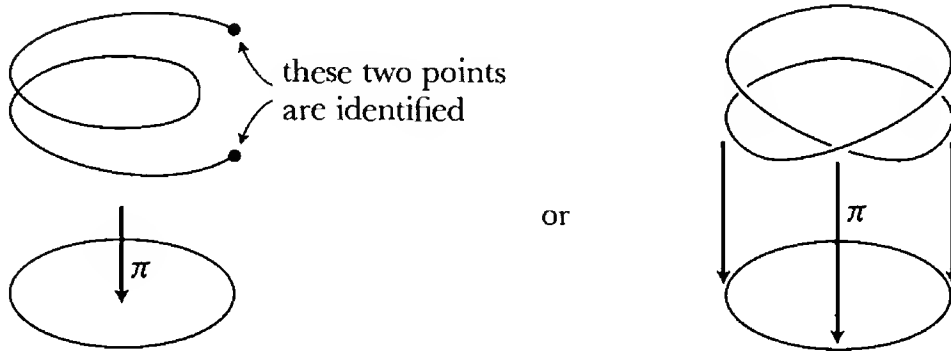

From the condition $\pi(u \cdot a) = \pi(a)$ we see that $\{u \cdot a : a \in G\} \subset \pi^{-1}(\pi(u))$. Using the property $\phi(u \cdot a) = \phi(u)a$ of the map ϕ , we see that we actually have $\{u \cdot a : a \in G\} = \pi^{-1}(\pi(u))$: for, if $v \in P$ satisfies $\pi(v) = \pi(u)$, and $\phi(v) = \phi(u)a$ for $a \in G$, then $\phi(v) = \phi(u \cdot a)$ and $\pi(v) = \pi(u \cdot a)$, so $v = u \cdot a$. Notice also that if $u \cdot a = u$ for some $u \in P$, then $a = e$.

Each “fibre” $\pi^{-1}(p)$ of P is clearly diffeomorphic to G . If $p = \pi(u)$ for $u \in P$, and $i: \pi^{-1}(p) \rightarrow P$ is the inclusion, then the image of the tangent space $i_*(\pi^{-1}(p)_u)$ is a subspace V_u of P_u , called the **vertical subspace** at u ; tangent vectors in this subspace are called **vertical** tangent vectors at u . Clearly $Y \in V_u$ is vertical if and only if $\pi_* Y = 0$.

The simplest example of a principal bundle is $M \times G$, with $\pi: M \times G \rightarrow M$ the projection on the first factor, and $(p, a) \cdot b = (p, ab)$. This is called the **trivial** principal bundle with group G . So far, we have given only one other example of a principal bundle, the bundle of frames $F(M)$, with group $\text{GL}(n, \mathbb{R})$. However, we can use the construction of this bundle to acquire many other examples. If $\pi: E \rightarrow M$ is any C^∞ vector bundle over M , we can let $F(E)$ be the collection of all frames u for the vector space $\pi^{-1}(p)$, for all $p \in M$; the projection map $\varpi: F(E) \rightarrow M$ takes a frame u for $\pi^{-1}(p)$ into $\varpi(u) = p$. Consider, in particular, the Möbius strip as a 1-dimensional vector bundle $\pi: E \rightarrow S^1$ over S^1 . A frame in a 1-dimensional vector space is just a non-zero vector, so $F(E)$ consists of the Möbius strip with the 0-section deleted. This space is connected (cut a paper Möbius strip along the center if you don't believe it); more generally, a vector bundle $\pi: E \rightarrow M$ over a connected space M is orientable if and only if $F(E)$ is disconnected.

Examples of a different sort are obtained if we begin with a vector bundle $\pi : E \rightarrow M$ equipped with a Riemannian metric, and define $O(E)$ to be the set of all *orthonormal* frames u for $\pi^{-1}(p)$, for all $p \in M$. This is a principal bundle over M with group $O(n)$. In the case of a 1-dimensional bundle $\pi : E \rightarrow M$, every fibre of $O(E)$ has exactly 2 points, and $O(1) = \mathbb{Z}_2$; the action of the non-zero element of $O(1)$ on $O(E)$ interchanges these 2 points in each fibre. For the Möbius strip, the principal bundle $O(E)$ looks like the picture below.

More precisely, the total space of $O(E)$ is a circle S^1 , and the projection map $S^1 \rightarrow S^1$ is given by $\theta \mapsto 2\theta$.

In the case of an *oriented* bundle $\pi : E \rightarrow M$, these constructions can be modified to give principal bundles $SF(E)$ and $SO(E)$, the bundle of positively oriented frames, and positively oriented orthonormal frames, respectively. For 1-dimensional bundles, the total space $SF(E)$ looks like $M \times (0, \infty)$, while $SO(E)$ looks just like M . For 2-dimensional bundles, $SO(E)$ has a circle above each point of M ; the action of $\theta \in SO(2) = S^1$ rotates each circle through an angle of θ .

Although examples in which the group G is discrete are the least interesting for us, we will nevertheless give two more, as examples of principal bundles are hard to come by. In the first example, the group is the integers \mathbb{Z} , the total space and base space are \mathbb{R} and S^1 , respectively, and the map $\pi : \mathbb{R} \rightarrow S^1$ is

$\pi(\theta) = (\cos \theta, \sin \theta)$. In the second example, we define $\pi : S^2 \rightarrow \mathbb{P}^2$ to be

$\pi(p) = \{p, -p\}$; the group is \mathbb{Z}_2 and the action of the non-zero element is to take $p \in S^2$ to $-p$.

Before discussing principal bundles in particular, we need some generalities about Lie groups acting on manifolds. Consider a Lie group G , a C^∞ manifold M , and a C^∞ map $(p, a) \mapsto p \cdot a$ from $M \times G$ to M . We say that G acts on M on the right (via this map) if

- (1) the map $R_a: M \rightarrow M$ defined by $R_a(p) = p \cdot a$ is a diffeomorphism for all $a \in G$
- (2) $p \cdot (ab) = (p \cdot a) \cdot b$ for all $p \in M$ and $a, b \in G$.

Condition (2) can also be written as $R_{ab} = R_b \circ R_a$; since each R_a is a diffeomorphism, it follows easily that R_e is the identity map of M . We say that G acts **effectively** if e is the only element a with R_a the identity map of M , and we say that G acts **without fixed point** if the following stronger condition holds: if $p \cdot a = p$ for some $p \in M$, then $a = e$.

Now let \mathfrak{g} be the Lie algebra of a Lie group G which acts on M on the right. For every $X \in \mathfrak{g}$, we have the curve $t \mapsto \exp tX$ in G ; for each $p \in M$ this gives rise to a curve $c_p(t) = p \cdot (\exp tX) = R_{\exp tX}(p)$. We denote $c_p'(0)$ by $\sigma(X)(p)$; we thus have a vector field $\sigma(X)$ on M , and hence a map $\sigma: \mathfrak{g} \rightarrow$ (vector fields on M). The 1-parameter group of diffeomorphisms generated by $\sigma(X)$ is $\phi_t(p) = p \cdot (\exp tX)$, by the very definition of $\sigma(X)$. It is important to note that we can also describe $\sigma(X)$ as follows. For $p \in M$, let $\sigma_p: G \rightarrow M$ be $\sigma_p(a) = p \cdot a$. Then

$$\sigma(X)(p) = \sigma_{p*}(X).$$

To discuss this operation σ we will also need to introduce an important map, the “adjoint map”

$$\text{Ad}(a) = (L_a R_a^{-1})_* = (R_a^{-1} L_a)_*: \mathfrak{g} \rightarrow \mathfrak{g},$$

where L_a and R_a now denote left and right translations in G . Thus $\text{Ad}(a)$ is the differential at e of the map $b \mapsto aba^{-1} = L_a R_a^{-1}(b) = R_a^{-1} L_a(b)$. Usually $(\text{Ad}(a))(X)$ is denoted simply by $\text{Ad}(a)X$. If \tilde{X} is the left invariant vector field on G with $\tilde{X}(e) = X \in \mathfrak{g}$, then

$$\text{Ad}(a)X = (R_a^{-1})_*(L_{a*}\tilde{X})(e) = [(R_a^{-1})_*\tilde{X}](e),$$

since $L_{a*}\tilde{X} = \tilde{X}$. Consider, in particular, the special case where $G = \text{GL}(n, \mathbb{R})$, so that $\mathfrak{g} = \mathfrak{gl}(n, \mathbb{R})$ is the set of all $n \times n$ matrices. For any $n \times n$ matrix N and any $A \in \text{GL}(n, \mathbb{R})$ we have

$$\text{Ad}(A)N = ANA^{-1},$$

since $L_{A*} = L_A$ and $R_{A*} = R_A$, because L_A and R_A are linear functions (compare Problem I.10-19).

1. PROPOSITION. Let G act on the right on M . Then

- (1) The map $\sigma: \mathfrak{g} \rightarrow (\text{vector fields on } M)$ is linear.
- (2) $\sigma([X, Y]) = [\sigma(X), \sigma(Y)]$.
- (3) If G acts effectively and $X \neq 0$, then $\sigma(X)$ is not the zero vector field.
- (4) If G acts without fixed point and $X \neq 0$, then $\sigma(X)$ is nowhere 0.

PROOF. Linearity is clear from the equation $\sigma(X)(p) = \sigma_{p*}(X)$.

To prove (2) we note that since the bracket of two vector fields is the same as the Lie derivative (Theorem I.5-10), we have

$$\begin{aligned}
 (1) \quad [X, Y] &= [\tilde{X}, \tilde{Y}](e) = \lim_{h \rightarrow 0} \frac{1}{h} [Y - (R_{\exp hX})_* \tilde{Y}(e)] \\
 &= \lim_{h \rightarrow 0} \frac{1}{h} [Y - \text{Ad}(\exp -hX)Y].
 \end{aligned}$$

(Compare Problem I.10-19.)

On the other hand, if R_a now denotes the map $p \mapsto p \cdot a$ from M to G , then

$$(2) \quad R_{\exp hX} \circ \sigma_{p \cdot (\exp -hX)}(a) = p \cdot ([\exp -hX]a \exp hX).$$

Since $\phi_t(p) = p \cdot (\exp tX)$ is the 1-parameter group of diffeomorphisms generated by $\sigma(X)$, on M we have

$$\begin{aligned}
 [\sigma(X), \sigma(Y)](p) &= \lim_{h \rightarrow 0} \frac{1}{h} [\sigma(Y)(p) - [R_{\exp hX}]_* \sigma(Y)(p)] \\
 &= \lim_{h \rightarrow 0} \frac{1}{h} [\sigma_{p*} Y - \sigma_p(\text{Ad}(\exp -hX)Y)] && \text{by (2)} \\
 &= \sigma_{p*} \left(\lim_{h \rightarrow 0} \frac{1}{h} [Y - \text{Ad}(\exp -hX)Y] \right) = \sigma_{p*}([X, Y]) && \text{by (1)} \\
 &= \sigma([X, Y]).
 \end{aligned}$$

To prove (3), suppose $\sigma(X) = 0$. Then for every p the 1-parameter group of diffeomorphisms $\phi_t(p) = p \cdot (\exp tX)$ must be $\phi_t(p) = p$ (for the unique integral curve c of $\sigma(X)$ through p is clearly $c(p) = p$). If G acts effectively, this means that all $\exp tX = 0$, so $X = 0$.

To prove (4), suppose $\sigma(X)(p) = 0$ for some p . Then $p \cdot (\exp tX) = p$ for all t . If G acts without fixed point, then all $\exp tX = e$, so $X = 0$. ♦

Let us now apply this construction to a principal bundle $\pi: P \rightarrow M$, with group G . The map \cdot from $P \times G \rightarrow P$ is an action of G on P to the right (the map $u \mapsto u \cdot a$ is a diffeomorphism by condition (3) of the definition) and G acts without fixed point (we have already pointed out that this follows from condition (3)). Therefore we have the **fundamental vector field** $\sigma(X)$ corresponding to X for all $X \in \mathfrak{g}$; for every $u \in P$, the map $X \mapsto \sigma(X)(u)$ is an isomorphism, since G acts without fixed point. Since the maps $R_a: P \rightarrow P$ take fibres to themselves, the set of all $\sigma(X)(u)$ is precisely the set of vertical vectors at u .

2. PROPOSITION. For all $X \in \mathfrak{g}$ and $a \in G$, the vector field $(R_a)_*\sigma(X)$ is the fundamental vector field

$$(R_a)_*\sigma(X) = \sigma(\text{Ad}(a^{-1})X).$$

PROOF. Since $\phi_t(p) = p \cdot \exp tX = R_{\exp tX}(p)$ is the 1-parameter group of diffeomorphisms generated by $\sigma(X)$, it follows from Lemma I.5-11 that $(R_a)_*\sigma(X)$ generates the 1-parameter group of diffeomorphisms

$$\psi_t = R_a \circ R_{\exp tX} \circ R_a^{-1} = R_{a^{-1} \exp tX a}.$$

Now $\{a^{-1} \exp tX a\}$ is the 1-parameter group of diffeomorphisms of G generated by $\text{Ad}(a^{-1})X$. So ψ_t generates $\sigma(\text{Ad}(a^{-1})X)$. ♦

The vector fields $\sigma(X)$ are rather difficult to picture, especially since most principal bundles themselves are impossible to visualize. Nevertheless they will be very important, as we shall see upon returning to the structure which began our whole discussion, the principal bundle of frames $F(M)$. A **section** s of this bundle over an open set $U \subset M$ is a C^∞ map $s: U \rightarrow F(M)$ with $\pi \circ s = \text{identity map of } U$. Clearly, a section s is just what we used to call a moving frame on U . Note that, unlike a vector bundle, which always has a section defined on all of M , namely the 0-section, a principal bundle need not have such a section. In fact, if the principal bundle $\pi: P \rightarrow M$ over M with group G has a section $s: M \rightarrow P$, then the bundle is trivial: we can let $(p, a) \in M \times G$ correspond to $s(p) \cdot a \in P$.

We can use some of this new language to give an alternative, but completely equivalent, definition of a Cartan connection: A Cartan connection is an assignment of an $n \times n$ matrix-valued 1-form $\omega_s [= (\omega_{sj}^i)]$ to every section $s: U \rightarrow F(M)$ in such a way that

$$(*) \quad \omega_{s \cdot a} = a^{-1} da + a^{-1} \omega_s a$$

for every C^∞ function $a: U \rightarrow \text{GL}(n, \mathbb{R})$. (Here $s \cdot a$ is the section $(s \cdot a)(p) = s(p) \cdot a(p)$, the \cdot denoting the action of $\text{GL}(n, \mathbb{R})$ on $F(M)$.) This formulation of the definition suggests how we may obtain a definition of a connection which has all the advantages of the Cartan definition but which is also “invariant”. We ask if there is an $n \times n$ matrix-valued 1-form ω on the manifold $F(M)$ such that for each section (moving frame) s we have

$$\omega_s = s^*(\omega);$$

notice that previously we used ω alone to denote the connection form for some moving frame, but from now on we will have to be careful to use subscripts to distinguish the forms on M from the form ω which we hope to find on $F(M)$. Since the forms ω_s for a Cartan connection satisfy $(*)$, our question is then the following:

If we are given a collection of ω_s satisfying $(*)$, is there an ω on $F(M)$ such that each $\omega_s = s^*(\omega)$? More generally, which $n \times n$ matrix-valued 1-forms ω on $F(M)$ have the property that for every section $s: U \rightarrow F(M)$ and $\text{GL}(n, \mathbb{R})$ -valued function a on U we have

$$(**) \quad (s \cdot a)^*(\omega) = a^{-1} da + a^{-1} s^*(\omega) \cdot a?$$

In order to answer these questions, we need to know something about the section $s \cdot a$. If a has the constant value $A \in \text{GL}(n, \mathbb{R})$, then $s \cdot a = R_A \circ s$, where $R_A(u) = u \cdot A$, the dot denoting the action of $\text{GL}(n, \mathbb{R})$ on $F(M)$. So for any tangent vector $X_p \in M_p$ we have $(s \cdot a)_*(X_p) = R_{A*}(s_* X_p)$; when a is not constant there is a correction term.

3. PROPOSITION. Let s be a section of $F(M)$, over some open set U , and let $a: U \rightarrow \text{GL}(n, \mathbb{R})$ be C^∞ . Then for any tangent vector X_p at a point $p \in U$ we have

$$(s \cdot a)_*(X_p) = R_{a(p)*}(s_* X_p) + \sigma(a(p)^{-1} \cdot X_p(a))(s(p) \cdot a(p)).$$

[Note that $X_p(a)$ is an $n \times n$ matrix, so that $a(p)^{-1} \cdot X_p(a)$ is also an $n \times n$ matrix, and hence may be considered as an element of $\mathfrak{gl}(n, \mathbb{R})$, so $\sigma(a(p)^{-1} \cdot X_p(a))$ is a vector field on $F(M)$.]

PROOF. For convenience, let

$$m: F(M) \times \text{GL}(n, \mathbb{R}) \rightarrow F(M)$$

be $m(u, A) = u \cdot A$. Remember that the tangent space W of $F(M) \times \text{GL}(n, \mathbb{R})$ at (u, A) is isomorphic to the direct sum $F(M)_u \oplus \text{GL}(n, \mathbb{R})_A$, so we can consider

every element of W as a pair $(Y_1, Y_2) = Y_1 \oplus Y_2$, where $Y_1 \in F(M)_u$ and $Y_2 \in \text{GL}(n, \mathbb{R})_A$. Note that if

$$\begin{aligned} c_1 & \text{ is an integral curve in } F(M) && \text{for } Y_1 \\ c_2 & \text{ is an integral curve in } \text{GL}(n, \mathbb{R}) && \text{for } Y_2, \end{aligned}$$

then

$$\begin{aligned} t \mapsto m(c_1(t), A) = c_1(t) \cdot A & \text{ is an integral curve for } X \oplus 0 \\ t \mapsto m(u, c_2(t)) = u \cdot c_2(t) & \text{ is an integral curve for } 0 \oplus Y. \end{aligned}$$

Now let c be an integral curve for X_p . Since $s \cdot a = m \circ (s, a)$, we have

$$\begin{aligned} (s \cdot a)_*(X_p) &= m_*(s_*(X_p), a_*(X_p)) = m_*(s_*(X_p) \oplus a_*(X_p)) \\ &= \left. \frac{d}{dt} \right|_{t=0} s(c(t)) \cdot a(p) + \left. \frac{d}{dt} \right|_{t=0} s(p) \cdot a(c(t)). \end{aligned}$$

The first term on the right can be written as

$$\begin{aligned} \left. \frac{d}{dt} \right|_{t=0} R_{a(p)}(s(c(t))) &= R_{a(p)*} \left(\left. \frac{ds(c(t))}{dt} \right|_{t=0} \right) \\ &= R_{a(p)*}(s_*X_p). \end{aligned}$$

To identify the second term, recall that for all $u \in F(M)$ we have

$$\sigma(N)(u) = \sigma_{u*}(N), \quad \text{where } \sigma_u(A) = u \cdot A \text{ for } A \in \text{GL}(n, \mathbb{R}).$$

We write

$$s(p) \cdot a(c(t)) = s(p) \cdot a(p) \cdot [a(p)^{-1} \cdot a(c(t))].$$

The term in brackets gives a curve $\gamma(t) = a(p)^{-1} \cdot a(c(t))$ in $\text{GL}(n, \mathbb{R})$ with $\gamma(0) = I$; then $\gamma'(0) \in \text{GL}(n, \mathbb{R})_I = \mathfrak{gl}(n, \mathbb{R})$ is the tangent vector corresponding to the matrix

$$\left. \frac{d}{dt} \right|_{t=0} a(p)^{-1} \cdot a(c(t)) = a(p)^{-1} \cdot \left. \frac{d}{dt} \right|_{t=0} a(c(t)) = a(p)^{-1} \cdot X_p(a),$$

when we identify the $n \times n$ matrices with $\mathfrak{gl}(n, \mathbb{R})$. Consequently,

$$\begin{aligned} \left. \frac{d}{dt} \right|_{t=0} s(p) \cdot a(c(t)) &= \left. \frac{d}{dt} \right|_{t=0} s(p) \cdot a(p) \cdot [a(p)^{-1} a(c(t))] \\ &= \sigma_{s(p) \cdot a(p)*} \left(\left. \frac{d}{dt} \right|_{t=0} a(p)^{-1} a(c(t)) \right) \\ &= \sigma_{s(p) \cdot a(p)*}(a(p)^{-1} \cdot X_p(a)) \\ &= \sigma(a(p)^{-1} \cdot X_p(a))(s(p) \cdot a(p)). \quad \spadesuit \end{aligned}$$

Remark: Proposition 3 can actually be formulated for any principal bundle $\pi: P \rightarrow M$ over M , with group G . If s is a section over U and $a: U \rightarrow G$ is C^∞ , then for any tangent vector X_p at $p \in U$ we have

$$(s \cdot a)_*(X_p) = R_{a(p)*}(s_*X_p) + \sigma(L_{a(p)^{-1}*}a_*(X_p))(s(p) \cdot a(p)).$$

With Proposition 3 at hand, let us reconsider our question. We want to know which $n \times n$ matrix-valued 1-forms ω on $F(M)$ have the property that for each section s we have

$$(**) \quad (s \cdot a)^*(\omega) = a^{-1}da + a^{-1}s^*(\omega)a.$$

This is equivalent to saying that for every $X_p \in M_p$ we have

$$\omega((s \cdot a)_*X_p) = a^{-1}(p)X_p(a) + a^{-1}(p)\omega(s_*X_p)a(p).$$

According to Proposition 3 this is equivalent to

$$\begin{aligned} \omega(R_{a(p)*}(s_*X_p)) + \omega(\sigma(a(p)^{-1} \cdot X_p(a))(s(p) \cdot a(p))) \\ = a^{-1}(p)X_p(a) + a^{-1}(p)\omega(s_*X_p)a(p). \end{aligned}$$

We can extract two separate equations from this, as follows:

(I) First suppose that $a(p) = I$. Then we obtain

$$\omega(s_*X_p) + \omega(\sigma(X_p(a))(s(p))) = X_p(a) + \omega(s_*X_p),$$

or

$$(I) \quad \omega(\sigma(X_p(a))(s(p))) = X_p(a) \quad \text{for } a(p) = I.$$

(2) Now suppose a has the constant value A . Then we obtain

$$(II) \quad \omega(R_{A*}(s_*X_p)) = A^{-1}\omega(s_*X_p)A.$$

Conversely, it is not hard to show that if ω satisfies (I) and (II), then ω satisfies (**).

Now the equations (I) and (II) can be simplified considerably, resulting in equations that do not involve s at all. In (I), the matrix $X_p(a)$ can obviously be any $n \times n$ matrix, since we just have to satisfy $a(p) = I$. Since we can also choose any s , we see that (I) is equivalent to

$$(I') \quad \omega(\sigma(N)(u)) = N \quad \text{for all } N \in \mathfrak{gl}(n, \mathbb{R}) \text{ and } u \in F(M).$$

We claim that (II) is equivalent to

$$(II') \quad \omega(R_{A*}Y) = A^{-1}\omega(Y)A \quad \text{for all } Y \in F(M)_u.$$

To see this we note that by choosing s appropriately we can make s_*X_p be any vector in $u = s(p)$ that is not vertical; since the vertical vectors are all of the form $\sigma(N)$, equation (II') for vertical vectors follows from (I') and Proposition 2, remembering that for $GL(n, \mathbb{R})$ we have $\text{Ad}(A)N = ANA^{-1}$.

Summing up, we see that a matrix-valued 1-form ω on $F(M)$ satisfies

$$(s \cdot a)^*(\omega) = a^{-1}da + a^{-1}s^*(\omega)a$$

[and consequently the assignment of $s^*\omega$ to s is a Cartan connection] if and only if

$$\begin{aligned} \omega(\sigma(N)) &= N & \text{for all } N \in \mathfrak{gl}(n, \mathbb{R}) \\ \omega(R_{A*}(Y)) &= A^{-1}\omega(Y)A = \text{Ad}(A^{-1})\omega(Y) & \text{for all } Y \in F(M)_u. \end{aligned}$$

We leave it to the reader to show that if we are given a Cartan connection $\{\omega_s\}$, then there is a unique such ω on $F(M)$ with $\omega_s = s^*(\omega)$. (Define $\omega(Y_u) = \omega_s(X_p)$ whenever $Y_u = s_*X_p$, and use Proposition 3 and the transformation rules for a Cartan connection to verify that ω is well-defined.) We are consequently ready for the final definition of a connection; since all our conditions make sense in *any* principal bundle, our new definition is not only more abstract, more elegant, and more incomprehensible, but also more general.

An **(Ehresmann) connection** in a principal bundle $\pi: P \rightarrow M$ over M with group G is a C^∞ \mathfrak{g} -valued 1-form ω on P such that

- (1) $\omega(\sigma(X)) = X$ for all $X \in \mathfrak{g}$
- (2) $\omega(R_{a*}Y) = \text{Ad}(a^{-1})\omega(Y)$ for all $a \in G$, and all tangent vectors Y on E .

If ω is an Ehresmann connection, then the map $\omega(u): P_u \rightarrow \mathfrak{g}$ is onto for every $u \in P$, by (1), so its kernel $H_u = \ker \omega(u)$ is a subspace of P_u having the same dimension as M . This subspace is called the **horizontal subspace** at u (determined by the connection), and tangent vectors in H_u are called **horizontal**. Thus every Ehresmann connection ω on P gives rise to a certain distribution H on P .

4. PROPOSITION. If H is the distribution on P determined by an Ehresmann connection ω , then

- (1) $P_u = V_u \oplus H_u$
- (2) $H_{u \cdot a} = (R_a)_* H_u$
- (3) H is a C^∞ distribution.

Conversely, if H is a distribution on P satisfying (1)–(3), then H is the distribution determined by a unique Ehresmann connection ω .

PROOF. Condition (1) is obvious from the definition of H_u as $\ker \omega(u)$ (and the fact that $\omega(u)$ is onto \mathfrak{g}).

If $Y \in H_u$, then

$$\begin{aligned} \omega(u \cdot a)(R_{a*}Y) &= \omega(R_{a*}Y) \\ &= \text{Ad}(a^{-1})\omega(Y) && \text{by condition (2) in the} \\ &= 0, && \text{definition of a connection} \end{aligned}$$

so $R_{a*}Y \in H_{u \cdot a}$. Since R_{a*} is one-one, and $\dim H_u = \dim H_{u \cdot a}$, it follows that $H_{u \cdot a} = (R_a)_* H_u$.

To prove that H is a C^∞ distribution, choose vector fields $Y_1, \dots, Y_n, \dots, Y_{n+k}$ which span P_v for all v in a neighborhood of u . Let X_1, \dots, X_k be a basis for \mathfrak{g} , so that we can write $\omega = \sum_j \omega^j \cdot X_j$ for ordinary C^∞ 1-forms ω^j on P . Let \bar{Y}_i be the vector field

$$\bar{Y}_i = Y_i - \sum_j \omega^j(Y_i) \sigma(X_j).$$

The C^∞ vector fields \bar{Y}_i are clearly horizontal and span the distribution H in a neighborhood of u .

Conversely, given H , we (must) define ω by $\omega(Y) = 0$ for Y horizontal and $\omega(\sigma(X)) = X$ for $X \in \mathfrak{g}$. Then ω is C^∞ , since $\omega(Y)$ is C^∞ when Y is a horizontal vector field, or when $Y = \sigma(X)$, and these vector fields span the set of all vector fields, over the C^∞ functions. Condition (1) for a connection holds by definition of ω . To prove condition (2), we need only prove it for horizontal Y and vertical Y . If Y is horizontal, then $(R_a)_*Y$ is also, by condition (2) on H , so we have

$$\omega((R_a)_*Y) = 0 = \text{Ad}(a^{-1})\omega(Y).$$

When Y is vertical, we may assume that $Y = \sigma(X)$ for $X \in \mathfrak{g}$. Then $(R_a)_*Y = \sigma(\text{Ad}(a^{-1})X)$ by Proposition 2. So

$$\omega((R_a)_*Y) = \text{Ad}(a^{-1})X = \text{Ad}(a^{-1})\omega(Y),$$

as desired. ♦

Often, a connection is *defined* to be a distribution H satisfying (1)–(3) of Proposition 4, and ω is defined as in the second part of the proof—it is then called the “connection form” for the connection H . Using the decomposition given by (1) of Proposition 4, we can write, for any tangent vector $Y \in P_u$, a unique expression

$$Y = v(Y) + h(Y)$$

where $v(Y)$, the **vertical component** of Y , is vertical and $h(Y)$, the **horizontal component** of Y , is horizontal. As we noted in the proof of Proposition 4,

$$h(Y) = Y - \sum_j \omega^j(Y) \sigma(X_j).$$

From this formula it is clear that $h(Y)$, and hence $v(Y)$, is C^∞ if Y is C^∞ .

From the decomposition $P_u = V_u \oplus H_u$ and the fact that V_u is the kernel of $\pi_*: P_u \rightarrow M_{\pi(u)}$, it is also clear that $\pi_*: H_u \rightarrow M_{\pi(u)}$ is an isomorphism for each $u \in P$. Consequently, for every vector field X on M there is a unique vector field X^* on P such that X^* is everywhere horizontal and $\pi_*(X^*_u) = X_{\pi(u)}$ for all $u \in P$; this vector field X^* is called the **lift** of X . There are two simple propositions about lifts.

5. PROPOSITION. If X is a C^∞ vector field on M , then X^* is a C^∞ vector field on P , and for all $a \in G$ we have $R_{a*}(X^*) = X^*$. Conversely, if Y is a horizontal vector field on P such that $R_{a*}(Y) = Y$ for all $a \in G$, then $Y = X^*$ for a unique vector field X on M .

PROOF. Using local triviality, we can choose a C^∞ vector field X' on some $\pi^{-1}(U) \subset P$ such that $\pi_*(X'_u) = X_{\pi(u)}$ for all $u \in \pi^{-1}(U)$. Then $X^* = h(X')$ is also C^∞ . The other parts are left to the reader. ♦

6. PROPOSITION. If X^* and Y^* are the lifts of vector fields X and Y on M , then

- (1) $X^* + Y^*$ is the lift of $X + Y$
- (2) for every $f: M \rightarrow \mathbb{R}$ we have $(fX)^* = (f \circ \pi) \cdot X^*$
- (3) $h([X^*, Y^*]) = [X, Y]^*$.

PROOF. The first two parts are trivial. For the third, we note that X^* and Y^* are π -related, so by Proposition I.6-3,

$$\pi_*(h[X^*, Y^*]_u) = \pi_*([X^*, Y^*]_u) = [X, Y]_{\pi(u)}. \quad \blacklozenge$$

Our aim now is to develop, and generalize, the material of the last three chapters, from the point of view of Ehresmann connections. The topics to be discussed include parallel translation, covariant derivatives, the curvature and torsion tensors, the structural equations, and the Bianchi identities. Presumably, somewhere along the way an elegant proof of the Test Case will also turn up. Be prepared for some unappetizing complexity—this is the price of invariance! One problem is that all the interesting information about a connection resides in the horizontal subspaces, but formulas about forms on a principal bundle also have to reckon with the vertical vectors [which is what clause (1) in the definition of an Ehresmann connection is designed to do].

We begin with a discussion of parallel translation. A piecewise C^1 curve $\gamma: [0, 1] \rightarrow P$ is called **horizontal** if all tangent vectors $\gamma'(t^+)$ and $\gamma'(t^-)$ are horizontal vectors. Now if $c: [0, 1] \rightarrow M$ is piecewise C^1 , we define a **lift** of c to be a horizontal curve $c^*: [0, 1] \rightarrow P$ such that c^* *covers* c , i.e., such that $\pi \circ c^* = c$. Notice that if c^* is a lift of c , then so is $R_a \circ c^*$, by Proposition 4(2).

7. PROPOSITION. Let $c: [0, 1] \rightarrow M$ be a piecewise C^1 curve, and choose $u_0 \in P$ with $\pi(u_0) = c(0)$. Then there is a unique lift c^* of c with $c^*(0) = u_0$.

PROOF. Using local triviality of the principal bundle, it is easy to show that there is a curve $\gamma: [0, 1] \rightarrow P$ with $\gamma(0) = u_0$ and $\pi \circ \gamma = c$. A lift c^* of c must be of the form $c^*(t) = \gamma(t) \cdot a(t)$ for some $a: [0, 1] \rightarrow G$ with $a(0) = e$. Using the method of proof for Proposition 3 (see also the Remark following it), we find that

$$c^{*'}(t) = R_{a(t)*}(\gamma'(t)) + \sigma(L_{a(t)^{-1}*}a'(t))(c^*(t)).$$

Consequently,

$$\omega(c^{*'}(t)) = \text{Ad}(a(t)^{-1})\omega(\gamma'(t)) + L_{a(t)^{-1}*}a'(t).$$

Now c^* is horizontal if and only if $\omega(c^{*\prime}(t)) = 0$; using the above equation, and remembering the definition of Ad , this means that

$$\begin{aligned} L_{a(t)^{-1}*}a'(t) &= -L_{a(t)^{-1}*}R_{a(t)*}\omega(\gamma'(t)), \\ a'(t) &= -R_{a(t)*}\omega(\gamma'(t)). \end{aligned}$$

In this equation, $\omega(\gamma'(t))$ is a given curve in \mathfrak{g} . If we introduce a coordinate system on G , this equation becomes a differential equation for a , and we know that a unique solution exists locally. So we can always find a lift c^* defined in a neighborhood of any $t \in [0, 1]$, with $c^*(t) = u$ for any given $u \in \pi^{-1}(c(t))$; moreover, this lift is unique.

We now have to show that the lift can be defined on all of $[0, 1]$; clearly we just have to show that a lift on $[0, t_0)$ can be extended past t_0 . To do this, pick a lift \bar{c}^* defined in a neighborhood of t_0 (with any old initial condition $\bar{c}^*(t_0)$). Choose $t_1 < t_0$ so that \bar{c}^* is defined at t_1 , and then choose $a \in G$ with $c^*(t_1) = \bar{c}^*(t_1) \cdot a$. Clearly we can extend c^* past t_0 by letting it be $R_a \circ \bar{c}^*$. ♦

Notice that the last part of this argument is just that used in the proof of Proposition I.5-17. The first part of the argument is much simpler when we are looking for a lift in a neighborhood of a point t with $c'(t) \neq 0$. For then (a portion of) c is the integral curve of a vector field X on M , and c^* is just an integral curve of the lift X^* .

Using Proposition 7, we can now define **parallel translation** of fibres of the principal bundle $\pi: P \rightarrow M$ along any curve $c: [0, 1] \rightarrow M$. For any $u \in \pi^{-1}(c(0))$ we let $\tau_t(u) \in \pi^{-1}(c(t))$ be $c^*(t)$, where c^* is the lift of c with $c^*(0) = u$. In this way we obtain a map

$$\tau_t: \pi^{-1}(c(0)) \rightarrow \pi^{-1}(c(t)).$$

It is clear that $\tau_t \circ R_a = R_a \circ \tau_t$, since $R_a \circ c^*$ is again a lift. The map τ_t is a diffeomorphism whose inverse is just the parallel translation along the reversed portion of c from t to 0.

Consider, in particular, the principal bundle of frames $\pi: F(M) \rightarrow M$. Every frame $u \in F(M)$ determines an isomorphism from \mathbb{R}^n to $M_{\pi(u)}$; namely, we send $e_i \in \mathbb{R}^n$ to $u_i \in M_{\pi(u)}$. This isomorphism will be denoted by the same letter, $u: \mathbb{R}^n \rightarrow M_{\pi(u)}$. It is easy to check that for $\xi \in \mathbb{R}^n$ we have

$$(u \cdot a)(\xi) = u(a \cdot \xi),$$

where the product $a \cdot \xi$ of an $n \times n$ matrix a and a vector $\xi \in \mathbb{R}^n$ is defined in the footnote on page 262. Now suppose $c: [0, 1] \rightarrow M$ is a piecewise C^1 curve,

$X_p \in M_p$ is a tangent vector at $p = c(0)$, and $c^*: [0, 1] \rightarrow F(M)$ is a lift of c with $c^*(0) = u$. There is a unique $\xi \in \mathbb{R}^n$ with $c^*(0)(\xi) = u(\xi) = X_p$; we let

$$\tau_t(X_p) = c^*(t)(\xi),$$

thus defining parallel translation of vectors. To check that this parallel translation is well-defined, we consider any other lift, which must be of the form $\bar{c}^* = R_a \circ c^*$. Then

$$\begin{aligned} X_p &= c^*(0)(\xi) = c^*(0) \cdot a(a^{-1} \cdot \xi) \\ &= \bar{c}^*(0)(a^{-1} \cdot \xi), \end{aligned}$$

so for the parallel translation $\bar{\tau}_t$ defined with respect to \bar{c}^* we have

$$\begin{aligned} \bar{\tau}_t(X_p) &= \bar{c}^*(t)(a^{-1} \cdot \xi) = c^*(t) \cdot a(a^{-1} \cdot \xi) = c^*(t)(\xi) \\ &= \tau_t(X_p). \end{aligned}$$

If we choose $c^*(0) = u$ so that $u((1, 0, \dots, 0)) = X_p$, we see that we can parallel translate X_p by making it the first vector in a basis, parallel translating the basis, and then taking the first vector in the translated basis. It is also easy to see that τ_t is a vector space isomorphism.

Having defined parallel translation of vectors, we can now define covariant differentiation of vector fields by the formula on page 234,

$$(*) \quad \nabla_{X_p} Y = \lim_{h \rightarrow 0} \frac{1}{h} (\tau_h^{-1} Y_{c(h)} - Y_p),$$

where $c(0) = p$ and $c'(0) = X_p$. It is not yet clear that this covariant differentiation is the same as the one we obtained on page 285 from the corresponding Cartan connection $\{s^*\omega\}$; to prove this we will need a Lemma that is also used frequently later on. Given the vector field Y , we consider the function $f_Y: F(M) \rightarrow \mathbb{R}^n$ whose value at a frame v is just the set of components of $Y_{\pi(v)}$ with respect to v —in symbols,

$$f_Y(v) = v^{-1}(Y_{\pi(v)}).$$

8. LEMMA. Let Y be a vector field on M , and let $X_p \in M_p$. Then for any $u \in F(M)$ with $p = \pi(u)$ we have

$$\nabla_{X_p} Y = u(X^*_u(f_Y)),$$

where $X^*_u \in P_u$ is the unique horizontal vector with $\pi_*(X^*_u) = X_p$ [notice that since $f: P \rightarrow \mathbb{R}^n$, the value $X^*_u(f_Y)$ of the vector X^*_u on f_Y is an element of \mathbb{R}^n , so $u(X^*_u(f_Y)) \in M_p$ makes sense].

PROOF. Let c be a curve with $c(0) = p$ and $c'(0) = X_p$, and let c^* be the lift of c with $c^*(0) = u$, so that $c^{*'}(0) = X_u^*$. Recall the definition of the parallel translation $\tau_h^{-1}(Y_{c(h)})$ of $Y_{c(h)}$ along the reversed part of c from 0 to h : we choose $\xi \in \mathbb{R}^n$ with

$$c^*(h)(\xi) = Y_{c(h)} \quad \text{or} \quad c^*(h)^{-1}(Y_{c(h)}) = \xi$$

and then define

$$\tau_h^{-1}(Y_{c(h)}) = c^*(0)(\xi) = u(\xi).$$

Consequently,

$$u \circ c^*(h)^{-1}(Y_{c(h)}) = \tau_h^{-1}(Y_{c(h)}).$$

So we have

$$\begin{aligned} \nabla_{X_p} Y &= \lim_{h \rightarrow 0} \frac{1}{h} [\tau_h^{-1}(Y_{c(h)}) - Y_p] \\ &= \lim_{h \rightarrow 0} \frac{1}{h} [u \circ c^*(h)^{-1}(Y_{c(h)}) - u \circ u^{-1}(Y_p)] \\ &= u \left(\lim_{h \rightarrow 0} \frac{1}{h} [c^*(h)^{-1}(Y_{c(h)}) - u^{-1}(Y_p)] \right) \\ &= u \left(\lim_{h \rightarrow 0} \frac{1}{h} [f_Y(c^*(h)) - f_Y(u)] \right) \\ &= u(X_u^*(f_Y)). \quad \blacklozenge \end{aligned}$$

9. PROPOSITION. The ∇ defined by (*) is a Koszul connection; that is,

- (1) $\nabla_{X_p + X'_p} Y = \nabla_{X_p} Y + \nabla_{X'_p} Y$
- (2) $\nabla_{X_p}(Y_1 + Y_2) = \nabla_{X_p} Y_1 + \nabla_{X_p} Y_2$
- (3) $\nabla_{aX_p} Y = a \nabla_{X_p} Y$ for all $a \in \mathbb{R}$
- (4) $\nabla_{X_p}(fY) = f(p) \cdot \nabla_{X_p} Y + X_p(f) \cdot Y_p$
- (5) if X and Y are C^∞ vector fields, then so is $p \mapsto \nabla_{X_p} Y$.

PROOF. Equations (2), (3), and (4) are easy to prove from the definition. Condition (5) follows from Lemma 8, since we can choose a C^∞ section $p \mapsto u(p)$ in a neighborhood of p . Equation (1) also follows from the Lemma, since we have $(X_p + X'_p)^* = X_u^* + X'^*_u$. \blacklozenge

Now let us compare this Koszul connection ∇ with the one obtained from the Cartan connection corresponding to an Ehresmann connection ω on $F(M)$. We can write $\omega = (\omega_j^i)$, where each ω_j^i in the matrix is an ordinary 1-form on $F(M)$. Equivalently, we can write

$$\omega = \sum_{i,j} \omega_j^i \cdot E_i^j,$$

where E_i^j is the matrix with zeros everywhere except for a 1 in the i^{th} row and the j^{th} column, so that

$$(E_i^j)_{\beta}^{\alpha} = \delta_i^{\alpha} \delta_{\beta}^j.$$

Let (x, U) be a coordinate system, and let $s: U \rightarrow F(M)$ be the “natural section”

$$s(q) = \left(\frac{\partial}{\partial x^1} \Big|_q, \dots, \frac{\partial}{\partial x^n} \Big|_q \right).$$

Then the Cartan connection corresponding to ω assigns $(s^* \omega_j^i)$ to this moving frame. So the operation $\bar{\nabla}$ defined on page 285 is determined on U by

$$\bar{\nabla}_{\frac{\partial}{\partial x^i}} \frac{\partial}{\partial x^j} = \sum_k s^* \omega_j^k \left(\frac{\partial}{\partial x^i} \right) \frac{\partial}{\partial x^k} = \sum_k \omega_j^k \left(s_* \frac{\partial}{\partial x^i} \right) \frac{\partial}{\partial x^k}.$$

10. PROPOSITION. These two connections are the same, $\bar{\nabla} = \nabla$.

PROOF. It obviously suffices to show that $\bar{\nabla}_{\partial/\partial x^i} \partial/\partial x^j = \nabla_{\partial/\partial x^i} \partial/\partial x^j$, since $\bar{\nabla}$ and ∇ are both Koszul connections. Let $f = f_{\partial/\partial x^i}$. By Proposition 8, it suffices to show that

$$\begin{aligned} \sum_k \omega_j^k \left(s_* \left(\frac{\partial}{\partial x^i} \Big|_p \right) \right) \frac{\partial}{\partial x^k} \Big|_p &= s(p) \left(\left(\frac{\partial}{\partial x^i} \right)^*_{s(p)} (f) \right) \\ &= \sum_k \left[\left(\frac{\partial}{\partial x^i} \right)^*_{s(p)} (f^k) \right] \cdot \frac{\partial}{\partial x^k} \Big|_p. \end{aligned}$$

So we need to show that

$$\omega_j^k \left(s_* \left(\frac{\partial}{\partial x^i} \Big|_p \right) \right) = \left(\frac{\partial}{\partial x^i} \right)^*_{s(p)} (f^k).$$

Now, by definition of f we have

$$(*) \quad \sum_k f^k(u) \cdot u_k = \frac{\partial}{\partial x^j} \Big|_{\pi(u)} \quad \text{for all } u = (u_1, \dots, u_n) \in F(M).$$

In particular,

$$f^k(s(q)) = \delta_j^k.$$

Writing equation (*) for $u = s(p) \cdot \exp tN$, and differentiating with respect to t , we obtain

$$\sum_k \frac{d}{dt} \Big|_{t=0} f^k(s(p) \cdot \exp tN) \cdot \frac{\partial}{\partial x^k} \Big|_p + \sum_k f^k(s(p)) \cdot \frac{d}{dt} \Big|_{t=0} (s(p) \cdot \exp tN) = 0,$$

and hence

$$\sum_k \sigma(N)_{s(p)}(f^k) \cdot \frac{\partial}{\partial x^k} \Big|_p = - \sum_k \delta_j^k(s(p) \cdot N)_k = -(s(p) \cdot N)_j.$$

In particular,

$$\begin{aligned} \sum_k \sigma(E_\mu^v)_{s(p)}(f^k) \cdot \frac{\partial}{\partial x^k} \Big|_p &= -(s(p) \cdot E_\mu^v)_j = -(E_\mu^v)_j^\beta \sum_\beta \frac{\partial}{\partial x^\beta} \Big|_p \\ &= -\delta_\mu^\beta \delta_j^v \sum_\beta \frac{\partial}{\partial x^\beta} \Big|_p = -\delta_j^v \frac{\partial}{\partial x^\mu} \Big|_p. \end{aligned}$$

So

$$\sigma(E_\mu^v)_{s(p)}(f^k) = \begin{cases} -\delta_\mu^v & k = \mu \\ 0 & k \neq \mu. \end{cases}$$

Now the lift $(\partial/\partial x^i)^*$ of $\partial/\partial x^i$ at points $s(q)$ is given by

$$\frac{\partial}{\partial x^i}^* = h \left(s_* \left(\frac{\partial}{\partial x^i} \right) \right) = s_* \left(\frac{\partial}{\partial x^i} \right) - \sum_{\mu, v} \omega_v^\mu \left(s_* \left(\frac{\partial}{\partial x^i} \right) \right) \sigma(E_\mu^v).$$

So

$$\begin{aligned} \left(\frac{\partial}{\partial x^i}^* \right)_{s(p)} (f^k) &= \frac{\partial(f^k \circ s)}{\partial x^i}(p) - \sum_{\mu, v} \omega_v^\mu \left(s_* \left(\frac{\partial}{\partial x^i} \Big|_p \right) \right) \sigma(E_\mu^v)_{s(p)}(f^k) \\ &= \frac{\partial(\delta_j^k)}{\partial x^i} - \sum_v \omega_v^k \left(s_* \left(\frac{\partial}{\partial x^i} \Big|_p \right) \right) (-\delta_j^v) \\ &= \omega_j^k \left(s_* \left(\frac{\partial}{\partial x^i} \Big|_p \right) \right) \cdot \diamond \end{aligned}$$

There is no need to repeat here the definition of $\nabla_X A$ for arbitrary tensor fields A ; this can be defined in either of the two ways used in Chapter 6, and we will use any results from that chapter which we require.

We return for a moment to a connection ω on a general principal bundle $\pi: P \rightarrow M$ with group G . Consider a k -form α on P , with values in a vector space V . We define a V -valued $(k+1)$ -form $D\alpha$, the **covariant differential** of α , by

$$D\alpha(Y_1, \dots, Y_{k+1}) = (d\alpha)(hY_1, \dots, hY_{k+1}),$$

where d is the ordinary differential and hY is the horizontal component of Y . In particular, we define the **curvature form** Ω of ω by $\Omega = D\omega$. Thus Ω is a \mathfrak{g} -valued 2-form on P .

11. PROPOSITION. For all $a \in G$, we have $R_a^* \Omega = \text{Ad}(a^{-1})\Omega$. In other words, for all tangent vectors $Y_1, Y_2 \in P_u$ we have

$$R_a^* \Omega(Y_1, Y_2) = \text{Ad}(a^{-1})\Omega(Y_1, Y_2)$$

[this makes sense since $\Omega(Y_1, Y_2) \in \mathfrak{g}$].

PROOF. We have

$$\begin{aligned} R_a^* \Omega(Y_1, Y_2) &= R_a^*(d\omega)(hY_1, hY_2) \\ &= d(R_a^* \omega)(hY_1, hY_2) \\ &= d(\text{Ad}(a^{-1})\omega)(hY_1, hY_2) \\ &= \text{Ad}(a^{-1})[d\omega(hY_1, hY_2)] && \text{since } \text{Ad}(a^{-1}): \mathfrak{g} \rightarrow \mathfrak{g} \\ &&& \text{is linear} \\ &= \text{Ad}(a^{-1})\Omega(Y_1, Y_2). \quad \spadesuit \end{aligned}$$

We will eventually see that this Ω does indeed correspond to the Ω in Chapter 7, but we first introduce the analogue of Θ . This analogue cannot be defined for connections in all principal bundles, but only for connections ω in the bundle of frames $\pi: F(M) \rightarrow M$. On this bundle we have a certain \mathbb{R}^n -valued 1-form θ , defined by

$$\theta_u(Y_u) = u^{-1}(\pi_* Y_u).$$

We will call this 1-form the **canonical form** or the **dual form** of the principal bundle $F(M)$. To see the appropriateness of the latter term, consider a section $s: U \rightarrow F(M)$ given by $s = (X_1, \dots, X_n)$. For any tangent vector $Y_p \in M_p$ we have

$$s^* \theta(Y_p) = \theta_{s(p)}(s_* Y_p) = s(p)^{-1}(Y_p),$$

so for the i^{th} component θ^i of θ we have

$$\begin{aligned} s^*\theta^i(Y_p) &= i^{\text{th}} \text{ component of } s(p)^{-1}(Y_p) \\ &= i^{\text{th}} \text{ component of } Y_p \text{ with respect to the basis } X_1(p), \dots, X_n(p). \end{aligned}$$

Thus, the $s^*\theta^i$ are just the dual forms for the moving frame (X_1, \dots, X_n) .

We now define the **torsion form** Θ of a connection ω on $F(M)$ by $\Theta = D\theta$ (this depends on ω , since h , and hence D , depends on ω).

12. PROPOSITION. For all $A \in \text{GL}(n, \mathbb{R})$ we have

$$R_A^*\theta = A^{-1} \cdot \theta, \quad R_A^*\Theta = A^{-1} \cdot \Theta.$$

In other words, for all tangent vectors $Y_1, Y_2 \in P_u$ we have

$$\begin{aligned} R_A^*\theta(Y_1) &= A^{-1} \cdot \theta(Y_1) \\ R_A^*\Theta(Y_1, Y_2) &= A^{-1} \cdot \Theta(Y_1, Y_2) \end{aligned}$$

[these equations make sense since $\theta(Y_1), \Theta(Y_1, Y_2) \in \mathbb{R}^n$].

PROOF. For θ we have

$$\begin{aligned} R_A^*\theta(Y_1) &= \theta_{u \cdot a}(R_{A*}Y_1) = (u \cdot A)^{-1}(\pi_*Y_1) \\ &= A^{-1} \cdot u^{-1}(\pi_*Y_1) \\ &= A^{-1} \cdot \theta(Y_1). \end{aligned}$$

Then for Θ we have

$$\begin{aligned} R_A^*\Theta(Y_1, Y_2) &= R_A^*(d\theta)(hY_1, hY_2) \\ &= d(R_A^*\theta)(hY_1, hY_2) \\ &= d(A^{-1} \cdot \theta)(hY_1, hY_2) \\ &= A^{-1} \cdot d\theta(hY_1, hY_2) \\ &= A^{-1} \cdot \Theta(Y_1, Y_2). \quad \spadesuit \end{aligned}$$

A connection ω in the bundle of frames $F(M)$ also allows us to define certain special vector fields in $F(M)$. For $\xi \in \mathbb{R}^n$ we define the **basic vector field** $B(\xi)$ **corresponding to** ξ by letting $B(\xi)_u$ be the unique horizontal vector at u such that $\pi_*(B(\xi)_u) = u(\xi)$. In particular, $B(e_i)_u$ is the unique horizontal vector at u which covers u_i .

13. PROPOSITION. For all $\xi \in \mathbb{R}^n$ we have

- (1) $\theta(B(\xi)) = \xi$
- (2) $R_{A*}B(\xi) = B(A^{-1} \cdot \xi)$ for all $A \in \text{GL}(n, \mathbb{R})$.

Moreover, if $\xi \neq 0$, then $B(\xi)$ is nowhere 0. Consequently, if ξ_1, \dots, ξ_n is a basis for \mathbb{R}^n , then $B(\xi_1)_u, \dots, B(\xi_n)_u$ is a basis for H_u .

PROOF. (1) and (2) are left to the reader. For the third assertion, note that if $B(\xi)_u = 0$, then

$$0 = \pi_*(B(\xi)_u) = u(\xi),$$

so $\xi = 0$. The final assertion follows immediately. ♦

To prove the structural equations in our new setup, we need two lemmas; the first involves fundamental vector fields and basic vector fields, but the second, which holds for connections in any bundle, involves fundamental vector fields and arbitrary horizontal vector fields.

14. LEMMA. Consider the basic vector fields determined by a connection on the bundle of frames $F(M)$. For every $N \in \mathfrak{gl}(n, \mathbb{R})$ and $\xi \in \mathbb{R}^n$ we have

$$[\sigma(N), B(\xi)] = B(N \cdot \xi).$$

PROOF. Since $\phi_t(u) = u \cdot \exp tN = R_{\exp tN}(u)$ is the 1-parameter group of diffeomorphisms generated by $\sigma(N)$, we have

$$\begin{aligned} [\sigma(N), B(\xi)] &= \lim_{t \rightarrow 0} \frac{1}{t} [B(\xi) - R_{\exp tN*}B(\xi)] \\ &= \lim_{t \rightarrow 0} \frac{1}{t} [B(\xi) - B([\exp -tN] \cdot \xi)] && \text{by Proposition 13} \\ &= B\left(\lim_{t \rightarrow 0} \frac{1}{t} (\xi - (\exp -tN) \cdot \xi)\right) && \text{since } \xi \mapsto B(\xi) \text{ is linear onto } H_u \\ &= B(N \cdot \xi). \quad \diamond \end{aligned}$$

15. LEMMA. Consider a connection on any principal bundle P over M with group G . For any $X \in \mathfrak{g}$ and any horizontal vector field Y on P , the vector field $[\sigma(X), Y]$ is also horizontal.

PROOF. We have

$$[\sigma(X), Y] = \lim_{t \rightarrow 0} \frac{1}{t} [Y - R_{\exp tX*}(Y)].$$

Since Y is horizontal, so is each $R_{\exp tX*}(Y)$. ♦

16. THEOREM. Let ω be a connection on a principal bundle P over M . If P is the bundle of frames, with the dual form θ , and the torsion form Θ determined by ω , then we have the **first structural equation**:

$$d\theta(Y_1, Y_2) = -\{\omega(Y_1) \cdot \theta(Y_2) - \omega(Y_2) \cdot \theta(Y_1)\} + \Theta(Y_1, Y_2) \quad \text{for all } Y_1, Y_2 \in P_u$$

[where $\omega(Y_1) \cdot \theta(Y_2)$ is the action of the matrix $\omega(Y_1)$ on $\theta(Y_2) \in \mathbb{R}^n$].

If P is any principal bundle, and Ω is the curvature form of ω , then we have the **second structural equation**:

$$d\omega(Y_1, Y_2) = -[\omega(Y_1), \omega(Y_2)] + \Omega(Y_1, Y_2) \quad \text{for all } Y_1, Y_2 \in P_u.$$

PROOF. Since each Y_i is the sum of a vertical and a horizontal vector, and since both sides of the first structural equation are skew-symmetric and bilinear, we can prove this equation by considering 3 cases.

Case 1. Y_1 and Y_2 are horizontal. Then $\omega(Y_i) = 0$, so the equation reduces to the definition of Θ as $D\theta$.

Case 2. Y_1 and Y_2 are vertical. Then the right side is 0. If we extend Y_1 and Y_2 to vertical vector fields \tilde{Y}_1 and \tilde{Y}_2 , then the left side is the value at u of

$$Y_1(\theta(Y_2)) - Y_2(\theta(Y_1)) - \theta([Y_1, Y_2]),$$

which is 0, since $[Y_1, Y_2]$ is also vertical.

Case 3. Y_1 is vertical and Y_2 is horizontal. Let $Y_1 = \sigma(N)_u$ for $N \in \mathfrak{gl}(n, \mathbb{R})$ and let $Y_2 = B(\xi)_u$ for $\xi \in \mathbb{R}^n$. Then

$$-\{\omega(Y_1) \cdot \theta(Y_2) - \omega(Y_2) \cdot \theta(Y_1)\} + \Theta(Y_1, Y_2) = -N \cdot \xi + 0 + 0,$$

while we have

$$\begin{aligned} d\theta(Y_1, Y_2) &= \sigma(N)(\theta(B(\xi)))(u) - B(\xi)(\theta(\sigma(N)))(u) - \theta([\sigma(N), B(\xi)])(u) \\ &= 0 - 0 - \theta(B(N \cdot \xi))(u) \quad \text{by Lemma 14} \\ &= -N \cdot \xi. \end{aligned}$$

This proves the first structural equation.

The second structural equation will be proved similarly.

Case 1. Y_1 and Y_2 are horizontal. The proof is as before.

Case 2. Y_1 and Y_2 are vertical. Let $Y_i = \sigma(X_i)_u$ for $X_i \in \mathfrak{g}$. Then $\Omega(Y_1, Y_2) = 0$, while

$$\begin{aligned} d\omega(Y_1, Y_2) &= \sigma(X_1)(\omega(\sigma(X_2)))(u) \\ &\quad - \sigma(X_2)(\omega(\sigma(X_1)))(u) - \omega([\sigma(X_1), \sigma(X_2)])(u) \\ &= 0 - 0 - \omega(\sigma([X_1, X_2]))(u) \quad \text{by Proposition 2} \\ &= -[X_1, X_2] = -[\omega(Y_1), \omega(Y_2)]. \end{aligned}$$

Case 3. Y_1 is vertical and Y_2 is horizontal. Then the right side is 0. If we extend Y_2 to a horizontal vector field \tilde{Y}_2 and let $Y_1 = \sigma(X)_u$ for $X \in \mathfrak{g}$, then the left side is the value at u of

$$\sigma(X)(\omega(\tilde{Y}_2)) - \tilde{Y}_2(\omega(\sigma(X))) - \omega([\sigma(X), \tilde{Y}_2]) = 0, \quad \text{by Lemma 15. } \spadesuit$$

The structural equations for a connection ω on the bundle of frames $F(M)$ can also be written in terms of ordinary forms. With respect to the standard basis e_1, \dots, e_n of \mathbb{R}^n we can write the \mathbb{R}^n -valued forms θ and Θ as

$$\theta = \sum_i \theta^i \cdot e_i \quad \Theta = \sum_i \Theta^i \cdot e_i,$$

for certain ordinary forms θ^i and Θ^i . Similarly, with respect to the basis E_i^j of $\mathfrak{gl}(n, \mathbb{R})$ introduced previously, we can write

$$\omega = \sum_{i,j} \omega_j^i \cdot E_i^j \quad \Omega = \sum_{i,j} \Omega_j^i \cdot E_i^j.$$

It is easy to see that the structural equations can then be written

$$\begin{aligned} d\theta^i &= -\sum_j \omega_j^i \wedge \theta^j + \Theta^i \\ d\omega_j^i &= -\sum_k \omega_k^i \wedge \omega_j^k + \Omega_j^i. \end{aligned}$$

Instead of introducing these forms explicitly, it will be convenient to write the structural equations in the abbreviated form

$$\begin{aligned} d\theta &= -\omega \wedge \theta + \Theta \\ d\omega &= -\omega \wedge \omega + \Omega. \end{aligned}$$

For a section $s: U \rightarrow F(M)$ we obtain

$$\begin{aligned} d(s^*\theta^i) &= -\sum_j s^*\omega_j^i \wedge s^*\theta^j + s^*\Theta^i \\ d(s^*\omega_j^i) &= -\sum_k s^*\omega_k^i \wedge s^*\omega_j^k + s^*\Omega_j^i. \end{aligned}$$

Since $s^*\theta^i$ are just the dual forms to the moving frame s , this shows that $s^*\Theta^i$ and $s^*\Omega_j^i$ are precisely the torsion and curvature forms* for the moving frame s which are determined by the Cartan connection which assigns $s^*\omega$ to s . Propositions 11 and 12 correspond to Proposition 15 of Chapter 7. Recall that the formulas of this proposition allowed us to define the tensors T and R . Essentially equivalent, but much neater, definitions will now be given directly from Propositions 11 and 12.

Let ω be a connection on $F(M)$ with torsion form Θ and curvature form Ω . For $X_1, X_2 \in M_p$, we let

$$T(X_1, X_2) = u(\Theta(\bar{X}_1, \bar{X}_2)) \in M_p,$$

where $\bar{X}_i \in F(M)_u$ are any vectors with $\pi_*(\bar{X}_i) = X_i$. This definition is inde-

*In Ehresmann's original treatment, the torsion and curvature forms Θ and Ω on $F(M)$ were defined by the structural equations. The definition in terms of D was given by Ambrose and Singer, *A Theorem on Holonomy*, Trans. Amer. Math. Soc. **75** (1953), 428–443. This paper also introduced much of the convenient terminology, like “horizontal vectors”.

pendent of the choice of u , and of $\bar{X}_i \in F(M)_u$. To see this, first note that if \bar{X}_1 is replaced by $\bar{\bar{X}}_1$ with $\pi_*(\bar{\bar{X}}_1) = X_1$, then $\bar{X}_1 - \bar{\bar{X}}_1$ is vertical, so

$$\Theta(\bar{X}_1 - \bar{\bar{X}}_1, \bar{X}_2) = D\theta(\bar{X}_1 - \bar{\bar{X}}_1, \bar{X}_2) = 0;$$

similarly, \bar{X}_2 may be replaced by any $\bar{\bar{X}}_2$ with $\pi_*(\bar{\bar{X}}_2) = X_2$, without changing the value of $u(\Theta(\bar{X}_1, \bar{X}_2))$. Then note that if we change u to $u \cdot A$, we can pick $R_{A*}\bar{X}_i$ for the new \bar{X}_i , and we have

$$\begin{aligned} (u \cdot A)(\Theta(R_{A*}\bar{X}_1, R_{A*}\bar{X}_2)) &= (u \cdot A)(A^{-1} \cdot \Theta(\bar{X}_1, \bar{X}_2)) && \text{by Proposition 12} \\ &= u(\Theta(\bar{X}_1, \bar{X}_2)). \end{aligned}$$

Since Θ is a form, it is clear that T is skew-symmetric.

Similarly, for $X_1, X_2, X_3 \in M_p$ we let

$$R(X_1, X_2)X_3 = u(\Omega(\bar{X}_1, \bar{X}_2) \cdot (u^{-1}X_3));$$

here $\Omega(\bar{X}_1, \bar{X}_2) \in \mathfrak{gl}(n, \mathbb{R})$ is an $n \times n$ matrix, so it acts on $u^{-1}X_3 \in \mathbb{R}^n$. Just as before, we see that the definition does not depend on the choice of \bar{X}_1 or \bar{X}_2 . If we change u to $u \cdot A$, then by Proposition 11,

$$\begin{aligned} (u \cdot A)(\Omega(R_{A*}\bar{X}_1, R_{A*}\bar{X}_2) \cdot ([u \cdot A]^{-1}X_3)) \\ &= (u \cdot A)([A^{-1}\Omega(\bar{X}_1, \bar{X}_2)A] \cdot (A^{-1} \cdot u^{-1}(X_3))) \\ &= u(\Omega(\bar{X}_1, \bar{X}_2) \cdot (u^{-1}X_3)). \end{aligned}$$

Since Ω is a 2-form, it is clear that R is skew-symmetric in X_1 and X_2 .

In Chapter 7, we mentioned that the structural equations could be used to prove that the torsion and curvature tensors T and R , defined for a Cartan connection in terms of Θ^i and Ω_j^i , were just those derived from the ∇ which could also be defined for the Cartan connection. Here we will actually carry out this proof for an Ehresmann connection.

17. PROPOSITION. For any vector fields X, Y, Z on M we have

$$\begin{aligned} T(X, Y) &= \nabla_X Y - \nabla_Y X - [X, Y] \\ R(X, Y)Z &= \nabla_X \nabla_Y Z - \nabla_Y \nabla_X Z - \nabla_{[X, Y]} Z. \end{aligned}$$

PROOF. Recall that we defined $f_Y: F(M) \rightarrow \mathbb{R}^n$ by $f_Y(u) = u^{-1}(Y_{\pi(u)})$. If Y^* is the lift of Y , we can write $f_Y(u) = \theta(Y^*_u)$. So Lemma 8 gives

$$\nabla_X Y(p) = u(X^*_u(\theta(Y^*))) \quad \text{for } u \in \pi^{-1}(p).$$

Consequently,

$$\begin{aligned} T(X_p, Y_p) &= u(\Theta(X^*_u, Y^*_u)) \\ &= u(D\theta(X^*_u, Y^*_u)) \\ &= u(d\theta(X^*_u, Y^*_u)) \\ &= u(X^*_u(\theta(Y^*)) - Y^*_u(\theta(X^*)) - \theta([X^*, Y^*](u))) \\ &= \nabla_{X_p} Y - \nabla_{Y_p} X - [X, Y]_p, \end{aligned}$$

since $\pi_*([X^*, Y^*]) = [X, Y]$.

To prove the second equality, we note that since X^* and Y^* are horizontal, we have

$$\begin{aligned} \Omega(X^*_u, Y^*_u) &= d\omega(X^*, Y^*)(u) \\ &= X^*(\omega(Y^*))(u) - Y^*(\omega(X^*))(u) - \omega([X^*, Y^*])(u) \\ &= -\omega([X^*, Y^*])(u). \end{aligned}$$

If we set the vertical component of $[X^*, Y^*]$ equal to

$$v[X^*, Y^*](u) = \sigma(N)_u \quad \text{for } N \in \mathfrak{gl}(n, \mathbb{R}),$$

then we obtain

$$\Omega(X^*_u, Y^*_u) = -N,$$

so

$$\begin{aligned} (1) \quad R(X_p, Y_p)Z_p &= u(\Omega(X^*_u, Y^*_u) \cdot (u^{-1}Z_p)) \\ &= u(-N \cdot f_Z(u)). \end{aligned}$$

On the other hand, since we also have $f_Z(u) = \theta(Z^*_u)$, we obtain

$$\begin{aligned}
(2) \quad & \nabla_X \nabla_Y Z(p) - \nabla_Y \nabla_X Z(p) - \nabla_{[X, Y]} Z(p) \\
&= u(X^*_u(Y^* f_Z) - Y^*_u(X^* f_Z) - (h[X^*, Y^*]_u) f_Z) \\
&= u((v[X^*, Y^*]_u) f_Z).
\end{aligned}$$

The expressions in (1) and (2) are equal, since

$$\begin{aligned}
\sigma(N)_u f_Z &= \lim_{t \rightarrow 0} \frac{1}{t} [f_Z(u \cdot \exp tN) - f_Z(u)] \\
&= \lim_{t \rightarrow 0} \frac{1}{t} [(\exp tN)^{-1} \cdot f_Z(u) - f_Z(u)] \\
&= -N \cdot f_Z(u). \quad \blacklozenge
\end{aligned}$$

One of the steps in this proof is of sufficient importance to be stated explicitly, along with a counterpart, in the following corollary of the structural equations.

18. PROPOSITION. If ω is a connection on the bundle of frames $F(M)$, and B_1, B_2 are basic vector fields, then the horizontal component of $[B_1, B_2](u)$ is the value of $B(-\Theta(B_{1u}, B_{2u}))$ at u .

If ω is a connection on any principal bundle P over M , and Y_1, Y_2 are horizontal vector fields, then the vertical component of $[Y_1, Y_2](u)$ is the value of $\sigma(-\Omega(Y_{1u}, Y_{2u}))$ at u .

PROOF. Since B_1 and B_2 are horizontal, the first structural equation gives

$$\begin{aligned}
\Theta(B_{1u}, B_{2u}) &= d\theta(B_1, B_2)(u) \\
&= B_1(\theta(B_2))(u) - B_2(\theta(B_1))(u) - \theta([B_1, B_2])(u) \\
&= -\theta(h[B_1, B_2](u)) \quad \text{since } \theta = 0 \text{ on vertical vectors.}
\end{aligned}$$

Since we can always write $h[B_1, B_2](u)$ as $B(\xi)_u$ for some $\xi \in \mathbb{R}^n$, the first result follows from Proposition 13(1).

Since Y_1 and Y_2 are horizontal, the second structural equation gives

$$\Omega(Y_{1u}, Y_{2u}) = d\omega(Y_1, Y_2)(u) = -\omega([Y_1, Y_2](u)),$$

which gives the second result. \blacklozenge

Suddenly, we are ready for

19. **THEOREM (THE TEST CASE; SEVENTH VERSION).** Let $(M, \langle \cdot, \cdot \rangle)$ be an n -dimensional Riemannian manifold for which the curvature tensor R (for the Levi-Civita connection) is 0. Then M is locally isometric to \mathbb{R}^n with its usual Riemannian metric.

PROOF. On the bundle of frames $F(M)$ we have a connection ω with $\Theta = 0$ and $\Omega = 0$, for which parallel translation preserves the inner product $\langle \cdot, \cdot \rangle$.

Step 1. The second part of Proposition 18 shows that the bracket of two horizontal vector fields is again horizontal. Thus, *the distribution H is integrable*. At a point $p \in M$ choose an *orthonormal* frame $u \in \pi^{-1}(p)$, and let N be the (n -dimensional) integral manifold of H through u . Clearly, N is locally the image of a section $s: U \rightarrow F(M)$ with $s(p) = u$.

Step 2. Consider the basic vector fields $B(e_i)$, for e_1, \dots, e_n the standard basis of \mathbb{R}^n . Since they are horizontal, the bracket $[B(e_i), B(e_j)]$ is horizontal. But the first part of Proposition 18 shows that the horizontal component is 0, so $[B(e_i), B(e_j)] = 0$. If we let $X_i(q) = \pi_*(B(e_i)(s(q)))$, then we also have $[X_i, X_j] = 0$, since $B(e_i)$ and X_i are π -related. But, by definition of $B(\xi)$, we have

$$\begin{aligned} \pi_*(B(e_i)(s(q))) &= s(q)(e_i) \\ &= i^{\text{th}} \text{ vector of the frame } s(q). \end{aligned}$$

Thus, $s = (X_1, \dots, X_n)$ where $[X_i, X_j] = 0$; hence there is a coordinate system x^1, \dots, x^n with $X_i = \partial/\partial x^i$.

Step 3. We claim this is the desired coordinate system. We just have to show that $s(q)$ is always orthonormal, so it suffices to show that $s(q)$ is the parallel translate of $u = s(p)$ along any curve c in U from p to q . This is obvious: to translate u along c , we choose a lift c^* of c with $c^*(0) = u$, and then the translate of u is $c^*(1)$; but clearly $c^* = s \circ c$. ♦

To wrap things up, we present the new version of the Bianchi identities.

20. THEOREM. For a connection ω on the bundle of frames $F(M)$, with dual form θ , torsion form Θ , and curvature form Ω , we have

- (1) (Bianchi's first identity) $D\Theta = \Omega \wedge \theta$. In other words, for $X, Y, Z \in F(M)_u$ we have

$$\begin{aligned} D\Theta(X, Y, Z) &= \frac{(2+1)!}{2!1!} \cdot \frac{1}{3!} \cdot [\Omega(X, Y) \cdot \theta(Z) - \Omega(Y, X) \cdot \theta(Z) \\ &\quad + \Omega(Y, Z) \cdot \theta(X) - \Omega(Z, Y) \cdot \theta(X) \\ &\quad + \Omega(Z, X) \cdot \theta(Y) - \Omega(X, Z) \cdot \theta(Y)] \\ &= \Omega(X, Y) \cdot \theta(Z) + \Omega(Y, Z) \cdot \theta(X) + \Omega(Z, X) \cdot \theta(Y). \end{aligned}$$

For a connection ω on any principal bundle, with curvature form Ω , we have

- (2) (Bianchi's second identity) $D\Omega = 0$.

PROOF. Applying d to the first structural equation, $d\theta = -\omega \wedge \theta + \Theta$, we obtain

$$0 = -(d\omega \wedge \theta) + (\omega \wedge d\theta) + d\Theta.$$

So

$$\begin{aligned} D\Theta(X, Y, Z) &= d\Theta(hX, hY, hZ) \\ &= (d\omega \wedge \theta)(hX, hY, hZ) - 0 \\ &= (\Omega \wedge \theta)(X, Y, Z), \end{aligned}$$

since $d\omega(hA, hB) = \Omega(A, B)$ and $\theta(hA) = \theta(A)$ for all $A, B \in F(M)_u$.

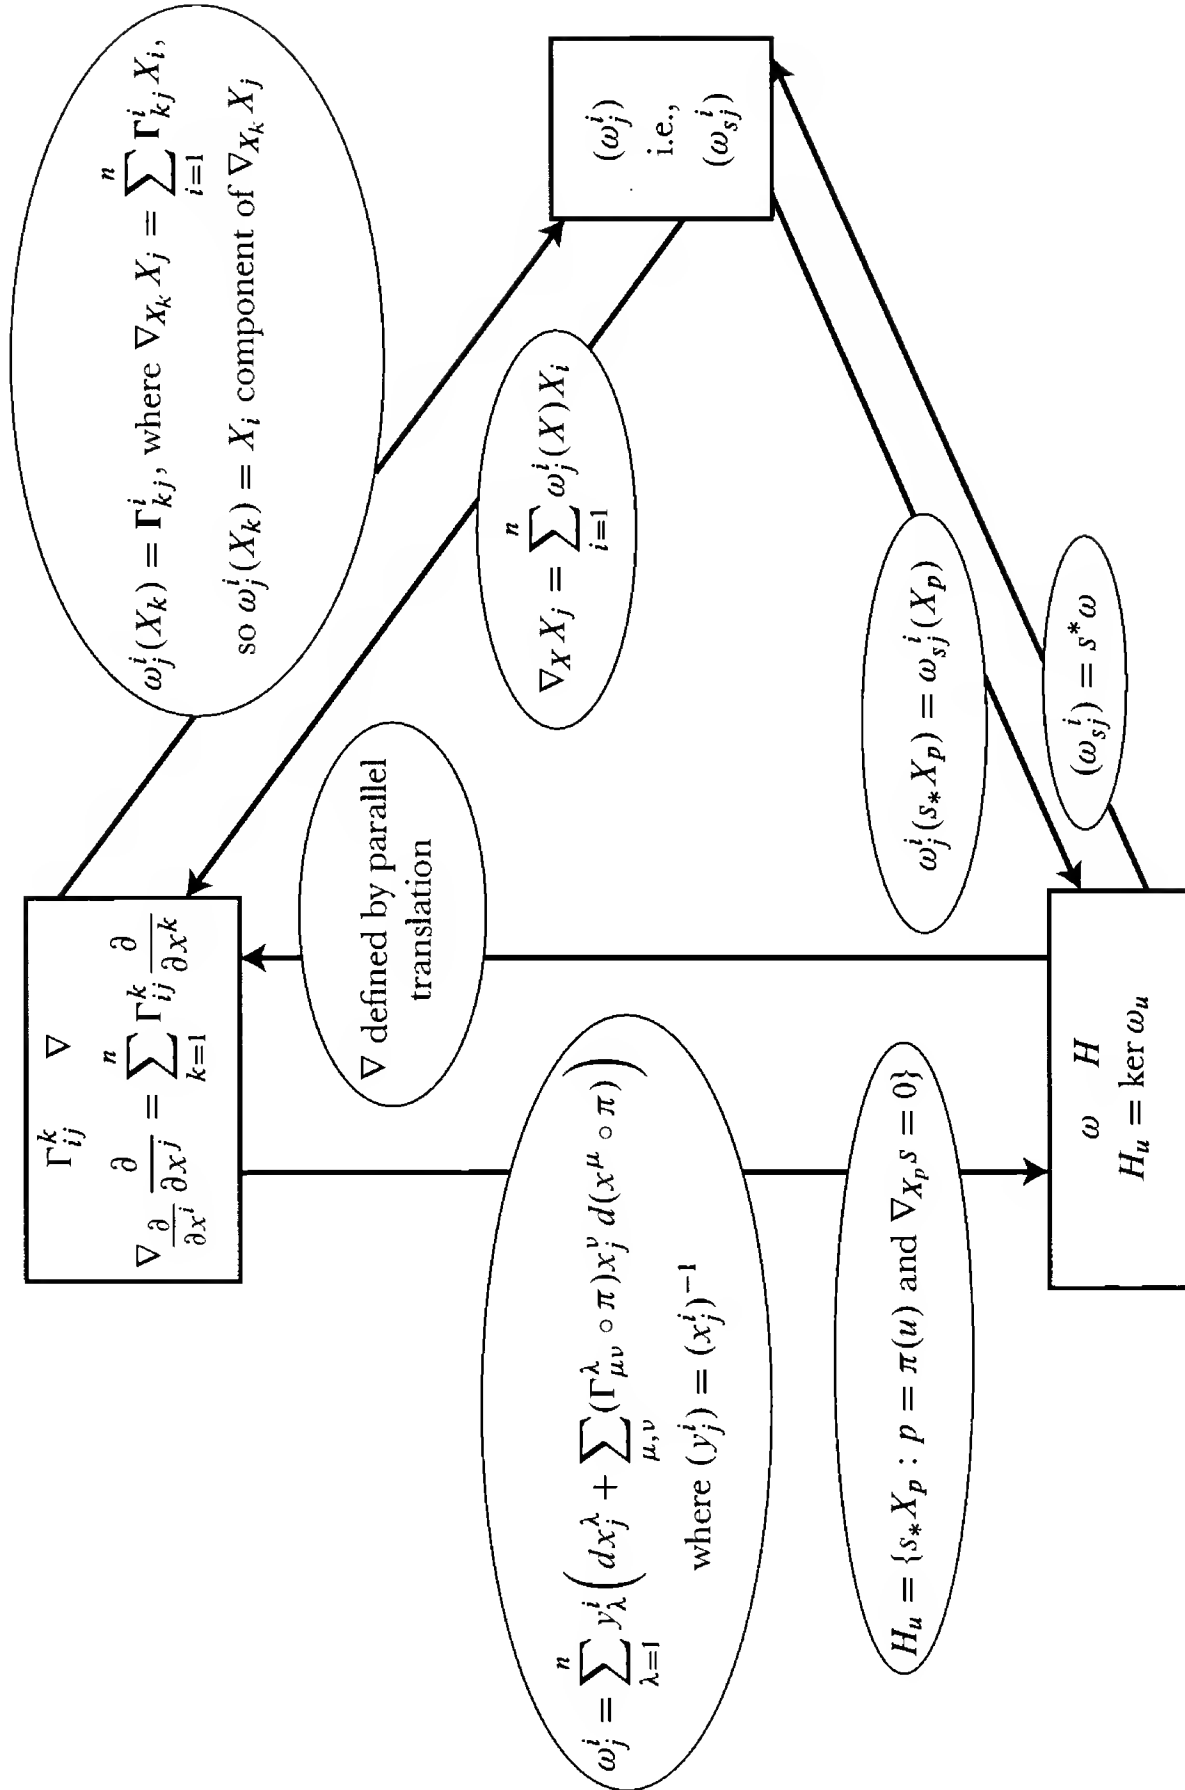

Applying d to the second structural equation, $d\omega = -\omega \wedge \omega + \Omega$, we obtain

$$0 = -(d\omega \wedge \omega) + (\omega \wedge d\omega) + d\Omega.$$

So

$$\begin{aligned}
 D\Omega(X, Y, Z) &= d\Omega(hX, hY, hZ) \\
 &= (d\omega \wedge \omega)(hX, hY, hZ) - (\omega \wedge d\omega)(hX, hY, hZ) \\
 &= 0,
 \end{aligned}$$

since $\omega(hA) = 0$ for all $A \in F(M)_u$ [but recall that $(d\omega \wedge \omega) - (\omega \wedge d\omega)$ is not itself 0, since matrix multiplication is not commutative]. ♦

SUMMARY

The diagram on the opposite page summarizes the relationship between the various definitions of a connection:

- (1) n^3 functions Γ_{ij}^k assigned to each coordinate system (classical),
- (2) ∇ operator on vector fields (Koszul),
- (3) $n \times n$ matrix of 1-forms (ω_j^i) assigned to each moving frame (É. Cartan),
- (4) $n \times n$ matrix-valued 1-form ω on $F(M)$ (Ehresmann),
- (5) distribution H on $F(M)$.

The relationship between (1) and (2) is immediate, as is the relationship between (4) and (5). In Chapter 7 we saw how to pass between (1)-(2) and (3), and in this chapter we saw how to pass between (4)-(5) and (3). We can also go directly from (5) to (1), since ∇ is defined by parallel translation. It remains to indicate how one passes directly from (1)-(2) to (5).

21. PROPOSITION. Let ∇ be a Koszul connection on M . For $u \in F(M)$, let

$$H_u = \{s_* X_p : p = \pi(u) \text{ and } \nabla_{X_p} s = 0\}$$

[where $\nabla_{X_p} s$ denotes $(\nabla_{X_p} X_1, \dots, \nabla_{X_p} X_n)$ if $s = (X_1, \dots, X_n)$]. Then H_u is a subspace of P_u , and the distribution $u \mapsto H_u$ defines a connection on $F(M)$ for which the covariant derivative is the given ∇ .

PROOF. Suppose that $s \cdot a$ is another section with $a(p) = I$ and $\nabla_{X_p}(s \cdot a) = 0$. Then

$$\begin{aligned} (1) \quad 0 &= \nabla_{X_p}(s \cdot a) = s \cdot X_p(a) + (\nabla_{X_p} s) \cdot a \\ &= s \cdot X_p(a), \end{aligned}$$

which implies that $X_p(a)$ is the zero matrix. So by Proposition 3 we have

$$\begin{aligned} (s \cdot a)_*(X_p) &= s_* X_p + \sigma(X_p(a))(s(p)) \\ &= s_* X_p. \end{aligned}$$

Thus H_u contains exactly one vector X_u^* with $\pi_*(X_u^*) = X_p$. Now given vectors $A_u, B_u \in H_u$, let $\pi_* A_u = X_p$ and $\pi_* B_u = Y_p$. We can choose s with $s(p) = u$ and $\nabla_{X_p} s = \nabla_{Y_p} s = 0$; then we also have $\nabla_{X_p + Y_p} s = 0$, and we must have

$$A_u + B_u = s_* X_p + s_* Y_p = s_*(X_p + Y_p) \in H_u.$$

Thus H_u is a subspace.* It has the same dimension as M , and contains no vertical vectors except 0, so we have $F(M)_u = V_u \oplus H_u$. It is clear that $R_{A*}H_u = H_{u \cdot A}$ for all $A \in \text{GL}(n, \mathbb{R})$, since $s \cdot A$ also satisfies $\nabla_{X_p} s \cdot A = 0$.

To prove that H is a C^∞ distribution, we consider a C^∞ vector field X on M , and a C^∞ section s . We claim that there is a function $a: U \rightarrow \text{GL}(n, \mathbb{R})$, defined in some open set U , such that $\nabla_{X_p}(s \cdot a) = 0$ for all $p \in U$. This is because equation (1) shows that this condition is equivalent to

$$0 = s \cdot X_p(a) + (\nabla_{X_p} s) \cdot a,$$

and this is a differential equation for a . For each $A \in \text{GL}(n, \mathbb{R})$ and $p \in U$, let $a_{p,A}$ be the solution with $a_{p,A}(p) = s(p) \cdot A$. For every $u \in F(M)$ we have $u = s(\pi(u)) \cdot A(u)$ for some $A(u) \in \text{GL}(n, \mathbb{R})$ which depends differentiably on u . Then the vector field

$$X^*(u) = [s \cdot a_{\pi(u), A(u)}]_*(X_{\pi(u)}) \in F(M)_u$$

is C^∞ , since $a_{p,A}$ is C^∞ in p and A .

Thus the distribution H is a connection on $F(M)$. For a curve c in M , consider a curve c^* in $F(M)$ with $\pi \circ c^* = c$ and all $c^{*'}(t)$ horizontal. By definition of the connection, this means that for some $X_p \in M_p = M_{c(t)}$ we have

$$c^{*'}(t) = s_*(X_p) \quad \text{where} \quad \nabla_{X_p} s = 0.$$

Of course, X_p must be $\pi_* s_* X_p = \pi_* c^{*'}(t) = c'(t)$. So $\nabla_{c'(t)} s = 0$. From this it is easy to see that the components of c^* are vector fields along c which are parallel along c , with respect to the original ∇ . Hence parallel translation defined with respect to the connection H is the same as parallel translation for ∇ . This implies that the covariant derivatives are also the same. ♦

Proposition 21 gives the most geometric way of going from ∇ to H , and hence to ω . We can also give a computational description of ω , in terms of a coordinate system (x, U) on M . Recall that $x_\# = (x^i \circ \pi, x_j^i)$ is a coordinate system on $\pi^{-1}(U)$, where we write a frame u as

$$u_j = \sum_{i=1}^n x_j^i(u) \cdot \frac{\partial}{\partial x^i} \Big|_{\pi(u)}.$$

At each u , the non-singular matrix $(x_j^i(u))$ has an inverse matrix $(y_j^i(u)) = (x_j^i(u))^{-1}$.

* We can also define H_u simply as $s_*(M_p)$, where s is a section with $s(p) = u$ and $(\nabla s)(p) = 0$.

22. PROPOSITION. Let Γ_{ij}^k be the n^3 functions assigned to the coordinate system (x, U) by a classical connection on M . For the corresponding Ehresmann connection $\omega = (\omega_j^i) = \sum_{i,j} \omega_j^i \cdot E_i^j$ we have

$$\omega_j^i = \sum_{\lambda=1}^n y_\lambda^i \left(dx_j^\lambda + \sum_{\mu, \nu} (\Gamma_{\mu\nu}^\lambda \circ \pi) x_j^\nu d(x^\mu \circ \pi) \right) \quad \text{on } \pi^{-1}(U).$$

PROOF. Let $s = (\partial/\partial x^1, \dots, \partial/\partial x^n)$ be the natural section. We know that the matrix of 1-forms (ω_{sj}^i) for the corresponding Cartan connection is given by

$$\Gamma_{\mu j}^i = (\omega_{sj}^i) \left(\frac{\partial}{\partial x^\mu} \right),$$

and consequently the corresponding Ehresmann connection satisfies

$$(1) \quad \Gamma_{\mu j}^i(p) = \omega_j^i \left(s_* \left(\frac{\partial}{\partial x^\mu} \Big|_p \right) \right).$$

If we write

$$s_* \left(\frac{\partial}{\partial x^\mu} \Big|_p \right) = \sum_i a^i \frac{\partial}{\partial (x^i \circ \pi)} \Big|_{s(p)} + \sum_{i,j} b_j^i \frac{\partial}{\partial x_j^i} \Big|_{s(p)},$$

then

$$\begin{aligned} a^i &= s_* \left(\frac{\partial}{\partial x^\mu} \Big|_p \right) (x^i \circ \pi) = \frac{\partial (x^i \circ \pi \circ s)}{\partial x^\mu} \Big|_p = \frac{\partial x^i}{\partial x^\mu} \Big|_p = \delta_\mu^i \\ b_j^i &= s_* \left(\frac{\partial}{\partial x^\mu} \Big|_p \right) (x_j^i) = \frac{\partial (x_j^i \circ s)}{\partial x^\mu} \Big|_p = \frac{\partial \delta_j^i}{\partial x^\mu} \Big|_p = 0, \end{aligned}$$

so

$$s_* \left(\frac{\partial}{\partial x^\mu} \Big|_p \right) = \frac{\partial}{\partial (x^\mu \circ \pi)} \Big|_{s(p)}.$$

A similar calculation shows that for any $A \in \text{GL}(n, \mathbb{R})$ we have

$$(2) \quad \frac{\partial}{\partial (x^\mu \circ \pi)} \Big|_{s(p) \cdot A} = (s \cdot A)_* \left(\frac{\partial}{\partial x^\mu} \Big|_p \right) = R_{A*} \left(\frac{\partial}{\partial x^\mu} \Big|_p \right).$$

Now any $u \in \pi^{-1}(U)$ can be written $u = s(\pi(u)) \cdot (x_j^i(u)) = s(p) \cdot A$, say. So for the matrix (ω_j^i) we have

$$\begin{aligned} (\omega_j^i) \left(\frac{\partial}{\partial(x^\mu \circ \pi)} \Big|_u \right) &= (\omega_j^i) \left(R_{A*} \frac{\partial}{\partial x^\mu} \Big|_p \right) && \text{by (2)} \\ &= A^{-1} (\omega_j^i) \left(\frac{\partial}{\partial x^\mu} \Big|_p \right) A && \text{by definition of an} \\ & && \text{Ehresmann connection} \\ &= A^{-1} (\Gamma_{\mu j}^i(p)) A && \text{by (1),} \end{aligned}$$

so that

$$\begin{aligned} \omega_j^i \left(\frac{\partial}{\partial(x^\mu \circ \pi)} \Big|_u \right) &= \sum_{\lambda, v} (A^{-1})_\lambda^i \Gamma_{\mu v}^\lambda(p) A_j^v \\ &= \sum_{\lambda, v} y_\lambda^i(u) \Gamma_{\mu v}^\lambda(\pi(u)) x_j^v(u). \end{aligned}$$

This accounts for the coefficient of $d(x^\mu \circ \pi)$ in the desired expression for ω_j^i .

Now let us write

$$\sigma(E_\beta^\alpha)(u) = \sum_{\lambda, j} a_j^\lambda \frac{\partial}{\partial x_j^\lambda} \Big|_u$$

(clearly each $\partial/\partial x_j^\lambda$ is vertical, since $\pi_*(\partial/\partial x_j^\lambda)(f) = \partial(f \circ \pi)/\partial x_j^\lambda = 0$, as $f \circ \pi$ is constant on fibres; hence the $\partial/\partial x_j^\lambda$ span V_u). Then

$$\begin{aligned} a_j^\lambda &= \sigma(E_\beta^\alpha)(x_j^\lambda)(u) \\ &= \sigma_{u*}(E_\beta^\alpha)(x_j^\lambda) \\ &= \lim_{h \rightarrow 0} \frac{x_j^\lambda(u \cdot \exp h E_\beta^\alpha) - x_j^\lambda(u)}{h} \\ &= x_j^\lambda(u \cdot E_\beta^\alpha) = \lambda^{\text{th}} \text{ component with respect to } s(\pi(u)) \text{ of } (u \cdot E_\beta^\alpha)_j \\ &= \text{''} \quad \text{''} \quad \text{''} \quad \text{''} \quad \text{''} \quad \text{''} \quad \text{''} \quad \sum_\gamma u_\gamma (E_\beta^\alpha)_j^\gamma \\ &= \text{''} \quad \text{''} \quad \text{''} \quad \text{''} \quad \text{''} \quad \text{''} \quad \text{''} \quad u_\beta \delta_j^\alpha \\ &= x_\beta^\lambda \delta_j^\alpha. \end{aligned}$$

So

$$\sigma(E_\beta^\alpha)(u) = \sum_\lambda x_\beta^\lambda \frac{\partial}{\partial x_\alpha^\lambda} \Big|_u.$$

Hence

$$\begin{aligned}
 \delta_\beta^i \delta_j^\alpha &= (E_\beta^\alpha)_j^i = \omega_j^i(\sigma(E_\beta^\alpha)(u)) \\
 &= \omega_j^i \left(\sum_\lambda x_\beta^\lambda \frac{\partial}{\partial x_\alpha^\lambda} \Big|_u \right) \\
 &= \sum_\lambda x_\beta^\lambda \omega_j^i \left(\frac{\partial}{\partial x_\alpha^\lambda} \Big|_u \right).
 \end{aligned}$$

This is easily seen to account for the other term, $\sum_\lambda y_\lambda^i dx_j^\lambda$, in the expression for ω_j^i . ♦

ADDENDUM 1

THE TANGENT BUNDLE
OF THE BUNDLE OF FRAMES

The existence of a connection on the bundle of frames $F(M)$ has some interesting implications.

23. PROPOSITION. If there is a connection on $F(M)$, then the tangent bundle of $F(M)$ is trivial.

PROOF. The $n^2 + n$ vector fields $\sigma(E_j^i)$ and $B(e_i)$ are everywhere linearly independent. ♦

24. COROLLARY. If there is a connection on $F(M)$, then M is paracompact.

PROOF. Since the tangent bundle of $F(M)$ is trivial, there is clearly a Riemannian metric on $F(M)$. So $F(M)$ is metrizable (Theorem I.9-7), so every component of $F(M)$ is σ -compact (Theorem I. A-1). Since $\pi: F(M) \rightarrow M$ is a continuous map onto M , it follows that each component of M is σ -compact, so M is metrizable (Theorem I. A-1). ♦

Of course, a non-paracompact manifold M may still have a connection in *some* principal bundle $\pi: P \rightarrow M$ with group G . For example, the trivial bundle $M \times G \rightarrow M$ has an obvious connection (the horizontal vectors Y are those with $\pi_{2*}Y = 0$, where $\pi_2: M \times G \rightarrow G$ is projection on the second coordinate).

If M is paracompact, then there is a connection in any principal bundle $\pi: P \rightarrow M$; this can be proved using partitions of unity, noting that any convex combination of Ehresmann connections is also a connection (a convex combination of connections ω_i makes sense, since the values of ω_i are in the vector space \mathfrak{g}).

For the special case of a Riemannian manifold $(M, \langle \cdot, \cdot \rangle)$, we have a specific connection in $F(M)$, the Levi-Civita connection. It is easy to see that the Levi-Civita connection for a Riemannian metric can also be defined for an indefinite Riemannian metric (a non-degenerate inner product in each tangent space); it is the unique symmetric connection for which parallel translation is an isometry, and the Γ_{ij}^k are given by exactly the same formula as the Christoffel symbols. So Corollary 24 implies

25. COROLLARY. If M has an indefinite Riemannian metric, then M is paracompact.

This result cannot be proved by modifying the proof of Theorem I.9-7, for there may be paths of negative length between two points. For another proof of the result, see Sachs and Wu, *General Relativity for Mathematicians*, section 8.2.1.

ADDENDUM 2

COMPLETE CONNECTIONS

If ω is a connection on $F(M)$, we define a **geodesic**, as usual, to be a curve c such that dc/dt is parallel along c . The connection ω is **complete** if every geodesic segment can be extended to \mathbb{R} . Unlike the Levi-Civita connection for a Riemannian metric, a general connection on $F(M)$ may not be complete even if M is compact. To construct an example, we begin with the Levi-Civita connection for the metric $\langle \cdot, \cdot \rangle = e^x dx \otimes dx$ on \mathbb{R} . A geodesic c has constant squared length

$$\langle c'(t), c'(t) \rangle_{c(t)} = e^{c(t)} c'(t)^2,$$

so $e^{c(t)/2} c'(t)$ must be constant, and thus

$$c(t) = 2 \log(a + bt).$$

Thus, $\langle \cdot, \cdot \rangle$ is not complete (the geodesics run off to infinity in a finite amount of time). If we identify the bundle of frames $F(\mathbb{R})$ with $\mathbb{R} \times (\mathbb{R} - \{0\})$, then the integral manifolds of the horizontal distribution H of our connection are the sets

$$\begin{aligned} \{(c(t), c'(t))\} &= \left\{ \left(2 \log(a + bt), \frac{2b}{a+bt} \right) \right\} \\ &= \{(x, 2be^{-x/2})\}. \end{aligned}$$

Now we will identify x with $x + 1$ for all $x \in \mathbb{R}$; the resulting manifold is a circle S^1 and we have a map $\pi: \mathbb{R} \rightarrow S^1$ given by $\pi(x) =$ equivalence class of x . The distribution H on $F(\mathbb{R})$ gives rise to an obvious distribution on $F(S^1)$, which determines a connection on $F(S^1)$. The geodesics for this connection are the curves

$$\pi \circ c(t) = \pi(2 \log(a + bt)).$$

They cannot be extended to all of \mathbb{R} , since they go around S^1 infinitely often in a finite amount of time.

There are other anomalies for general connections. For example, even though a connection ω is complete, it may not be possible to join every pair of points with a geodesic. If we consider a Lie group G , it is easy to see that there is a unique connection ω on $F(G)$ which makes all left invariant vector fields parallel. Then geodesics through e are just 1-parameter subgroups. The connection is complete, since 1-parameter subgroups can be extended to all of \mathbb{R} , but (Problem I.10-27) it is not necessarily true that every element lies on a 1-parameter

subgroup. It is not known whether every two points can be joined by a geodesic in a compact manifold with a complete connection.

Finally, it should be pointed out that results about geodesics for the Levi-Civita connection of a Riemannian metric need not hold for the Levi-Civita connection of an indefinite Riemannian metric. For example, there is an indefinite metric whose Levi-Civita connection is complete but for which not every pair of points can be joined by a geodesic (see J. W. Smith, *Lorentz structures on the plane*, Trans. Amer. Math. Soc. **95** (1960), 226–237).

ADDENDUM 3

CONNECTIONS IN VECTOR BUNDLES

Suppose $\pi: E \rightarrow M$ is a C^∞ vector bundle over M . We have already seen how to form a principal bundle $\varpi: F(E) \rightarrow M$, in which* every $u \in \varpi^{-1}(p)$ is a frame for $\pi^{-1}(p)$. We can then define a **connection** in the original vector bundle E to be a connection in the principal bundle $F(E)$. However, there is a more direct way of defining a connection in E , which makes certain things work out more simply, since the bundle of frames contains a lot of superfluous stuff in it.

For a vector bundle $\pi: E \rightarrow M$ (as for a principal bundle) we define the **vertical subspace** $V_e \subset E_e$ at any point $e \in E$ to be the image $i_*(\pi^{-1}(p)_e)$, where $p = \pi(e)$; vectors in V_e are called **vertical**, and V_e is clearly the kernel of $\pi_*: E_e \rightarrow M_p$. For every frame $u \in \varpi^{-1}(p)$ and every $\xi \in \mathbb{R}^n$ we also have $u(\xi) \in \pi^{-1}(p)$ defined by $u(\xi) = \sum_i \xi^i \cdot u^i$. Finally, for every non-zero $\alpha \in \mathbb{R}$, we let $\bar{\alpha}: E \rightarrow E$ be the diffeomorphism defined by $\bar{\alpha}(e) = \alpha \cdot e$. We define a **connection** in E to be a distribution H such that

- (1) $E_e = H_e \oplus V_e$ for all $e \in E$
- (2) $\bar{\alpha}_*(H_e) = H_{\bar{\alpha}(e)} = H_{\alpha \cdot e}$ for all non-zero $\alpha \in \mathbb{R}$
- (3) H is a C^∞ distribution.

The subspace H_e is called the **horizontal subspace** at e , and vectors in H_e are called **horizontal**. Applying (2) with any $\alpha \neq 1$, and using a local trivialization, we see that if $s: M \rightarrow E$ is the zero section, then $H_{s(p)}$ must be $s_*(M_p)$.

We will first show how such a connection arises from a connection ω on the principal bundle $F(M)$. Let H be the distribution on $F(M)$ determined by ω .

*This bundle is a special case of the “associated principal bundle”, which is used in the theory of fibre bundles.

Given $e \in \pi^{-1}(p)$, choose any frame $u \in \pi^{-1}(p)$; then there is a unique $\xi \in \mathbb{R}^n$ with $u(\xi) = e$. Now we can define a map $\phi_\xi: F(E) \rightarrow E$ by $\phi_\xi(v) = v(\xi)$ for all $v \in F(E)$; this map takes fibres of $F(E)$ to fibres of E . We let $H_e = \phi_{\xi*}(H_u)$. This is well-defined, for if we choose $u \cdot A$ instead of u , then we must choose $A^{-1} \cdot \xi$ instead of ξ ; since

$$\phi_{A^{-1} \cdot \xi}(v) = v(A^{-1} \cdot \xi) = v \cdot A^{-1}(\xi),$$

we have $\phi_{A^{-1} \cdot \xi} = \phi_\xi \circ R_{A^{-1}}$, so

$$\begin{aligned} (\phi_{A^{-1} \cdot \xi})_*(H_{u \cdot A}) &= \phi_{\xi*} R_{A^{-1}*}(H_{u \cdot A}) \\ &= \phi_{\xi*} H_u, \quad \text{by Proposition 4.} \end{aligned}$$

We leave it to the reader to verify that these well-defined H_e do satisfy conditions (1), (2), (3).

We also want to show that every connection H in E does arise in this way from some connection H in $F(E)$. To do this, we first consider parallel translation. If $c: [0, 1] \rightarrow M$ is a curve, then the parallel translation

$$\tau_t: \pi^{-1}(c(0)) \rightarrow \pi^{-1}(c(t))$$

determined by H is defined in the obvious way: $\tau_t(e) = c^\dagger(t)$ where $c^\dagger: [0, 1] \rightarrow E$ is the unique curve with $c^\dagger(0) = e$ such that each $c^{\dagger'}(t)$ is horizontal; the existence of c^\dagger in E is proved similarly to the existence of c^* in a principal bundle. Clearly τ_t is a diffeomorphism, whose inverse is the parallel translation along the reversed part of c from $c(t)$ to $c(0)$. From condition (2) for H it follows that $\tau_t(\alpha \cdot e) = \alpha \cdot \tau_t(e)$ for $\alpha \neq 0$. This is true even for $\alpha = 0$, i.e., τ_t takes the zero vector at $c(0)$ to the zero vector at $c(t)$; this follows from the fact that $H_{s(p)} = s_*(M_p)$ when s is the zero section. It now follows that τ_t is a *vector space isomorphism*, because of the following

CLEVER OBSERVATION: If $f: \mathbb{R}^n \rightarrow \mathbb{R}^m$ is differentiable at 0 and satisfies $f(\alpha \cdot v) = \alpha f(v)$ for all $v \in \mathbb{R}^n$ and $\alpha \in \mathbb{R}$, then f is linear.

PROOF. Let $T = Df(0): \mathbb{R}^n \rightarrow \mathbb{R}^m$. Then

$$\begin{aligned} T(v) &= \lim_{\alpha \rightarrow 0} \frac{1}{\alpha} [f(\alpha v) - f(0)] = \lim_{\alpha \rightarrow 0} \frac{1}{\alpha} f(\alpha v) \\ &= \lim_{\alpha \rightarrow 0} f(v) = f(v). \quad \spadesuit \end{aligned}$$

We now define the connection H in $F(E)$. Let $u \in \varpi^{-1}(p)$. For every C^∞ curve $c: [0, 1] \rightarrow M$ with $c(0) = p$, we define the curve $c^*: [0, 1] \rightarrow F(E)$ by

$$(c^*(t))_i = c^\dagger(t)(u_i) \quad i = 1, \dots, n,$$

the subscript i denoting the i^{th} component of the frame. Then we define H_u to be the set of all vectors $c^*(0)$ for all such curves c . The reader may verify that H is an Ehresmann connection, and that it gives rise to the connection H on E (the fact that τ_t is a vector space isomorphism is used to prove that $R_{A*}H_u = H_{u \cdot A}$).

Given a connection H on E , we use the direct sum decomposition $E_e = H_e \oplus V_e$, to define the **horizontal component** hX and **vertical component** vX of any tangent vector $X \in E_e$. Condition (2) for H is equivalent to the equation $\bar{\alpha}_* hX = h(\bar{\alpha}_* X)$, or to $\bar{\alpha}_* vX = v(\bar{\alpha}_* X)$. Remember that the tangent space $\pi^{-1}(p)_e$ at e of the vector space $\pi^{-1}(p)$ can be identified with $\pi^{-1}(p)$ itself. Since $vX \in i_*(\pi^{-1}(p)_e)$, we therefore can, and henceforth will, regard vX as an element of $\pi^{-1}(p)$.

The equation $\bar{\alpha}_* vX = v(\bar{\alpha}_* X)$ then becomes

$$(*) \quad v(\bar{\alpha}_* X) = \alpha \cdot vX.$$

Now consider a section $s: M \rightarrow E$ of the bundle $\pi: E \rightarrow M$, and a vector $X_p \in M_p$. We define

$$\nabla_{X_p} s = v s_*(X_p) \in \pi^{-1}(p).$$

It is clear that $\nabla_{X_p} s$ is linear in X_p and in s . For a C^∞ function $f: M \rightarrow \mathbb{R}$, the analogue of Proposition 3 is the formula

$$(**) \quad (f \cdot s)_*(X_p) = \overline{f(p)}_*(s_* X_p) + X_p(f) \cdot s(p),$$

where $s(p) \in \pi^{-1}(p)$ is identified with a tangent vector in $\pi^{-1}(p)$ at $f(p) \cdot s(p)$; to prove this formula, we introduce a local trivialization, and observe that it becomes the product rule for the derivative. If we take the vertical component of both sides of (**) and use (*), we find that

$$\nabla_{X_p}(f \cdot s) = f(p) \nabla_{X_p} s + X_p(f) \cdot s(p).$$

Thus ∇ is a Koszul connection. If the connection H in E comes from the connection H in $F(E)$, then this ∇ is the same as that determined by H ; this is an easy consequence of Lemma 8 (although Lemma 8 is concerned only with $F(M) = F(TM)$, it is easy to see that it generalizes to any $F(E)$).

Finally, we point out that if we are given ∇ , then H_e is simply $\{s_*(X_p) : p = \pi(e) \text{ and } \nabla_{X_p} s = 0\}$; it can also be defined as $s_*(M_p)$, where s is a section such that $\nabla s(p) = 0$.

ADDENDUM 4

FLAT CONNECTIONS

Consider the trivial principal bundle $\pi: M \times G \rightarrow M$, and let $\pi_2: M \times G \rightarrow G$ be projection on the second factor. We can define the **canonical flat connection** H on $M \times G$ by letting $H_{(p,a)} = \ker \pi_{2*}: (M \times G)_{(p,a)} \rightarrow G_a$. It is easy to see that the corresponding \mathfrak{g} -valued 1-form ω on $M \times G$ is given by $\omega = \pi_2^*(\omega')$, where ω' is the natural \mathfrak{g} -valued 1-form on G (defined on pg. I.403). Using the equations of structure of G , in the form given on pg. I.404, we now have, for all $Y_1, Y_2 \in (M \times G)_u$

$$\begin{aligned} d\omega(Y_1, Y_2) &= d\pi_2^*(\omega')(Y_1, Y_2) \\ &= \pi_2^*(d\omega')(Y_1, Y_2) \\ &= d\omega'(\pi_{2*}Y_1, \pi_{2*}Y_2) \\ &= -[\omega'(\pi_{2*}Y_1), \omega'(\pi_{2*}Y_2)] \\ &= -[\omega(Y_1), \omega(Y_2)]. \end{aligned}$$

Comparing with the structural equations of the principal bundle $M \times G$ (Theorem 16), we see that for this connection ω we have $\Omega = 0$.

Conversely, suppose $\pi: P \rightarrow M$ is a principal bundle with group G , and a connection ω such that $\Omega = 0$. By Proposition 18, the distribution H corresponding to ω is integrable. From this it is easy to see that around any point $p \in M$ there is a neighborhood U and a diffeomorphism $t: \pi^{-1}(U) \rightarrow U \times G$ of the form $t(u) = (\pi(u), \phi(u))$, where $\phi(u \cdot a) = \phi(u) \cdot a$, such that $t_*(H_u)$ is the horizontal subspace at $t(u)$ for the canonical flat connection in $U \times G$. (One part of our final proof of the Test Case essentially used this fact.)

It should be noted that the second structural equation of Euclidean space (Proposition 7-1), with which we began our whole investigation of moving frames, could have been deduced from the equations of structure of $GL(n, \mathbb{R})$, by a process essentially equivalent to the deduction just given for the equation $d\omega(Y_1, Y_2) = -[\omega(Y_1), \omega(Y_2)]$. To obtain the *first* structural equation, we would have had to consider the equations of structure for the group of affine motions [an “affine motion” is a translation followed by an element of $GL(n, \mathbb{R})$]. In general, for a connection ω on $F(M)$, the torsion form and the first structural equation for ω can be interpreted in terms of a connection in the bundle $A(M)$ of affine frames of M , where an “affine frame” of M_p is a pair (v, u_1, \dots, u_n) , for $v \in M_p$ and (u_1, \dots, u_n) a frame for M_p . For this interpretation, the reader is referred to Kobayashi and Nomizu, *Foundations of Differential Geometry*, Vol. 1, pp. 125–130.

PREFACE

These final three volumes are regarded as constituting a single volume, with Chapters 1 to 6 in Volume III, Chapters 7 to 9 in Volume IV, and Chapters 10 to 13 in Volume V. After finishing this multi-volume, I felt somewhat like a man who has tried to cleanse the Augean stables with a Johnny-Mop. Leafing through Mathematical Reviews for the past thirty years, and gazing at the dignified tomes which represent the glories of the classical era, one quickly senses that Differential Geometry is a field of overwhelming extent, beyond the comprehension of any mortal. I suppose such lucubrations ought to buoy up one's spirit with admiration for human achievement, but I must confess that they usually lead me instead to a state of brooding melancholy.

Although the strident word "comprehensive" still stands emblazoned in the title, the Bibliography, in Volume V, will begin to give some idea how much as has necessarily been left out. There are also mini-bibliographies in Volumes III and IV for the works explicitly cited there. Problems have been restricted practically to the absolute minimum, basically facts left to the reader as exercises.

As a glance at the table of contents will show, Volume III is essentially a course in classical surface theory, the only difference being that Chapter 1 prepares the ground for applying the intrinsic geometry of Riemannian manifolds, which was discussed in Volume II. Although much space is devoted to classical material, much of the generalized material in Chapter 7 would be almost incomprehensible without the prior treatment of surface theory. The only exception is the second half of Chapter 2 (from page 75 on), which can (and probably should) be omitted completely without loss of continuity. For those who don't care for the motivational twiddle-twaddle, an introduction to "modern" differential geometry can be extracted from Chapters 1, 7 (parts D and E), 8, and 13, with an assist from Chapter 5, and the first halves of Chapters 9 and 12.

References like Theorem 6-3 or 7-2, when quoted in Volumes III or IV, say, refer to Chapter 6 of Volume III, and Chapter 7 of Volume IV, respectively. References to results of Volumes I and II, or page numbers from any other volume, carry an additional Roman numeral, e.g., Theorem I.6-3, or pg. IV.167.

As acknowledged in the first edition, I am grateful to the Sonderforschungsbereich Theoretische Mathematik in Bonn, the University of California at Berkeley, and the following individuals (as well as many readers and others whom I may have inadvertently omitted): R. Bassein, R. Bishop, R. Böhme, D. Bourghelia, E. Calabi, B. Cenk, S. S. Chern, M. do Carmo, P. Eberlein, J. Ehrbacher, W. Fulton, R. Gardner, P. Gilkey, R. Greene, R. Gulliver, R. Hartshorne, S. Hildebrandt, M. Hirsch, F. Hirzebruch, G. Hochschild, H. Jacobowitz, J. Kazdan, W. Klingenberg, S. Kobayashi, R. Kulkarni, B. Lawson, R. Maltz, P. Melvin, J. Milnor, T. Milnor, J. Moore, C. Morrey, J. Nash, L. Nirenberg, K. Nomizu, B. O'Neill, R. Osserman, T. Ōtsuki, R. Palais, H. Pittie, J. Polking, E. Portnoy, M. Protter, R. Reilly, R. Risch, H. Royden, E. Ruh, P. Ryan, R. Sacksteder, S. Sasaki, D. Schaeffer, J. Sjögren, C. Snugg, E. Spanier, J. Stallings, E. Thomas, F. Warner, J. Weiner, A. Weinstein, J. White, J. Wolf, H. Wu, A. Vasquez, D. Zagier, W. Ziller.

TABLE OF CONTENTS

Although the chapters are not divided into sections,
the listing for each chapter gives some indication
which topics are treated, and on what pages.

CHAPTER 1. THE FUNDAMENTAL EQUATIONS FOR HYPERSURFACES

Covariant differentiation in a submanifold of a Riemannian manifold	1
The second fundamental form, the Gauss formulas, and Gauss' equation; Synge's inequality	4
The Weingarten equations and the Codazzi-Mainardi equations for hypersurfaces	7
The classical tensor analysis description	12
The moving frame description	16
Addendum. Auto-parallel and totally geodesic submanifolds . . .	22
Problems	28

CHAPTER 2. ELEMENTS OF THE THEORY OF SURFACES IN \mathbb{R}^3

The first and second fundamental forms	31
Classification of points on a surface; the osculating paraboloid and the Dubin indicatrix	35
Principal directions and curvatures, asymptotic directions, flat points and umbilics; all-umbilic surfaces	48
The classical Gauss formulas, Weingarten equations, Gauss equation, and Codazzi-Mainardi equations	51
Fundamental theorem of surface theory	56
The third fundamental form	62
Convex surfaces; Hadamard's theorem	64
The fundamental equations via moving frames	68
Review of Lie groups	71

Application of Lie groups to surface theory; the fundamental equations and the structural equations of $SO(3)$	72
Affine surface theory; the osculating paraboloids and the affine invariant conformal structure	75
The special affine first fundamental form	82
Quadratic and cubic forms; apolarity	91
The affine normal direction; the special affine normal	97
The special affine Gauss formulas and special affine second fundamental form	103
The Pick invariant; surfaces with Pick invariant 0	111
The special affine Weingarten formulas	121
The special affine Codazzi-Mainardi equations; the fundamental theorem of special affine surface theory	128
Problems	134

CHAPTER 3. A COMPENDIUM OF SURFACES

Basic calculations	135
The classical flat surfaces	141
Ruled surfaces	146
Quadric surfaces	151
Surfaces of revolution	156
Rotation surfaces of constant curvature	161
Minimal surfaces	167
Addendum. Envelopes of 1-parameter families of planes	176
Problems	182

CHAPTER 4. CURVES ON SURFACES

Normal and geodesic curvature	187
The Darboux frame; geodesic torsion	191
Laguerre's theorem	193
General properties of lines of curvature, asymptotic curves, and geodesics	195
The Beltrami-Eininger theorem	200
Lines of curvature and Dupin's theorem	203
Conformal maps of \mathbb{R}^3 ; Liouville's theorem	208
Geodesics and Clairaut's theorem	211

Addendum 1. Special parameter curves	217
Addendum 2. Singularities of line fields	218
Problems	224
CHAPTER 5. COMPLETE SURFACES OF CONSTANT CURVATURE	
Hilbert's lemma; complete surfaces of constant curvature $K > 0$. .	233
Analysis of flat surfaces; the classical classification	
of developable surfaces	235
Complete flat surfaces	244
Complete surfaces of constant curvature $K < 0$	247
CHAPTER 6. THE GAUSS-BONNET THEOREM AND RELATED TOPICS	
The connection form for an orthonormal moving frame on a surface; the change in angle under parallel translation	261
The integral of $K dA$ over a polygonal region	265
The Gauss-Bonnet theorem; consequences	270
Total absolute curvature of surfaces	278
Surfaces of minimal total absolute curvature	280
Total curvature of curves; Fenchel's theorem, and the Fary-Milnor theorem	286
Addendum 1. Compact surfaces with constant negative curvature .	292
Addendum 2. The degree of the normal map	299
Problems	303
MINI-BIBLIOGRAPHY FOR VOLUME III	305
NOTATION INDEX	307
INDEX	309

VOLUME THREE

CHAPTER 1

THE FUNDAMENTAL EQUATIONS FOR HYPERSURFACES

In this chapter we are going to begin by considering a very general situation. Let $i: M^n \rightarrow N^m$ be an immersion of an n -dimensional manifold M into an m -dimensional manifold N ; it is customary to refer to N as the “ambient space” and to define $m - n$ to be the **codimension** of M in N . We will be interested in the case where N has a Riemannian metric $\langle \cdot, \cdot \rangle$, so that M can be given the induced Riemannian metric $i^*\langle \cdot, \cdot \rangle$. (This setup is often described a little differently: we can begin with two Riemannian manifolds $(N, \langle \cdot, \cdot \rangle)$ and $(M, \langle \cdot, \cdot \rangle)$, and consider isometric immersions of M in N , that is, immersions $i: M \rightarrow N$ which satisfy $i^*\langle \cdot, \cdot \rangle = \langle \cdot, \cdot \rangle$.)

For every $p \in M$, we can consider the tangent space M_p as a subspace of the tangent space $N_{i(p)}$, by identifying M_p with $i_*M_p \subset N_{i(p)}$. Since all the results of this chapter are going to be local ones, it will simplify our notation considerably to assume that M is actually an imbedded submanifold of N , with $i: M \rightarrow N$ the inclusion map. We can then regard M_p as a subspace $M_p \subset N_p$. In the vector space N_p , with the inner product $\langle \cdot, \cdot \rangle_p$, the subspace M_p has an orthogonal complement $M_p^\perp \subset N_p$, and we can use the decomposition $N_p = M_p \oplus M_p^\perp$ to define two projections

$$\begin{aligned} \mathsf{T}: N_p &\rightarrow M_p && \text{(the tangential projection)} \\ \mathsf{\perp}: N_p &\rightarrow M_p^\perp && \text{(the normal, or perpendicular, projection)} \end{aligned}$$

with

$$X = \mathsf{T}X + \mathsf{\perp}X \quad \text{for all } X \in N_p.$$

Now let $X_p \in M_p$ be any vector, and let Y be a vector field on M which is everywhere “tangent to M ”, meaning that $Y_q \in M_q$ for $q \in M$. Then

$\nabla_{X_p} Y \in M_p$ is defined, where ∇ denotes the covariant differentiation in M which is determined by the induced Riemannian metric $i^*\langle \cdot, \cdot \rangle$. If ∇' denotes the covariant differentiation determined by $\langle \cdot, \cdot \rangle$ in the ambient space N , then $\nabla'_{X_p} Y$ is also well-defined; in fact, the value of $\nabla'_{X_p} Y$ depends only on the values of Y along some curve c with $c'(0) = X_p$. The relation between these two covariant differentiations is as nice as one could hope:

1. THEOREM. Let $i: M \rightarrow N$ be an immersion, where N has the Riemannian metric $\langle \cdot, \cdot \rangle$, and let ∇ and ∇' be the covariant derivatives for $(M, i^*\langle \cdot, \cdot \rangle)$ and $(N, \langle \cdot, \cdot \rangle)$, respectively. If $X_p \in M_p$, and Y is a vector field on M which is everywhere tangent to M , then

$$\nabla_{X_p} Y = \mathbf{T}(\nabla'_{X_p} Y).$$

PROOF. Let X, Y, Z be vector fields on N . Since ∇' is compatible with $\langle \cdot, \cdot \rangle$, we have (Corollary II.6-7)

$$\begin{aligned} X\langle Y, Z \rangle &= \langle \nabla'_X Y, Z \rangle + \langle Y, \nabla'_X Z \rangle \\ Y\langle Z, X \rangle &= \langle \nabla'_Y Z, X \rangle + \langle Z, \nabla'_Y X \rangle \\ -Z\langle X, Y \rangle &= -\langle \nabla'_Z X, Y \rangle - \langle X, \nabla'_Z Y \rangle. \end{aligned}$$

We also have $\nabla'_X Y - \nabla'_Y X = [X, Y]$, etc., and in particular, $\nabla'_X Y + \nabla'_Y X = 2\nabla'_X Y - [X, Y]$. Adding the above three equations, we thus obtain

$$\begin{aligned} (*) \quad X\langle Y, Z \rangle + Y\langle Z, X \rangle - Z\langle X, Y \rangle \\ = 2\langle \nabla'_X Y, Z \rangle - \langle [X, Y], Z \rangle + \langle [X, Z], Y \rangle + \langle [Y, Z], X \rangle. \end{aligned}$$

This equation shows that $\langle \nabla'_X Y, Z \rangle$ is completely determined by $\langle \cdot, \cdot \rangle$ (and is essentially equivalent to our proof of Lemma II.6-8).

Now consider three vector fields X, Y, Z on N which are tangent to M at all points of M , so that there are vector fields $\bar{X}, \bar{Y}, \bar{Z}$ with $i_*\bar{X}(p) = X(p)$, etc. On M we have the same equation (*) for the vector fields $\bar{X}, \bar{Y}, \bar{Z}$, but with $\nabla'_X Y$ replaced by $\nabla_{\bar{X}} \bar{Y}$. For a bracket term like $[\bar{X}, \bar{Y}]$ we have $[\bar{X}, \bar{Y}](p) = [X, Y](p)$ for $p \in M$, by Proposition I.6-3. We thus see that

$$\langle \nabla'_{X_p} Y, Z_p \rangle = \langle \nabla_{X_p} Y, Z_p \rangle \quad \text{for all } Z_p \in M_p.$$

This is equivalent to the desired result. ♦

2. COROLLARY. If c is a curve in M and Y is a vector field along c which is tangent to M along c , then

$$\frac{DY}{dt} = \mathsf{T} \left(\frac{D'Y}{dt} \right).$$

Consequently, Y is parallel along c , in the sense of parallel that pertains to M , if and only if $D'Y/dt$ is always perpendicular to M . In particular, if Y is parallel along c in the sense that pertains to N , then it is also parallel along c in the sense that pertains to M .

PROOF. There is a unique operation $V \mapsto DV/dt$, from C^∞ vector fields V in M along c to C^∞ vector fields in M along c , with the properties in Proposition II.6-2. From the Theorem it is clear that $V \mapsto \mathsf{T}(DV/dt)$ has these properties. ♦

Merely by combining this information with our previous formulation of other concepts in the ∇ setup, we can immediately deduce further results.

3. COROLLARY. A curve c in M is a geodesic if and only if $D'/dt(dc/dt)$ is everywhere perpendicular to M . In particular, if a geodesic c of N lies entirely in M , then c is also a geodesic in M .

PROOF. The curve c is a geodesic if and only if dc/dt is parallel along c . (The second part also follows from the fact that geodesics are precisely the critical points for the energy function.) ♦

4. COROLLARY. Let M be isometrically immersed in \mathbb{R}^m (with its usual Riemannian metric). A curve c in M is a geodesic if and only if $c''(t)_{c(t)}$ is perpendicular to $M_{c(t)}$ for all t . In particular, a straight line in M is always a geodesic.

PROOF. This is a special case of Corollary 3, for if \mathbb{R}^m has its usual metric, then ∇' is just the directional derivative, so $D'/dt(dc/dt) = c''(t)_{c(t)}$. (In Chapter II.3B we obtained the result (for $m = 3$) by a completely different method.) ♦

Remark: Classically, the tangential component $\mathsf{T}(D'/dt(dc/dt)) = \mathsf{T}(c''(t))$ was called the **geodesic curvature vector** of c . We will meet it again in Chapter 4.

Having considered the tangential component $\mathbb{T}(\nabla'_{X_p} Y)$, it is only fair that we next consider the normal component $\mathbb{L}(\nabla'_{X_p} Y)$. Notice that

$$\mathbb{L}(\nabla'_{X_p} fY) = \mathbb{L}(X_p(f) \cdot Y_p + f(p) \cdot \nabla'_{X_p} Y) = f(p) \cdot \mathbb{L}(\nabla'_{X_p} Y).$$

It follows from our general principal (Theorem I.4-2) that there is a well-defined tensor field s , with $s: M_p \times M_p \rightarrow M_p^\perp$ for each $p \in M$, such that

$$s(X_p, Y_p) = \mathbb{L}(\nabla'_{X_p} Y)$$

for any vector field Y extending Y_p .

5. THEOREM. The tensor s is symmetric.

PROOF. Let X and Y be any extensions of $X_p, Y_p \in M_p$ to all of N which are tangent to M at all points of M . Then

$$\begin{aligned} \mathbb{L}(\nabla'_{X_p} Y) - \mathbb{L}(\nabla'_{Y_p} X) &= \mathbb{L}(\nabla'_{X_p} Y - \nabla'_{Y_p} X) \\ &= \mathbb{L}(\nabla'_X Y(p) - \nabla'_Y X(p)) \\ &= \mathbb{L}([X, Y](p)) = 0, \end{aligned}$$

since $[X, Y]$ is also tangent to M at all points of M (Proposition I.6-3). ♦

By combining Theorems 1 and 5 we can now rewrite the decomposition

$$\nabla'_{X_p} Y = \mathbb{L}(\nabla'_{X_p} Y) + \mathbb{T}(\nabla'_{X_p} Y)$$

in the following form:

The Gauss Formulas:

$$\nabla'_{X_p} Y = \nabla_{X_p} Y + s(X_p, Y_p),$$

where $X_p \in M_p$, and Y is a vector field tangent along M .

Although we seem to be dealing with a single formula here, we will obtain a set of formulas when we choose a coordinate system x^1, \dots, x^n on M and let $X_p = \partial/\partial x^i|_p$ and $Y = \partial/\partial x^j$. Consequently, we will adhere to this classical terminology; it should be compared to the (likewise classical) nomenclature of the next result.

6. THEOREM. Let M be isometrically immersed in N , and let R and R' denote the curvature tensors of M and N , respectively. Then for all $X_p, Y_p, Z_p, W_p \in M_p$ we have

Gauss' Equation (Gauss' Theorema Egregium):

$$\langle R'(X_p, Y_p)Z_p, W_p \rangle = \langle R(X_p, Y_p)Z_p, W_p \rangle + \langle s(X_p, Z_p), s(Y_p, W_p) \rangle - \langle s(Y_p, Z_p), s(X_p, W_p) \rangle$$

PROOF. Extend X_p, Y_p, Z_p, W_p to vector fields X, Y, Z, W which are tangent along M . Then the Gauss formulas yield

$$\begin{aligned} (1) \quad \nabla'_X(\nabla'_Y Z) &= \nabla'_X(\nabla_Y Z) + \nabla'_X(s(Y, Z)) \\ &= \nabla_X(\nabla_Y Z) + s(X, \nabla_Y Z) + \nabla'_X(s(Y, Z)), \end{aligned}$$

and similarly

$$(1') \quad \nabla'_Y(\nabla'_X Z) = \nabla_Y(\nabla_X Z) + s(Y, \nabla_X Z) + \nabla'_Y(s(X, Z)),$$

as well as

$$(2) \quad \nabla'_{[X, Y]} Z = \nabla_{[X, Y]} Z + s([X, Y], Z).$$

Substituting (1), (1'), (2) into the formula $R'(X, Y)Z = \nabla'_X \nabla'_Y Z - \nabla'_Y \nabla'_X Z - \nabla'_{[X, Y]} Z$, and noting that W is orthogonal to any term $s(\cdot, \cdot)$, we obtain

$$(3) \quad \langle R'(X, Y)Z, W \rangle = \langle R(X, Y)Z, W \rangle + \langle \nabla'_X(s(Y, Z)) - \nabla'_Y(s(X, Z)), W \rangle.$$

On the other hand, since $\langle s(Y, Z), W \rangle = 0$ we have

$$\begin{aligned} (4) \quad 0 &= X(\langle s(Y, Z), W \rangle) = \langle \nabla'_X s(Y, Z), W \rangle + \langle s(Y, Z), \nabla'_X W \rangle \\ &= \langle \nabla'_X s(Y, Z), W \rangle + \langle s(Y, Z), \nabla_X W + s(X, W) \rangle \\ &= \langle \nabla'_X s(Y, Z), W \rangle + \langle s(Y, Z), s(X, W) \rangle, \end{aligned}$$

since $\nabla_X W$ is orthogonal to $s(Y, Z)$. The desired result is now obtained by substituting (4), and the similar result with X and Y interchanged, into (3). ♦

Recall that if $P \subset M_p$ is a 2-dimensional subspace of M_p , we define the **sectional curvature** $K(P)$ as $\langle R(X, Y)Y, X \rangle$ for orthonormal $X, Y \in P$. We will let $K'(P)$ denote the corresponding sectional curvature in N .

7. COROLLARY (SYNGE'S INEQUALITY). Let M be isometrically immersed in N , and let $\gamma: [a, b] \rightarrow M$ be a curve in M which is a geodesic in N (and hence also a geodesic in M , by Corollary 3). Then for all 2-dimensional $P \subset M_{\gamma(t)}$ with $\gamma'(t) \in P$ we have

$$K(P) \leq K'(P).$$

In particular, if M is a *surface*, then for all $p = \gamma(t)$ we have

$$K(M_p) \leq K'(M_p).$$

Moreover, in this case equality holds for all $p = \gamma(t)$ if and only if $M_{\gamma(t)}$ is parallel along γ , in the sense that pertains to N .

PROOF. Assume γ is parameterized by arclength. Let $X_p = \gamma'(t)$ and let $Y_p \in P$ be a unit vector perpendicular to X_p . Applying Gauss' equation with $Z_p = Y_p$ and $W_p = X_p$, we obtain

$$K'(P) = K(P) + \langle s(X_p, Y_p), s(X_p, Y_p) \rangle - \langle s(Y_p, Y_p), s(X_p, X_p) \rangle.$$

If we let X be the vector field $X(t) = \gamma'(t)$ along γ , then X is parallel along γ , so we have $0 = \nabla'_X X$. This implies that

$$0 = \perp(\nabla'_X X)(p) = s(X_p, X_p),$$

which gives the desired inequality.

In the case of a surface, we choose $X(t) = \gamma'(t)$ once again, and we let $Y(t)$ be a unit vector in $M_{\gamma(t)}$ which is perpendicular to $X(t)$. Now Gauss' equation gives

$$K'(M_p) = K(M_p) + \langle s(X_p, Y_p), s(X_p, Y_p) \rangle - \langle s(Y_p, Y_p), s(X_p, X_p) \rangle.$$

Once again we have $s(X_p, X_p) = 0$, so equality holds for all p if and only if $s(X_p, Y_p) = 0$ for all p . Moreover, on the *surface* M , the vector field X is parallel along γ , while Y is a unit vector field which makes a constant angle with X along γ . It follows that Y is also parallel along γ , *in the sense that pertains to M* . Therefore

$$0 = \nabla_X Y = \mathbf{T}(\nabla'_X Y).$$

Since

$$s(X_p, Y_p) = \perp(\nabla'_X Y(p)),$$

this shows that $s(X_p, Y_p) = 0$ for all p if and only if $\nabla'_X Y(p) = 0$ for all p ; the latter condition means that $M_{\gamma(t)}$ is parallel along γ . ♦

Remark: We can state the slightly more precise result for M a surface: $K(M_p) = K'(M_p)$ at a particular point p if and only if $\nabla'_X Y(p) = 0$.

As another application of Theorem 6, we give a new proof of an old result: If $W \subset N_p$ is 2-dimensional, and $\mathcal{O} \subset W$ is a sufficiently small neighborhood of 0, then $K(W)$ is the Gaussian curvature at p of the surface $M = \exp(\mathcal{O})$. Clearly we just have to show that $s(X_p, Y_p) = 0$ for $X_p, Y_p \in M_p$, so we just need to show that $s(X_p, X_p) = 0$ for all $X_p \in M_p$. But there is a vector field X tangent to M with $X = c'$ along the geodesic $c(t) = \exp(tX_p)$ of N . Then $\nabla'_X X(p) = 0$, so $s(X_p, X_p) = 0$.

The proof of Corollary 7 has probably already explained why Theorem 6 is referred to in the singular, as “Gauss’ equation”: when M is 2-dimensional and x^1, x^2 is a coordinate system on M , essentially the only interesting case of Theorem 6 occurs for $X_p = W_p = \partial/\partial x^1|_p$ and $Y_p = Z_p = \partial/\partial x^2|_p$, so that we really are dealing with a single equation. This equation actually occurs in Gauss’ paper, as we shall soon see, when we specialize our results somewhat.

For the remainder of this chapter we consider the more specific situation where M is a **hypersurface** in N , that is, a submanifold of codimension 1; we will return only much later to the more general situation. In the case of hypersurfaces we can locally choose a **unit normal field** for M : on a neighborhood U of a point $p \in M$ we can choose a vector field ν such that $\langle \nu, \nu \rangle = 1$ and $\nu(q) \in M_q^\perp$ for all $q \in U$; in fact, there are only two possible choices for ν . Since ν is a vector field of N , defined along M , the symbol $\nabla'_{X_p} \nu$ makes sense for $X_p \in M_p$.

8. THEOREM. Let M be a hypersurface in N , and let ν be a unit normal field on a neighborhood of p in M .

(a) For all $X_p \in M_p$ we have

$$\nabla'_{X_p} \nu \in M_p.$$

(b) If Y is a vector field tangent along M , then we have

The Weingarten Equations:

$$\langle \nabla'_{X_p} \nu, Y_p \rangle = -\langle \nu, \nabla'_{X_p} Y \rangle = -\langle \nu, s(X_p, Y_p) \rangle.$$

(c) Consequently,

$$\langle \nabla'_{X_p} \nu, Y_p \rangle = \langle X_p, \nabla'_{Y_p} \nu \rangle.$$

PROOF. (a) Since $\langle \nu, \nu \rangle = 1$ along M , we have

$$0 = X_p(\langle \nu, \nu \rangle) = 2\langle \nabla'_{X_p} \nu, \nu \rangle,$$

which means that $\nabla'_{X_p} \nu \in M_p$, since M_p^\perp is 1-dimensional.

(b) Since $\langle \nu, Y \rangle = 0$ along M , we have

$$0 = X_p(\langle \nu, Y \rangle) = \langle \nabla'_{X_p} \nu, Y \rangle + \langle \nu, \nabla'_{X_p} Y \rangle,$$

which implies the first equality in the Weingarten equations. The second equality comes from the definition $s(X_p, Y_p) = \perp(\nabla'_{X_p} Y)$, and the fact that $\perp(\nabla'_{X_p} Y)$ is a multiple of ν .

(c) follows from (b) and symmetry of s . ♦

The reader may recall that the “Weingarten equations” have already appeared in Volume II, pg. 124. The relationship between those equations and the ones in Theorem 8, as well as the reason for choosing the notation $s(X_p, Y_p)$, may come out in the following special case of Theorem 8.

9. COROLLARY. Let M^n be a hypersurface in \mathbb{R}^{n+1} and let ν be a unit normal field on a neighborhood of p in M . Then for all $X_p, Y_p \in M_p$ we have

$$s(X_p, Y_p) = \text{II}(X_p, Y_p) \cdot \nu(p),$$

where $\text{II}(X_p, Y_p)$ is the second fundamental form of M defined for the choice ν of unit normal field, namely

$$\text{II}(X_p, Y_p) = -\langle d\nu(X_p), Y_p \rangle.$$

(Here $d\nu(X_p)$ is interpreted as follows [pg. II.121ff.]: Since we can think of ν as a map $\nu: M \rightarrow S^{n-1} \subset \mathbb{R}^{n+1}$, we have the vector-valued differential form $d\nu: M_p \rightarrow \mathbb{R}^{n+1}$, and $d\nu(X_p) \in \mathbb{R}^{n+1}$ is to be moved back to a parallel vector in M_p ; equivalently, $d\nu(X_p)$ denotes $\nu_*(X_p) \in S^{n-1}_{\nu(p)}$ moved back to a parallel vector in M_p .)

PROOF. Since $\nabla'_{X_p} \nu$ is now simply the directional derivative of ν , we have

$$\nabla'_{X_p} \nu = [X_p(\nu)]_p = [d\nu(X_p)]_p = d\nu(X_p),$$

in the notation we have just adopted. So the Theorem says that

$$\begin{aligned} \langle \nu, s(X_p, Y_p) \rangle &= -\langle d\nu(X_p), Y_p \rangle \\ &= \text{II}(X_p, Y_p), \end{aligned}$$

which is equivalent to the desired result. ♦

The reader should now be able to see that the Weingarten equations of Theorem 8 reduce to equations (a)–(c) on pg. II.124 for a surface in \mathbb{R}^3 . More precisely, the equation $\langle \nabla'_{X_p} v, Y_p \rangle = -\langle v, s(X_p, Y_p) \rangle$ establishes the relationship between s and II , and the equation $\langle v, \nabla'_{X_p} Y \rangle = \langle v, s(X_p, Y_p) \rangle$ then reduces to equations (a)–(c). One further point is worth checking: our present proof that s is symmetric is essentially equivalent to our second proof, in Volume II, that II is symmetric.

10. COROLLARY. Let M be a surface immersed in \mathbb{R}^3 , and let $X_p, Y_p \in M_p$. Then

$$\langle R(X_p, Y_p)Y_p, X_p \rangle = \text{II}(X_p, X_p) \cdot \text{II}(Y_p, Y_p) - [\text{II}(X_p, Y_p)]^2.$$

In particular, if (x, y) is a coordinate system on M , and we introduce the classical notation

$$\begin{aligned} \langle \cdot, \cdot \rangle &= \text{I} = E dx \otimes dx + F dx \otimes dy + F dy \otimes dx + G dy \otimes dy \\ \text{II} &= l dx \otimes dx + m dx \otimes dy + m dy \otimes dx + n dy \otimes dy, \end{aligned}$$

then

$$\frac{R_{1212}}{EG - F^2}(p) = \frac{ln - m^2}{EG - F^2}(p) = K(p),$$

where $K(p)$ is the Gaussian curvature of M at p .

PROOF. The first equation follows from Theorem 8, Corollary 9, and the fact that $R' = 0$ for \mathbb{R}^3 . For the second equation we recall the formulas on pp. II.190 and 129. ♦

As we have already noted in the proof of Proposition II.4-7, when we expand R_{1212} using formula (***) on pg. II.188, the second equation in Corollary 10 is exactly equivalent to Gauss' equation for K . The reader probably suspects that our more general Gauss equations can be used to obtain generalizations of the Theorema Egregium to higher dimensions. However, we will defer all such considerations until after we have studied surfaces in more detail. For the present we wish to consider only one more result, which depends on a definition motivated by Corollary 9. If $M \subset N$ is a hypersurface, we produce a symmetric tensor II on M by *defining*

$$s(X_p, Y_p) = \text{II}(X_p, Y_p) \cdot v(p);$$

naturally, the sign of II depends on the choice of the local unit normal field v . Some authors call s the second fundamental form of $M \subset N$, while others

reserve that name for \mathbb{I} . The tensor \mathbb{I} merely gives the length of s up to sign; but since it is real-valued, rather than M_p^\perp valued, the symbol $\nabla_{Z_p}\mathbb{I}$ makes sense. Indeed, we have defined $\nabla_{Z_p}\mathcal{T}$ for any tensor field \mathcal{T} (see Volume II, pp. 229ff.).

11. THEOREM. Let M be a hypersurface in N , and let ν be a unit normal field on a neighborhood of p in M , with corresponding \mathbb{I} . Then for all $X_p, Y_p, Z_p \in M_p$, we have

The Codazzi-Mainardi Equations:

$$\langle R'(X_p, Y_p)Z_p, \nu(p) \rangle = (\nabla_{X_p}\mathbb{I})(Y_p, Z_p) - (\nabla_{Y_p}\mathbb{I})(X_p, Z_p).$$

Remark: This formula gives us the normal component of $R'(X_p, Y_p)Z_p$, while Gauss' equation essentially gives us the tangential component.

PROOF. We begin with the equations derived in the proof of Theorem 6:

$$\begin{aligned} (1) \quad & \nabla'_X(\nabla'_Y Z) = \nabla_X(\nabla_Y Z) + s(X, \nabla_Y Z) + \nabla'_X(s(Y, Z)) \\ (1') \quad & \nabla'_Y(\nabla'_X Z) = \nabla_Y(\nabla_X Z) + s(Y, \nabla_X Z) + \nabla'_Y(s(X, Z)) \\ (2) \quad & \nabla'_{[X, Y]}Z = \nabla_{[X, Y]}Z + s([X, Y], Z) \\ & = \nabla_{[X, Y]}Z + s(\nabla_X Y, Z) - s(\nabla_Y X, Z). \end{aligned}$$

From these we see that the normal component of $R'(X, Y)Z$ is given by

$$\begin{aligned} (3) \quad & \text{normal component of } R'(X, Y)Z = \\ & [\perp \nabla'_X(s(Y, Z)) - s(\nabla_X Y, Z) - s(Y, \nabla_X Z)] \\ & - [\perp \nabla'_Y(s(X, Z)) - s(\nabla_Y X, Z) - s(X, \nabla_Y Z)]. \end{aligned}$$

On the other hand, since

$$(4) \quad s(Y, Z) = \mathbb{I}(Y, Z) \cdot \nu,$$

we have

$$\nabla'_X(s(Y, Z)) = X(\mathbb{I}(Y, Z)) \cdot \nu + \mathbb{I}(Y, Z) \cdot \nabla'_X \nu,$$

and consequently

$$(5) \quad \langle \nabla'_X(s(Y, Z)), \nu \rangle = X(\mathbb{I}(Y, Z)),$$

since $\nabla'_X v$ is tangent to M . Using (3), (5), and the definition (4) again, we obtain

$$\begin{aligned} \langle R'(X, Y)Z, v \rangle &= [X(\Pi(Y, Z)) - \Pi(\nabla_X Y, Z) - \Pi(Y, \nabla_X Z)] \\ &\quad - [Y(\Pi(X, Z)) - \Pi(\nabla_Y X, Z) - \Pi(X, \nabla_Y Z)]. \end{aligned}$$

The result now follows from* Corollary II.6-5. ❖

It will be useful to examine the form which our fundamental equations take when the ambient space N has constant curvature K_0 . Then by Lemma II.7-18 the curvature tensor R' of N satisfies

$$\begin{aligned} (1) \quad \langle R'(X, Y)Z, W \rangle &= K_0[\langle X, W \rangle \cdot \langle Y, Z \rangle - \langle X, Z \rangle \cdot \langle Y, W \rangle] \\ &\quad \Downarrow \\ (2) \quad R'(X, Y)Z &= K_0[\langle Y, Z \rangle X - \langle X, Z \rangle Y]. \end{aligned}$$

12. COROLLARY. Let N have constant curvature K_0 . Then for M isometrically immersed in N we have

Gauss' Equation:

$$\begin{aligned} \langle R(X_p, Y_p)Z_p, W_p \rangle + \langle s(X_p, Z_p), s(Y_p, W_p) \rangle &- \langle s(Y_p, Z_p), s(X_p, W_p) \rangle \\ &= K_0[\langle X_p, W_p \rangle \cdot \langle Y_p, Z_p \rangle - \langle X_p, Z_p \rangle \cdot \langle Y_p, W_p \rangle]. \end{aligned}$$

And if M is a hypersurface we have

The Codazzi-Mainardi Equations:

$$(\nabla_{X_p} \Pi)(Y_p, Z_p) = (\nabla_{Y_p} \Pi)(X_p, Z_p).$$

PROOF. The first result follows from Theorem 6 and equation (1). The second follows from Theorem 11 and equation (2), which shows that $R'(X_p, Y_p)Z_p$ is tangent to M . ❖

*This Corollary holds also for tensors of type $\binom{k}{0}$; see also Problem 1.

We have carried our analysis of submanifolds as far as we presently wish to go. However, it is also important that we indicate how things work out when we use moving frames. Before doing this, we will first examine the classical tensor analysis treatment of submanifolds. This is included mainly for the sake of completeness, and because you may be unfortunate enough to encounter it again in a classical work which you need to consult. If you are inclined to skip this part, I cannot in good conscience caution you against such a course of action, except to say that reading it must be good for you, because you certainly won't like it.

We will simplify things slightly by beginning with hypersurfaces from the outset. We consider a coordinate system y^1, \dots, y^{n+1} on N , with

$$\langle \ , \ \rangle = \sum_{\alpha, \beta=1}^{n+1} g'_{\alpha\beta} dy^\alpha \otimes dy^\beta,$$

and let x^1, \dots, x^n be a coordinate system on a hypersurface M , so that

$$\langle \ , \ \rangle = \sum_{i,j=1}^n g_{ij} dx^i \otimes dx^j \quad \text{on } M,$$

for certain functions g_{ij} . We adopt the convention that the indices i, j , etc., range from 1 to n , while α, β , etc., range from 1 to $n+1$, even in summation signs, so that \sum_i , for example, denotes $\sum_{i=1}^n$. It is easy to see that

$$\sum_{\alpha, \beta} g'_{\alpha\beta} \frac{\partial y^\alpha}{\partial x^i} \frac{\partial y^\beta}{\partial x^j} = g_{ij} \quad \text{on } M.$$

It will be convenient to let y^α also denote the restriction of y^α to M . Then we can use the symbol $y^\alpha_{;i} = \partial y^\alpha / \partial x^i$, introduced on pg. II.211, for the components of dy^α on M , and we can write

$$(1) \quad \sum_{\alpha, \beta} g'_{\alpha\beta} y^\alpha_{;i} y^\beta_{;j} = g_{ij} \quad \text{on } M.$$

If $v = \sum_{\alpha} v^\alpha \cdot \partial / \partial y^\alpha$ is a unit normal field, then we also have

$$(2) \quad \sum_{\alpha, \beta} g'_{\alpha\beta} y^\alpha_{;i} v^\beta = 0,$$

$$(3) \quad \sum_{\alpha, \beta} g'_{\alpha\beta} v^\alpha v^\beta = 1.$$

We now wish to take the covariant derivative of (1) on M . Notice that $y^\alpha{}_{;i} y^\beta{}_{;j}$ is the (i, j) component of the tensor $dy^\alpha \otimes dy^\beta$ on M ; on the other hand, each $g'_{\alpha\beta}$ is just a function on M . Writing

$$\frac{\partial g'_{\alpha\beta}}{\partial x^k} \quad \text{as} \quad \sum_{\gamma} \frac{\partial g'_{\alpha\beta}}{\partial y^\gamma} \frac{\partial y^\gamma}{\partial x^k} = \sum_{\gamma} \frac{\partial g'_{\alpha\beta}}{\partial y^\gamma} y^\gamma{}_{;k},$$

and using Proposition II.5-2, we obtain from (1)

$$\begin{aligned} \sum_{\alpha, \beta, \gamma} \frac{\partial g'_{\alpha\beta}}{\partial y^\gamma} y^\alpha{}_{;i} y^\beta{}_{;j} y^\gamma{}_{;k} + \sum_{\alpha, \beta} g'_{\alpha\beta} (y^\alpha{}_{;ik} y^\beta{}_{;j} + y^\beta{}_{;jk} y^\alpha{}_{;i}) &= g_{ij;k} \\ &= 0, \quad \text{by Ricci's Lemma (Proposition II.5-3).} \end{aligned}$$

If we write this equation with i and k interchanged, the term

$$\sum_{\alpha, \beta, \gamma} \frac{\partial g'_{\alpha\beta}}{\partial y^\gamma} y^\alpha{}_{;k} y^\beta{}_{;j} y^\gamma{}_{;i} \quad \text{can be replaced by} \quad \sum_{\alpha, \beta, \gamma} \frac{\partial g'_{\gamma\beta}}{\partial y^\alpha} y^\alpha{}_{;i} y^\beta{}_{;j} y^\gamma{}_{;k}.$$

A similar replacement can be made when we rewrite the original equation with j and k interchanged. Adding the two equations so obtained, and subtracting the original, we get

$$\sum_{\alpha, \beta} g'_{\alpha\beta} y^\alpha{}_{;k} y^\beta{}_{;ij} + \sum_{\alpha, \beta, \gamma} [\alpha\beta, \gamma]' y^\alpha{}_{;i} y^\beta{}_{;j} y^\gamma{}_{;k} = 0,$$

where $[\ , \]'$ indicates the Christoffel symbols for the y coordinate system. This can also be written as

$$(4) \quad \sum_{\alpha, \beta} g'_{\alpha\beta} y^\beta{}_{;k} \left(y^\alpha{}_{;ij} + \sum_{\rho, \sigma} \Gamma'^{\alpha}_{\rho\sigma} y^\rho{}_{;i} y^\sigma{}_{;j} \right) = 0,$$

which shows that the expression in parentheses is the α component of a vector perpendicular to M . As a matter of fact, a calculation (Problem 2) shows that it is the coefficient of $\partial/\partial y^\alpha$ in the expression for $\nabla'_{\partial/\partial x^i} \partial/\partial x^i - \nabla_{\partial/\partial x^i} \partial/\partial x^i$. Consequently, (4) is equivalent to Theorem 1, and despite the ugliness of the equations involved, its derivation is clearly closely related to that of Theorem 1.

Since $\sum_{\alpha} v^\alpha \cdot \partial/\partial y^\alpha$ is a unit normal field, and M_p^\perp has dimension 1, equation (4) implies that

$$(5) \quad y^\alpha{}_{;ij} + \sum_{\rho, \sigma} \Gamma'^{\alpha}_{\rho\sigma} y^\rho{}_{;i} y^\sigma{}_{;j} = \Pi_{ij} v^\alpha$$

for certain functions Π_{ij} ; multiplying by $\sum_{\beta} g'_{\alpha\beta} v^{\beta}$ and using (3), this can be written

$$(6) \quad \Pi_{ij} = \sum_{\alpha, \beta} g'_{\alpha\beta} v^{\beta} y^{\alpha}_{;ij} + \sum_{\rho, \sigma, \beta} [\rho\sigma, \beta]' y^{\rho}_{;i} y^{\sigma}_{;j} v^{\beta}.$$

This shows that the Π_{ij} satisfy the transformation rule for a covariant tensor of order 2 on M , since the $y^{\alpha}_{;ij}$ and $y^{\rho}_{;i} y^{\sigma}_{;j}$ do, and since the other terms don't involve the coordinate system x but only the coordinate system y on N (at the same time we see that the whole right side doesn't even depend on y). It is also clear that $\Pi_{ij} = \Pi_{ji}$. Equation (5) is equivalent to the Gauss formulas.

We next take the covariant derivative of equation (2) on M (now both $g'_{\alpha\beta}$ and v^{β} are functions on M). We obtain

$$\begin{aligned} \sum_{\alpha, \beta} g'_{\alpha\beta} (y^{\alpha}_{;ij} v^{\beta} + y^{\alpha}_{;i} v^{\beta}_{;j}) &= - \sum_{\alpha, \beta, \sigma} y^{\alpha}_{;i} y^{\sigma}_{;j} v^{\beta} \frac{\partial g'_{\alpha\beta}}{\partial y^{\sigma}} \\ &= - \sum_{\alpha, \beta, \sigma} y^{\alpha}_{;i} y^{\sigma}_{;j} v^{\beta} ([\alpha\sigma, \beta]' + [\beta\sigma, \alpha]'). \end{aligned}$$

Then (6) gives

$$\Pi_{ij} = - \sum_{\alpha, \beta} g'_{\alpha\beta} y^{\alpha}_{;i} v^{\beta}_{;j} - \sum_{\rho, \sigma, \beta} [\beta\sigma, \rho]' y^{\rho}_{;i} y^{\sigma}_{;j} v^{\beta},$$

or

$$-\Pi_{ij} = \sum_{\alpha, \beta} g'_{\alpha\beta} y^{\alpha}_{;i} \left(v^{\beta}_{;j} + \sum_{\rho, \sigma} \Gamma'^{\beta}_{\rho\sigma} y^{\rho}_{;j} v^{\sigma} \right),$$

which can also be written as

$$(7) \quad -\Pi_{ij} = \sum_{\alpha, \beta} g'_{\alpha\beta} y^{\alpha}_{;i} \left(\sum_{\rho} v^{\beta}_{;\rho} y^{\rho}_{;j} \right),$$

where $v^{\beta}_{;\rho}$ now denotes the covariant derivative, in N , of the vector field with components v^{β} , so that

$$v^{\beta}_{;\rho} = \frac{\partial v^{\beta}}{\partial y^{\rho}} + \sum_{\sigma} \Gamma'^{\beta}_{\rho\sigma} v^{\sigma}.$$

Equation (7) is clearly equivalent to one part of the Weingarten equations, namely $-\langle v, s(X_p, Y_p) \rangle = \langle \nabla'_{X_p} v, Y_p \rangle$. If we treat (3) in a similar manner, we end up with

$$(8) \quad \sum_{\alpha, \beta} g'_{\alpha\beta} v^{\alpha} \left(\sum_{\rho} v^{\beta}_{;\rho} y^{\rho}_{;j} \right) = 0,$$

which is equivalent to the fact that $\nabla'_{X_p} v \in M_p$.

Since (8) shows that we can write

$$(9) \quad \sum_{\rho} v^{\beta}{}_{;\rho} y^{\rho}{}_{;j} = \sum_k A_j^k y^{\beta}{}_{;k} \quad \text{for some functions } A_j^k \text{ on } M,$$

equation (7) gives

$$\begin{aligned} -\Pi_{ij} &= \sum_{\alpha, \beta, k} g'_{\alpha\beta} y^{\alpha}{}_{;i} y^{\beta}{}_{;k} A_j^k \\ &= \sum_k g_{ik} A_j^k \quad \text{by (I),} \end{aligned}$$

so

$$A_j^m = \sum_l -\Pi_{lj} g^{lm},$$

and hence from (9)

$$\sum_{\rho} v^{\beta}{}_{;\rho} y^{\rho}{}_{;j} = - \sum_{l,m} \Pi_{lj} g^{lm} y^{\beta}{}_{;m},$$

or equivalently

$$(10) \quad v^{\beta}{}_{;j} + \sum_{\rho, \sigma} \Gamma'_{\rho\sigma}{}^{\beta} y^{\rho}{}_{;j} v^{\sigma} = - \sum_{l,m} \Pi_{lj} g^{lm} y^{\beta}{}_{;m}.$$

We return to equation (5), equivalent to Gauss' formulas. We can apply Ricci's identity (Proposition II.5-4)

$$\lambda_{i;jk} - \lambda_{i;kj} = \sum_m \lambda_m R^m{}_{ijk} = \sum_{m,h} \lambda_m g^{mh} R_{hijk}$$

to $\lambda_i = y^{\alpha}{}_{;i}$, obtaining

$$\sum_{m,h} y^{\alpha}{}_{;m} g^{mh} R_{hijk} = y^{\alpha}{}_{;ijk} - y^{\alpha}{}_{;ikj}.$$

Computing the $y^{\alpha}{}_{;ijk}$ from (5), and using (5) and (10) in the result, we obtain finally

$$\begin{aligned} \sum_{m,h} y^{\alpha}{}_{;m} g^{mh} [R_{hijk} - (\Pi_{hj} \Pi_{ik} - \Pi_{hk} \Pi_{ij})] - v^{\alpha} (\Pi_{ij;k} - \Pi_{ik;j}) \\ - \sum_{\rho, \sigma, \lambda} R'^{\alpha}{}_{\rho\sigma\lambda} y^{\rho}{}_{;i} y^{\sigma}{}_{;j} y^{\lambda}{}_{;k} = 0. \end{aligned}$$

Multiplying by $\sum_{\alpha} g'_{\alpha\beta} y^{\beta}_{;l}$ or by $\sum_{\alpha} g'_{\alpha\beta} v^{\beta}$, we get

$$(11) \quad R_{ijkl} = (\Pi_{ik}\Pi_{jl} - \Pi_{il}\Pi_{jk}) + \sum_{\alpha,\beta,\gamma,\delta} R'_{\alpha\beta\gamma\delta} y^{\alpha}_{;i} y^{\beta}_{;j} y^{\gamma}_{;k} y^{\delta}_{;l}$$

$$(12) \quad \Pi_{ij;k} - \Pi_{ik;j} = \sum_{\alpha,\beta,\gamma,\delta} R'_{\alpha\beta\gamma\delta} y^{\alpha}_{;i} y^{\gamma}_{;j} y^{\delta}_{;k} v^{\beta}.$$

Equations (11) and (12) are equivalent to Gauss' Equation and the Codazzi-Mainardi equations, respectively. Whew!

When we turn to the method of moving frames, we find ourselves in a situation completely different from the mass of calculations in which we have just been mired. Although the moving frame method will not have the geometric appeal of the ∇ theory, it is far superior computationally. Not only are all the equations short and simple, but all the results follow naturally, almost without thought, from the structural equations. Indeed, everything happens so quickly that the real problem is recognizing a result when it appears.

Consider first an orthonormal moving frame X_1, \dots, X_n on an open subset of M . Recall that the **dual 1-forms** θ^i are defined by $\theta^i(X_j) = \delta^i_j$, and that there are unique 1-forms ω^i_j , the **connection forms**, satisfying the two equations

$$(1) \quad \omega^i_j = -\omega^j_i$$

$$(2) \quad d\theta^i = -\sum_{k=1}^n \omega^i_k \wedge \theta^k \quad (\text{The first structural equation}).$$

The **curvature forms** Ω^i_j are then defined by

$$(3) \quad d\omega^i_j = -\sum_{k=1}^n \omega^i_k \wedge \omega^k_j + \Omega^i_j \quad (\text{The second structural equation}).$$

The relationship between ω^i_j, Ω^i_j and ∇, R is given by

$$(4) \quad \nabla_{X_k} X_j = \sum_{i=1}^n \omega^i_j(X_k) X_i \quad \text{or} \quad \langle \nabla_X X_j, X_i \rangle = \omega^i_j(X)$$

$$(5) \quad R(X_k, X_l)X_j = \sum_{i=1}^n \Omega^i_j(X_k, X_l) X_i \quad \text{or} \quad \langle R(X, Y)X_j, X_i \rangle = \Omega^i_j(X, Y).$$

Now let us consider an orthonormal moving frame X_1, \dots, X_m , defined on an open subset of N , with the property that X_1, \dots, X_n are tangent to M at points of M , and consequently X_{n+1}, \dots, X_m are normal to M at points of M ; such an orthonormal moving frame is said to be **adapted to M** . An adapted

orthonormal moving frame gives us an orthonormal moving frame X_1, \dots, X_n along M , with corresponding forms $\theta^i, \omega_j^i, \Omega_j^i$ ($i, j \leq n$). We also want to consider the corresponding forms for the entire moving frame X_1, \dots, X_m on N ; these will be denoted by $\phi^\alpha, \psi_\beta^\alpha, \Psi_\beta^\alpha$. We adopt the convention that i, j , etc., always range from 1 to n , while α, β , etc., always range from 1 to m , even in summation signs, so that \sum_i , for example, means $\sum_{i=1}^n$; it will also be convenient to use r, s , etc., for numbers that range from $n+1$ to m .

Now the forms $\phi^\alpha, \psi_\beta^\alpha, \Psi_\beta^\alpha$ can be restricted to TM (that is, to tangent vectors of M). Clearly

$$\begin{aligned} \phi^i &= \theta^i & \text{on } TM & \quad i \leq n \\ \phi^r &= 0 & \text{on } TM & \quad r > n. \end{aligned}$$

To obtain some information about the forms ψ_β^α on TM , we look at the first structural equation,

$$d\phi^\alpha = - \sum_\gamma \psi_\gamma^\alpha \wedge \phi^\gamma.$$

Restricting to TM we obtain

$$\begin{aligned} \text{(a)} \quad d\theta^i &= - \sum_k \psi_k^i \wedge \theta^k & \text{on } TM & \quad i \leq n \\ \text{(b)} \quad 0 &= \sum_k \theta^k \wedge \psi_k^r & \text{on } TM & \quad r > n. \end{aligned}$$

Recall that ω_j^i were the *unique* forms satisfying (1), (2). Since $\psi_\beta^\alpha = -\psi_\alpha^\beta$, equation (a) therefore shows that

$$\text{(c)} \quad \psi_j^i = \omega_j^i \quad \text{on } TM \quad i, j \leq n.$$

This equation already contains some information! In fact, equation (4) shows that

$$\langle \nabla_X X_j, X_i \rangle = \omega_j^i(X) = \psi_j^i(X) = \langle \nabla'_X X_j, X_i \rangle \quad \text{for } X \in TM;$$

this is exactly equivalent to Theorem 1, for it shows that $\nabla'_X X_j(p)$ has the same inner product with every element of M_p as $\nabla_X X_j(p) \in M_p$.

Next, we look at the forms $\psi_k^r = -\psi_r^k$ on TM , for $k \leq n < r$. Equation (b) tells us that they satisfy the hypothesis of the following Lemma.

13. LEMMA (CARTAN'S LEMMA). If $\lambda^1, \dots, \lambda^n$ are (C^∞) linearly independent 1-forms on a manifold M (of dimension $n' \geq n$), and μ_1, \dots, μ_n are (C^∞) 1-forms on M satisfying

$$(*) \quad \sum_{i=1}^n \lambda^i \wedge \mu_i = 0,$$

then there are unique (C^∞) functions f_{ij} on M such that

$$\mu_i = \sum_{j=1}^n f_{ij} \lambda^j;$$

moreover,

$$f_{ij} = f_{ji}.$$

Remark: This result (or at least the corresponding result for vector spaces) has already been given in Problem I.7-11.

PROOF. In a neighborhood of any point we can choose (C^∞) 1-forms $\lambda^{n+1}, \dots, \lambda^{n'}$ so that $\lambda^1, \dots, \lambda^{n'}$ are everywhere independent. Then there are (C^∞) functions f_{ij} ($i \leq n, j \leq n'$) with

$$\mu_i = \sum_{j=1}^{n'} f_{ij} \lambda^j.$$

Equation $(*)$ implies that

$$0 = \sum_{i=1}^n \sum_{j=1}^{n'} f_{ij} \lambda^i \wedge \lambda^j = \sum_{1 \leq i < j \leq n} (f_{ij} - f_{ji}) \lambda^i \wedge \lambda^j + \sum_{i=1}^n \sum_{j > n} f_{ij} \lambda^i \wedge \lambda^j.$$

Since the $\lambda^i \wedge \lambda^j$ for $i < j$ are linearly independent, we have $f_{ij} - f_{ji} = 0$ for $i, j \leq n$ and $f_{ij} = 0$ for $j > n$. ♦

Applying Cartan's Lemma to the ψ_k^r , we conclude that there are unique functions s_{ij}^r on M satisfying

$$(d) \quad \begin{aligned} \psi_j^r &= -\psi_r^j = \sum_i s_{ij}^r \theta^i \quad \text{on } TM \quad r > n, \\ s_{ij}^r &= s_{ji}^r. \end{aligned}$$

Equation (4) now shows that

$$\langle \nabla'_{X_k} X_j, X_r \rangle = \psi_j^r(X_k) = s_{kj}^r \quad r > n,$$

and hence

$$\langle \nabla'_{X_j} X_k, X_r \rangle = \langle \nabla'_{X_k} X_j, X_r \rangle \quad r > n.$$

This is basically Theorem 5, asserting the symmetry of s , which in our present notation can be defined by setting

$$(e) \quad s(X_j, X_k) = \sum_r \psi_j^r(X_k) \cdot X_r = \sum_r s_{jk}^r X_r,$$

and extending s by linearity. It should be noted that this definition of s involves a choice of a moving frame; when one is developing everything from the moving frame approach, a little calculation (Problem 3) must be supplied to show that the definition of s is really independent of the choice. Equations (c) and (d) together are equivalent to the Gauss formulas.

Now let us look at the second structural equation

$$d\psi_\beta^\alpha = - \sum_\gamma \psi_\gamma^\alpha \wedge \psi_\beta^\gamma + \Psi_\beta^\alpha.$$

Restricting to TM we obtain, for $\alpha, \beta = i, j \leq n$,

$$(f) \quad d\omega_j^i = - \sum_k \omega_k^i \wedge \omega_j^k + \sum_r \psi_r^i \wedge \psi_j^r + \Psi_j^i \quad \text{on } TM \quad i, j \leq n.$$

Comparing with (3) we obtain

$$(g) \quad \Psi_j^i = \Omega_j^i - \sum_r \psi_r^i \wedge \psi_j^r \quad \text{on } TM.$$

Then equation (5) gives

$$\begin{aligned} \langle R'(X, Y)X_j, X_i \rangle &= \Psi_j^i(X, Y) = \langle R(X, Y)X_j, X_i \rangle \\ &\quad - \sum_r (\psi_r^i(X) \psi_j^r(Y) - \psi_r^i(Y) \psi_j^r(X)). \end{aligned}$$

Since we have, for example,

$$\begin{aligned}\sum_r \psi_i^r(X) \psi_j^r(Y) &= \sum_r \langle s(X_i, X), X_r \rangle \cdot \langle s(X_j, Y), X_r \rangle \\ &= \langle s(X_i, X), s(X_j, Y) \rangle,\end{aligned}$$

it follows that (g) is exactly equivalent to Theorem 6 (Gauss' Equation).

If we instead choose $\alpha = r > n$, and $\beta = j \leq n$, we obtain

$$(h) \quad d\psi_j^r = - \sum_i \psi_i^r \wedge \omega_j^i - \sum_s \psi_s^r \wedge \psi_j^s + \Psi_j^r \quad \text{on } TM.$$

As before, we now restrict ourselves to the case $m = n + 1$; then X_{n+1} is a unit normal field on M . Notice that the equation $\psi_{n+1}^j = -\psi_j^{n+1}$ gives

$$\langle \nabla'_{X_k} X_{n+1}, X_j \rangle = \psi_{n+1}^j(X_k) = -\psi_j^{n+1}(X_k) = -\langle X_{n+1}, s(X_j, X_k) \rangle,$$

which are the Weingarten equations. Equation (h) takes the form

$$d\psi_j^{n+1} = - \sum_i \psi_i^{n+1} \wedge \omega_j^i + \Psi_j^{n+1}.$$

A little work (Problem 4) shows that this is equivalent to the Codazzi-Mainardi equations.

SUMMARY

$$\begin{array}{l} \phi^i = \theta^i \quad \text{on } TM \\ \phi^r = 0 \quad \text{on } TM \end{array}$$

Although the derivation of the fundamental equations was so much easier in terms of moving frames than in terms of tensors, the resultant equations have the same disadvantage as the moving frame treatment of connections itself—our equations are not “invariant”, they are merely a set of equations which hold for each choice of adapted orthonormal moving frame. Moreover, it is very hard to get any geometric feel for the equations—the tensor form of the equations seem much more geometric, especially Gauss’ equation. As one might guess, an invariant description of the moving frame equations can be obtained by considering an appropriate principal bundle—the “bundle of adapted orthonormal frames”. In Chapter 7 we will actually consider this construction in detail, even for submanifolds of higher codimension, but we will do this mainly for the sake of completeness, since the results which we will derive from this construction will also be obtained in other ways. On the whole, it seems uneconomical to construct the elaborate machinery of a principal bundle just to have a gadget on which we can give an invariant formulation of the fundamental equations for submanifolds, especially since the invariant equations are even more abstract and ungeometric. It is much easier, and more satisfying, to state these equations in terms of tensors down on the submanifold itself. On the other hand, when it comes to *using* these equations to prove theorems about submanifolds, the equations in terms of moving frames will almost always prove to be superior.

ADDENDUM

AUTO-PARALLEL AND TOTALLY GEODESIC SUBMANIFOLDS

The material of this section, besides being of interest in its own right, will play an important role on several occasions later on. We will not require any tools not already developed within the chapter, even though we will be dealing with submanifolds of arbitrary codimension, and even with manifolds whose connection does not come from a Riemannian metric.

Let N be a manifold with a connection ∇' , and let M be a submanifold of N . We say that M is **auto-parallel** if the parallel translation in N along a curve c in M always takes vectors tangent to M into vectors tangent to M . For example, a straight line or a plane in \mathbb{R}^3 is auto-parallel.

14. PROPOSITION. A submanifold M of (N, ∇') is auto-parallel if and only if $\nabla'_X Y$ is tangent to M whenever X and Y are.

PROOF. We know from Proposition II.6-3 that

$$\nabla'_{X_p} Y = \lim_{h \rightarrow 0} \frac{1}{h} (\tau_h^{-1} Y_{c(h)} - Y_p),$$

where c is a curve with $c'(0) = X_p$, and τ_h is parallel translation along c from $c(0)$ to $c(h)$. This makes it immediately clear that if M is auto-parallel, then $\nabla'_{X_p} Y$ is tangent to M if X and Y are.

Conversely, suppose $\nabla'_{X_p} Y$ is tangent to M whenever X and Y are. Let c be a curve in M and let V be a parallel vector field along c . Choose a coordinate system $x^1, \dots, x^n, x^{n+1}, \dots, x^m$ for N such that $x^r = 0$ on M for all $r > n$. If $V_t \in N_{c(t)}$ is given by

$$V_t = \sum_{\alpha=1}^m v^\alpha(t) \cdot \frac{\partial}{\partial x^\alpha} \Big|_c(t),$$

then we have (pg. II.233)

$$(1) \quad 0 = \frac{dv^\gamma(t)}{dt} + \sum_{\alpha, \beta} \frac{dc^\alpha(t)}{dt} \Gamma_{\alpha\beta}^\gamma(c(t)) v^\beta(t).$$

Now $c^r(t) = 0$ for $r > n$, since c lies in M . Moreover, if $i, j \leq n$, then the vector

$$\nabla' \frac{\partial}{\partial x^i} \frac{\partial}{\partial x^j} = \sum_{\gamma} \Gamma_{ij}^{\gamma} \frac{\partial}{\partial x^{\gamma}}$$

is tangent to M by hypothesis, so we must have $\Gamma_{ij}^r = 0$ for $r > n$. So for $\gamma = s > n$, equation (1) becomes

$$\frac{dv^s(t)}{dt} = - \sum_{r=n+1}^m \sum_{i=1}^n \frac{dc^i(t)}{dt} \Gamma_{ir}^s(c(t)) v^r(t).$$

This set of $m - n$ equations for the $m - n$ functions v^s has a unique solution for a given initial condition. The solution with all $v^s(0) = 0$ is clearly just $v^s(t) = 0$ for all $s > n$. In other words, if V_0 is tangent to M , then so are all V_t . ♦

15. COROLLARY. If M is an auto-parallel submanifold of (N, ∇') , then

$$R'(X_p, Y_p)Z_p \in M_p \quad \text{for all } X_p, Y_p, Z_p \in M_p.$$

PROOF. Use the definition

$$R'(X, Y)Z = \nabla'_X \nabla'_Y Z - \nabla'_Y \nabla'_X Z - \nabla'_{[X, Y]} Z$$

(and Proposition I.6-3). ♦

In the particular case where the connection ∇' on N is the unique symmetric connection compatible with a Riemannian metric $\langle \cdot, \cdot \rangle$ on N , we can characterize auto-parallel submanifolds $M \subset N$ in a different way.

16. PROPOSITION. If $(N, \langle \cdot, \cdot \rangle)$ is a Riemannian manifold, then a submanifold $M \subset N$ is auto-parallel if and only if the second fundamental form s of M is zero.

PROOF. By definition, s is zero if and only if $\nabla'_X Y$ is tangent to M whenever X and Y are. So the result follows from Proposition 14. ♦

Notice that whenever M is an auto-parallel submanifold of (N, ∇') , we can define a connection ∇ on M by letting $\nabla_X Y = \nabla'_X Y$ for X and Y tangent to M . This connection ∇ on M is called the **induced connection** on M . (In the

Riemannian case, ∇ clearly coincides with the connection M has as a Riemannian submanifold.) If c is a curve in M and V is a vector field along c which is everywhere tangent to M , then the covariant derivative DV/dt along c which is determined by ∇ is exactly the same as the covariant derivative $D'V/dt$ along c which is determined by ∇' : for the proof we just apply Proposition II.6-2, which essentially defines DV/dt . In particular, if V is parallel along c with respect to the connection ∇ in M , then it is also parallel along c with respect to the connection ∇' in N .

Auto-parallel submanifolds can also be characterized in yet another way. A submanifold M of (N, ∇') is called **geodesic at p** if every geodesic γ with $\gamma(0) = p$ and $\gamma'(0) \in M_p$ remains in M on some interval $(-\varepsilon, \varepsilon)$. It is called **totally geodesic** if it is geodesic at every point; it is easy to see that $M \subset N$ is totally geodesic if and only if every geodesic in M is also a geodesic in N .

17. PROPOSITION. Let M be a submanifold of a manifold (N, ∇') .

- (1) If M is auto-parallel, then M is totally geodesic.
- (2) If M is totally geodesic, and ∇' is symmetric, then M is auto-parallel.

PROOF. (1) Let c be a geodesic of N with $c'(0) \in M_p$. Let \bar{c} be the geodesic in M , with respect to the induced connection ∇ , satisfying $\bar{c}'(0) = c'(0)$. To prove that an interval of c lies in M , it certainly suffices to prove that $\bar{c} = c$ along some interval containing 0. Now by the definition of a geodesic, $d\bar{c}/dt$ is parallel along c with respect to ∇ . As we have already noted, this implies that $d\bar{c}/dt$ is parallel along c with respect to ∇' . Thus \bar{c} is a geodesic in N . Since $\bar{c}'(0) = c'(0)$, the geodesics \bar{c} and c must coincide on their common domain.

(2) In a neighborhood of a point $p \in M$ we can choose a coordinate system $x^1, \dots, x^n, x^{n+1}, \dots, x^m$ for N such that $x^r = 0$ on M for $r > n$. Let c be a geodesic with

$$c(0) = p \quad \text{and} \quad c'(0) = \sum_{i=1}^n a^i \frac{\partial}{\partial x^i} \Big|_p \in M_p.$$

Then by hypothesis we have $c(t) \in M$ for sufficiently small t . Now c satisfies (pg. II.246)

$$\frac{d^2 c^\gamma}{dt^2} + \sum_{\alpha, \beta} \Gamma_{\alpha\beta}^\gamma(c(t)) \frac{dc^\alpha}{dt} \frac{dc^\beta}{dt} = 0.$$

For $\gamma = s > n$ we have

$$\sum_{i,j=1}^n \Gamma_{ij}^s(c(t)) \frac{dc^i}{dt} \frac{dc^j}{dt} = 0 \quad \text{for small } t.$$

Letting $t = 0$, we obtain

$$\sum_{i,j=1}^n \Gamma_{ij}^s(p) a^i a^j = 0.$$

Choosing $a^i = 1$, all other $a^j = 0$, we get

$$(a) \quad 0 = \Gamma_{ii}^s(p).$$

Choosing $a^i = a^j = 1$, all other $a^k = 0$, we get

$$(b) \quad 0 = \Gamma_{ii}^s(p) + \Gamma_{ij}^s(p) + \Gamma_{ji}^s(p) + \Gamma_{jj}^s(p) = \Gamma_{ij}^s(p) + \Gamma_{ji}^s(p).$$

Using symmetry of the Γ 's, we find that $\Gamma_{ij}^s(p) = 0$ for all i, j . This is true for all $p \in M$, so we find that $\nabla'_X Y$ is tangent to M if X and Y are. The result then follows from Proposition 14. ♦

Every n -dimensional plane $P \subset \mathbb{R}^m$ is clearly totally geodesic. (Conversely, if $M \subset \mathbb{R}^m$ is a totally geodesic submanifold, and p is a point of M , then M must clearly contain a neighborhood of its tangent space $M_p \subset \mathbb{R}^m$; so if M is a connected n -dimensional totally geodesic submanifold of \mathbb{R}^m , then M must be part of an n -dimensional plane $P \subset \mathbb{R}^m$.) It is just as clear that if we give S^m its standard Riemannian metric, then any n -sphere $S^n \subset S^m$ is totally geodesic. Now let us consider the Riemannian manifold $(N, \langle \ , \ \rangle)$ mentioned on pg. II.301, with constant curvature -1 : the manifold N is

$$N = \left\{ a \in \mathbb{R}^m : \sum_{\alpha=1}^m (a^\alpha)^2 < 4 \right\},$$

and the components $g_{\alpha\beta}$ of $\langle \ , \ \rangle$ with respect to the usual coordinate system x^1, \dots, x^m are given by

$$g_{\alpha\beta} = \frac{\delta_{\alpha\beta}}{\left[1 - \frac{1}{4} \sum_{\alpha=1}^m (x^\alpha)^2 \right]^2}.$$

Let $M \subset N$ be

$$M = \{a \in N : a^{n+1} = \dots = a^m = 0\}.$$

The formulas for the Γ 's on pg. II.299 show that $\Gamma_{ij}^r = 0$ on M whenever $i, j \leq n$ and $r > n$, which means that $\nabla'_X Y$ is tangent to M whenever X and Y are. So M is a totally geodesic submanifold of N , by Propositions 14 and 16. Since the metric $\langle \cdot, \cdot \rangle$ is radially symmetric around 0, it is clear that we can find a totally geodesic submanifold M of N with M_0 being any n -dimensional subspace of N_0 . The same is true at any other point $p \in N$, because the fact that N has constant curvature implies that p has a neighborhood isometric to a neighborhood of 0 (Corollary II.7-13); in fact, since N is simply-connected and complete, there is actually an isometry of N onto itself taking any point p to 0 (Problem 5).*

The possibility of finding so many totally geodesic submanifolds is very exceptional:

18. THEOREM. Let $(N, \langle \cdot, \cdot \rangle)$ be a connected Riemannian manifold of dimension $m \geq 3$. Suppose that for all $p \in N$ and all 2-dimensional subspaces $P \subset N_p$ there is a totally geodesic submanifold M of N with $p \in M$ and $M_p = P$. Then N has constant curvature.

PROOF. Each submanifold M is auto-parallel, by Proposition 17, so Corollary 15 shows that

$$\langle R'(X_p, Y_p)Z_p, W_p \rangle = 0$$

for $X_p, Y_p, Z_p \in M_p$ and $W_p \in M_p^\perp$. Since M_p can be any 2-dimensional subspace $P \subset N_p$, we see that

$$(1) \quad \langle R'(X_p, Y_p)X_p, W_p \rangle = 0 \quad \text{for orthonormal } X_p, Y_p, W_p \in N_p.$$

Applying (1) to $X_p, \bar{Y}_p, \bar{W}_p$ with

$$\begin{aligned} \bar{Y}_p &= (\cos \alpha)Y_p + (\sin \alpha)W_p \\ \bar{W}_p &= (-\sin \alpha)Y_p + (\cos \alpha)W_p, \end{aligned}$$

we obtain

$$\begin{aligned} 0 &= \sin \alpha \cos \alpha [\langle R'(X_p, W_p)X_p, W_p \rangle - \langle R'(X_p, Y_p)X_p, Y_p \rangle] \\ &\quad + \cos^2 \alpha \langle R'(X_p, Y_p)X_p, W_p \rangle - \sin^2 \alpha \langle R'(X_p, W_p)X_p, Y_p \rangle \\ &= \sin \alpha \cos \alpha [\langle R'(X_p, W_p)X_p, W_p \rangle - \langle R'(X_p, Y_p)X_p, Y_p \rangle] \quad \text{by (1).} \end{aligned}$$

*More detailed information about the manifold N will be found in Chapter 7, Part A.

Thus $\langle R'(X_p, W_p)X_p, W_p \rangle = \langle R'(X_p, Y_p)X_p, Y_p \rangle$ for all orthonormal X_p, Y_p, W_p , which implies that all sectional curvatures at p are equal. Since this is true for all p , Schur's Theorem (II.7-19) shows that M has constant curvature. ❖

It seems rather clear that if one takes a Riemannian manifold $(N, \langle \cdot, \cdot \rangle)$ “at random”, then it will not have any totally geodesic submanifolds of dimension > 1 . But I must admit that I don't know of any specific example of such a manifold.

PROBLEMS

1. (a) In Corollary II.6-5, each $A(p)$ is regarded as a map $M_p \times \cdots \times M_p \rightarrow M_p$. If we instead regard each $A(p)$ as a map $M_p \times \cdots \times M_p \times M_p^* \rightarrow \mathbb{R}$, show that

$$\begin{aligned} (\nabla_{X_p} A)(Y_1(p), \dots, Y_k(p), \omega(p)) &= \nabla_{X_p}(A(Y_1, \dots, Y_k, \omega)) \\ &- \sum_{i=1}^k A(Y_1(p), \dots, \nabla_{X_p} Y_i, \dots, Y_k(p), \omega(p)) + A(Y_1(p), \dots, Y_k(p), \nabla_{X_p} \omega). \end{aligned}$$

(b) If A is a tensor field of type $\binom{k}{l}$, where each $A(p)$ is regarded as a map $M_p \times \cdots \times M_p \times M_p^* \times \cdots \times M_p^* \rightarrow \mathbb{R}$, show that

$$\begin{aligned} (\nabla_{X_p} A)(Y_1(p), \dots, \omega_l(p)) &= \nabla_{X_p}(A(Y_1, \dots, \omega_l)) \\ &- \sum_{i=1}^k A(\dots, \nabla_{X_p} Y_i, \dots, \omega_l(p)) \\ &+ \sum_{i=1}^l A(Y_1(p), \dots, \nabla_{X_p} \omega_i, \dots). \end{aligned}$$

Consider in particular the cases $l = 0$ and $k = 0$.

(c) If we instead regard each $A(p)$ as a map from $M_p \times \cdots \times M_p$ to the set of maps $M_p^* \times \cdots \times M_p^* \rightarrow \mathbb{R}$, then

$$\begin{aligned} (\nabla_{X_p} A)(Y_1(p), \dots, Y_k(p)) &= \nabla_{X_p}(A(Y_1, \dots, Y_k)) \\ &- \sum_{i=1}^k A(Y_1(p), \dots, \nabla_{X_p} Y_i, \dots, Y_k(p)). \end{aligned}$$

2. Consider the situation on page 12. Writing

$$\frac{\partial}{\partial x^i} = \sum_{\rho} \frac{\partial y^{\rho}}{\partial x^i} \frac{\partial}{\partial y^{\rho}} = \sum_{\rho} y^{\rho}{}_{;i} \frac{\partial}{\partial y^{\rho}},$$

and similarly for $\partial/\partial x^j$, show that

$$\nabla'_{\partial/\partial x^j} \partial/\partial x^i = \sum_{\alpha} \left(\sum_{\rho, \sigma} \Gamma'_{\rho\sigma}{}^{\alpha} y^{\rho}{}_{;i} y^{\sigma}{}_{;j} \right) \frac{\partial}{\partial y^{\alpha}} + \sum_{\alpha} \left(\sum_{\rho} y^{\rho}{}_{;j} \frac{\partial y^{\alpha}{}_{;i}}{\partial y^{\rho}} \right) \frac{\partial}{\partial y^{\alpha}}.$$

Using

$$y^{\alpha}{}_{;ij} = \frac{\partial y^{\alpha}{}_{;i}}{\partial x^j} - \sum_k y^{\alpha}{}_{;k} \Gamma_{ji}^k = \sum_{\rho} y^{\rho}{}_{;j} \frac{\partial y^{\alpha}{}_{;i}}{\partial y^{\rho}} - \sum_k y^{\alpha}{}_{;k} \Gamma_{ji}^k,$$

verify the assertion near the bottom of page 13.

3. (The calculations in this Problem are similar to those on pages 79–82 and 97–100 and might be postponed until then, or they may be regarded as a rehearsal for the latter.) Let $\mathbf{X} = X_1, \dots, X_m$ and $\mathbf{X}' = X'_1, \dots, X'_m$ be two adopted orthonormal moving frames on $M^n \subset N$. Let s_{ij}^r and $s_{ij}'^r$ be the unique functions with

$$\psi_j^r = \sum_i s_{ij}^r \theta^i, \quad \psi_j'^r = \sum_i s_{ij}'^r \theta'^i.$$

Say that $\mathbf{X}' = \mathbf{X} \cdot a$ for an orthogonal matrix of functions a , so that we have (pp. II.280, 282)

$$\theta' = a^{-1} \cdot \theta \quad \text{and} \quad \psi' = a^{-1} da + a^{-1} \psi a.$$

The matrix a must satisfy $a_r^r = 0 = a_r^j$, since \mathbf{X} and \mathbf{X}' are both adopted to M . Conclude that

$$\psi_j'^r = \sum_{i,t} (a^{-1})_t^r \psi_i^t a_j^i,$$

and thus that

$$\sum_i s_{ij}'^r (a^{-1})_h^i = \sum_{i,t} (a^{-1})_t^r s_{ih}^t a_j^i \implies \sum_r s_{kj}'^r a_r^u = \sum_{i,h} s_{ih}^u a_j^i a_k^h.$$

Hence show that the definition

$$s(X'_j, X'_k) = \sum_r s_{jk}'^r X'_r$$

is compatible with the definition

$$s(X_i, X_h) = \sum_u s_{ih}^u X_u.$$

4. Apply the equation for ψ_j^{n+1} on page 20 to (X_k, X_l) . Noting that

$$\begin{aligned} d\psi_j^{n+1}(X_k, X_l) &= X_k(\psi_j^{n+1}(X_l)) - X_l(\psi_j^{n+1}(X_k)) - \psi_j^{n+1}([X_k, X_l]) \\ [X_k, X_l] &= \nabla'_{X_k} X_l - \nabla'_{X_l} X_k = \sum_i \omega_l^i(X_k) X_i - \omega_k^i(X_l) X_i, \end{aligned}$$

deduce the last equation in the proof of Theorem 11.

5. Let N and \bar{N} be two n -dimensional Riemannian manifolds of constant curvature K_0 . Let X_1, \dots, X_n be an orthonormal basis of N_p , and $\bar{X}_1, \dots, \bar{X}_n$ be an orthonormal basis of $\bar{N}_{\bar{p}}$. Let $c: [0, 1] \rightarrow N$ be a curve with $c(0) = p$. By Corollary II.7-13, there is an isometry f from a neighborhood U_0 of p to a neighborhood of \bar{p} , with $f_*(X_i) = \bar{X}_i$. A **continuation** of f along c is a family $\{f_t\}$ of isometries $f_t: U_t \rightarrow \bar{N}$ where U_t is a neighborhood of $c(t)$, with $f_0 = f$, satisfying the following condition: for each t there is $\delta > 0$ so that $|t - t'| < \delta \Rightarrow f_t = f_{t'}$ on $U_t \cap U_{t'}$.

(a) If $\{f_t\}$ and $\{g_t\}$ are two continuations of f , then each $f_t = g_t$ in some neighborhood of $c(t)$.

(b) If N is connected, then there is at most one isometry $\phi: N \rightarrow \bar{N}$ with $\phi_* X_i = \bar{X}_i$.

(c) Let \bar{N} be complete, and let $K = \{q \in \bar{N} : d(\bar{p}, q) \leq \text{length of } c\}$. Then K is compact (see pg. I.343). Conclude that there is $\delta > 0$ such that for any orthonormal $Y_1, \dots, Y_n \in N_{c(t)}$ ($0 \leq t \leq 1$) and orthonormal $\bar{Y}_1, \dots, \bar{Y}_n \in \bar{N}_q$ ($q \in K$), there is an isometry taking Y_i to \bar{Y}_i whose domain contains all $c(t')$ for $|t - t'| < \delta$. Then show that a continuation always exists.

(d) If N is simply-connected, show that for two paths $c, \gamma: [0, 1] \rightarrow M$ with $c(0) = \gamma(0) = p$ and $c(1) = \gamma(1) = q$, the continuations $\{f_t\}, \{g_t\}$ of f along c and γ must satisfy $f_1(q) = g_1(q)$. Conclude that for \bar{N} complete and N simply-connected, there is a (unique) isometry $\phi: N \rightarrow \bar{N}$ with $\phi_* X_i = \bar{X}_i$.

(e) Any two simply-connected complete manifolds of constant curvature K_0 are isometric, and there is an isometry taking any orthonormal basis of such a manifold to any other orthonormal basis.

CHAPTER 2

ELEMENTS OF THE THEORY OF SURFACES IN \mathbb{R}^3

This chapter will parallel as closely as possible the first chapter of Volume II. Our interest will now be directed away from the intrinsic geometry of surfaces, and toward those properties which describe the particular ways they are immersed in \mathbb{R}^3 .

We recall that in our study of curves, we defined certain quantities, the curvature κ and the torsion τ , which describe the local appearance of a curve in \mathbb{R}^3 . The curvature was first defined in an extremely geometric way, by taking limits of circles passing through three points of the curve. But it could be defined quite simply as $\kappa = |\mathbf{t}'|$, and exactly this approach was used to define τ . We then showed that these quantities actually describe the curve completely, up to Euclidean motions. We also investigated certain global properties connected with positive curvature. Finally, we showed how our investigations could be reformulated in terms of Lie groups, with Theorem I.10-18 playing a leading role, and then went on to investigate properties of curves invariant under a different group of motions of Euclidean space.

Our investigation of surfaces will proceed in just this order; however it will differ from the study of curves in one important respect. For curves we found that the definition and study of κ and τ [or of the affine curvature κ] was greatly simplified by considering curves parameterized only by arclength [or affine arclength]. But for surfaces there is no natural choice of a parameterization; to a certain extent this is responsible for the considerably greater complications one encounters in surface theory.

In Chapter II.3B we considered a submanifold $M \subset \mathbb{R}^3$, with $i: M \rightarrow \mathbb{R}^3$ the inclusion map, and we defined the **first fundamental form** I by $I = i^*\langle \ , \ \rangle$, where $\langle \ , \ \rangle$ is the usual Riemannian metric on \mathbb{R}^3 . In terms of a coordinate system $\chi = (x, y)$ on M , we wrote the tensor I on M as

$$I = E dx \otimes dx + F dx \otimes dy + F dy \otimes dx + G dy \otimes dy$$

for certain functions E, F, G on M ; and we noted that if the inverse of χ is

$f: U \rightarrow \mathbb{R}^3$ (for $U \subset \mathbb{R}^2$ open), then

$$\begin{aligned} E(f(s, t)) &= \left\langle \frac{\partial f}{\partial s}(s, t), \frac{\partial f}{\partial s}(s, t) \right\rangle = \langle f_1(s, t), f_1(s, t) \rangle \\ F(f(s, t)) &= \langle f_1(s, t), f_2(s, t) \rangle \\ G(f(s, t)) &= \langle f_2(s, t), f_2(s, t) \rangle. \end{aligned}$$

This means that $E = \langle f_1, f_1 \rangle \circ f^{-1}$, etc., which sometimes makes the functions E, F, G rather awkward to work with; consequently, we will often find it convenient to change our view slightly, and define everything explicitly in terms of a given immersion.

If $f: M \rightarrow \mathbb{R}^3$ is an immersion, we define the **first fundamental form** I_f of f to be the tensor $f^*\langle \ , \ \rangle$ on M . In particular, when $f: U \rightarrow \mathbb{R}^3$ (for $U \subset \mathbb{R}^2$ open) we have a form I_f on U , with

$$I_f(s, t)(v, w) = \langle f_*v, f_*w \rangle \quad \text{for } v, w \in \mathbb{R}^2_{(s, t)}.$$

We can then define functions E, F, G directly on U by

$$\begin{aligned} E &= \left\langle \frac{\partial f}{\partial s}, \frac{\partial f}{\partial s} \right\rangle = \langle f_1, f_1 \rangle \\ F &= \langle f_1, f_2 \rangle \\ G &= \langle f_2, f_2 \rangle. \end{aligned}$$

These functions are nothing but the components of $I_f = f^*\langle \ , \ \rangle$ with respect to the standard coordinate system (s, t) on \mathbb{R}^2 [and they have essentially already been introduced on pg. II.128]. Since $f^*\langle \ , \ \rangle$ is positive definite, we have $EG - F^2 > 0$ (pg. I.308); moreover (see Problem I.9-5), we have

$$|f_1 \times f_2| = \sqrt{EG - F^2}.$$

It will often be much more convenient to use the subscript notation, which was classically used for the higher dimensional cases,

$$g_{ij} = \langle f_i, f_j \rangle, \quad \text{so that} \quad g_{11} = E, \quad g_{12} = g_{21} = F, \quad g_{22} = G.$$

We also introduce the functions g^{ij} which satisfy

$$\sum_k g_{ik} g^{kj} = \delta_i^j.$$

The functions E, F, G are analogous to the single function $t \mapsto |c'(t)|$, defined for a curve c . We usually reparameterized our curves so that this function was equal to 1, but for surfaces, where no convenient reparameterization is available, the functions E, F, G always play a vital role, analogous to the arclength function of a curve.

We next seek an analogue of the functions κ and τ of a curve c . The definition of κ and τ depended very much on the possibility of parameterizing c by arclength, so that $\mathbf{t}(s) = c'(s)$ has length 1, and consequently $\mathbf{t}'(s) = \kappa(s)\mathbf{n}(s)$ for some unit vector $\mathbf{n}(s)$ perpendicular to the curve. In the case of a surface $M \subset \mathbb{R}^3$, we do not have a special parameterization to work with, but we already have an analogue of \mathbf{n} , namely a unit normal field ν , which can at least be defined in a neighborhood of each point. We recall that a choice of ν is equivalent to a choice of an orientation for M , for we can let $(X_1, X_2) \in M_p$ be positively oriented if and only if $(X_1, X_2, \nu(p))$ is positively oriented in \mathbb{R}^3 .

When we are not dealing with a submanifold, but with an immersion $f: M \rightarrow \mathbb{R}^3$, the normal field should be considered as a “vector field along f ”, since we may have points $p, q \in M$ with $f(p) = f(q)$, but with different normals at this

point. We will denote this vector field along f by

$$q \mapsto N(q)_{f(q)} \in \mathbb{R}^3_{f(q)}.$$

Thus N is a function $N: M \rightarrow S^2 \subset \mathbb{R}^3$. We will always adhere to the convention of using ν when we are specifically considering imbedded submanifolds $M \subset \mathbb{R}^3$, and using N when we are considering immersions (and imbeddings) $f: M \rightarrow \mathbb{R}^3$; when necessary, we will write N_f to indicate the dependence of N on f . If $W \subset M$ is an open set on which f is an imbedding, then a unit normal field ν on $M = f(W) \subset \mathbb{R}^3$ is determined by the condition that $N = \nu \circ f$ on W (naturally we have to regard ν as a map $\nu: M \rightarrow S^2 \subset \mathbb{R}^3$ in order to write this). In terms of ν we have already defined the **second fundamental form II on M** by

$$\begin{aligned} \text{II}(p)(v_p, w_p) &= \langle -d\nu(v_p), w_p \rangle \\ &= \langle -\nu_*(v_p), w_p \rangle \quad \text{for } v_p, w_p \in M_p. \end{aligned}$$

We can define the **second fundamental form** \mathbf{II}_f of f to be the tensor on M defined by

$$\begin{aligned}\mathbf{II}_f(q)(v_q, w_q) &= \langle -dN(v_q), f_*(w_q) \rangle \\ &= \langle -N_*(v_q), f_*(w_q) \rangle \quad \text{for } v_q, w_q \in M_q.\end{aligned}$$

Equivalently, we have $\mathbf{II}_f = f^*\mathbf{II}$.

In particular, let us consider an immersion $f: U \rightarrow \mathbb{R}^3$, for $U \subset \mathbb{R}^2$ open. We can specifically choose N to be

$$N = \frac{f_1 \times f_2}{|f_1 \times f_2|} = \frac{f_1 \times f_2}{\sqrt{EG - F^2}} \quad \begin{array}{l} \text{(the negative square root gives} \\ \text{the other possible choice for } N\text{).} \end{array}$$

Then

$$\begin{aligned}\mathbf{II}_f(s, t)(v, w) &= \langle -dN(v), f_*(w) \rangle \\ &= \langle -N_*(v), f_*(w) \rangle \quad v, w \in \mathbb{R}^2_{(s, t)}.\end{aligned}$$

We will define functions l, m, n directly on U by

$$\begin{aligned}l &= \left\langle -\frac{\partial N}{\partial s}, \frac{\partial f}{\partial s} \right\rangle = \langle -N_1, f_1 \rangle = \langle N, f_{11} \rangle \\ m &= \langle -N_1, f_2 \rangle = \langle N, f_{12} \rangle \\ n &= \langle -N_2, f_2 \rangle = \langle N, f_{22} \rangle.\end{aligned}$$

These functions l, m, n are simply the components of \mathbf{II}_f with respect to the standard coordinate system (s, t) on \mathbb{R}^2 (compare with the proof of Theorem 1 on pg. II.123). Once again, it will often be more convenient to use subscript notation:

$$l_{ij} = \langle -N_i, f_j \rangle = \langle N, f_{ij} \rangle.$$

Before we go any further, we should clear up one problem. Let us suppose that $f: U \rightarrow \mathbb{R}^3$ is actually an imbedding, and let $M = f(U) \subset \mathbb{R}^3$. In geometric considerations, it is usually the linear transformation $-dv: M_p \rightarrow M_p$ which interests us, rather than the second fundamental form \mathbf{II} itself. Now for $p = f(s, t)$, the map $-dv: M_p \rightarrow M_p$ is related to the matrix $(l_{ij}(s, t))$ in the following way:

$$l_{ij}(s, t) = \langle -dv(f_i(s, t)_p), f_j(s, t)_p \rangle.$$

Unfortunately, this does *not* mean that $(l_{ij}(s, t))$ is the matrix of $-dv$ with respect to the basis $f_1(s, t)_p, f_2(s, t)_p$, because these vectors are not necessarily orthonormal. To avoid going out of our minds now, and especially in the next chapter, we make note of the following:

0. FACT. Let v_1, \dots, v_n be a basis for the vector space V , with the inner product $\langle \cdot, \cdot \rangle$. Suppose that A is the matrix of a linear transformation $T: V \rightarrow V$ with respect to v_1, \dots, v_n , while B and C are the matrices $B = (\langle T v_i, v_j \rangle)$ and $C = (\langle v_i, v_j \rangle)$. Then

$$A = (BC^{-1})^t,$$

where t denotes the transpose.

PROOF. We have $T v_i = \sum_j A_{ji} v_j$, and consequently

$$B_{ik} = \langle T v_i, v_k \rangle = \sum_j A_{ji} \langle v_j, v_k \rangle = (A^t \cdot C)_{ik},$$

so $B = A^t \cdot C$. ♦

We apply this observation with

$$A = \begin{pmatrix} \text{matrix of } -dv: M_p \rightarrow M_p \\ \text{with respect to } (f_1)_p, (f_2)_p \end{pmatrix}$$

and

$$B = (l_{ij}), \quad C = (g_{ij}),$$

where f_i, l_{ij}, g_{ij} are all evaluated at (s, t) , and $p = f(s, t)$. Since B and C are symmetric, we have $(BC^{-1})^t = C^{-1}B$; so we find that

$$\begin{aligned} \text{(I)} \quad \begin{pmatrix} \text{matrix of } -dv: M_p \rightarrow M_p \\ \text{with respect to } (f_1)_p, (f_2)_p \end{pmatrix} &= (g_{ij})^{-1}(l_{ij}) \\ &= \frac{1}{EG - F^2} \cdot \begin{pmatrix} G & -F \\ -F & E \end{pmatrix} \begin{pmatrix} l & m \\ m & n \end{pmatrix} \\ &[f_i, g_{ij}, l_{ij} \text{ evaluated at } (s, t); p = f(s, t)]. \end{aligned}$$

The functions l, m, n certainly seem to be good candidates for the desired analogues of the functions κ and τ . As a first test of their appropriateness, we will investigate how well these functions describe f up to second order in a neighborhood of a point p .

What we are interested in is the shape of $M = \text{image } f$, not the particular parameterization f itself; so we will essentially fix the parameterization by describing our surface M in terms of the distance of a point from the tangent plane at p . For convenience we will assume that $p = 0 \in \mathbb{R}^3$ and that the

tangent plane at p is the (x, y) -plane. Then our surface M is the graph of a

function $h: \mathbb{R}^2 \rightarrow \mathbb{R}$ with $h_1(0, 0) = h_2(0, 0) = 0$. Applying Taylor's formula for functions of two variables, we have

$$h(s, t) = \frac{1}{2}(h_{11}(0, 0) \cdot s^2 + 2h_{12}(0, 0) \cdot st + h_{22}(0, 0) \cdot t^2) + R(s, t),$$

where $R(s, t)/|(s, t)|^2 = R(s, t)/(s^2 + t^2) \rightarrow 0$ as $(s, t) \rightarrow 0$. We therefore say that the quadratic surface

$$P = \left\{ (s, t, \frac{1}{2}(h_{11}(0, 0) \cdot s^2 + 2h_{12}(0, 0) \cdot st + h_{22}(0, 0) \cdot t^2)) \right\}$$

“approximates M up to order 2 at 0”.

Now we want to make an elementary observation which is crucial for avoiding confusion. Suppose that $\mathbf{X} = (X_1, X_2)$ is any basis for \mathbb{R}^2 , say with $X_1 = (a_{11}, a_{21})$ and $X_2 = (a_{12}, a_{22})$. Our surface M can also be described as the graph of a function in terms of the “ $X_1, X_2, (0, 0, 1)$ coordinate system”. In

other words, we can consider the function $h^{\mathbf{X}}$ with $h^{\mathbf{X}}(s, t) =$ the height above the (x, y) -plane of the point of M lying above $sX_1 + tX_2$. This means that

$$h^{\mathbf{X}}(s, t) = h(sX_1 + tX_2) = h(a_{11}s + a_{12}t, a_{21}s + a_{22}t).$$

If we momentarily denote (s, t) by (s^1, s^2) , then we can write more conveniently

$$h^{\mathbf{X}}(s^1, s^2) = h\left(\sum_{i=1}^2 a_{1i}s^i, \sum_{i=1}^2 a_{2i}s^i\right),$$

and for the partial derivatives of $h^{\mathbf{X}}$ we easily compute that

$$\begin{aligned} h^{\mathbf{X}}_{\alpha}(s^1, s^2) &= \sum_{j=1}^2 a_{j\alpha} h_j\left(\sum_{i=1}^2 a_{1i}s^i, \sum_{i=1}^2 a_{2i}s^i\right) \\ h^{\mathbf{X}}_{\alpha\beta}(s^1, s^2) &= \sum_{j,k=1}^2 a_{j\alpha} a_{k\beta} h_{jk}\left(\sum_{i=1}^2 a_{1i}s^i, \sum_{i=1}^2 a_{2i}s^i\right), \end{aligned}$$

so that in particular

$$(*) \quad \begin{cases} h^{\mathbf{X}}_{\alpha}(0, 0) = 0 \\ h^{\mathbf{X}}_{\alpha\beta}(0, 0) = \sum_{j,k=1}^2 a_{j\alpha} a_{k\beta} h_{jk}(0, 0). \end{cases}$$

Now the quadratic surface $Q \subset \mathbb{R}^3 = \mathbb{R}^2 \times \mathbb{R}$ defined by

$$Q = \left\{ (sX_1 + tX_2, \frac{1}{2}(h^{\mathbf{X}}_{11}(0, 0) \cdot s^2 + 2h^{\mathbf{X}}_{12}(0, 0) \cdot st + h^{\mathbf{X}}_{22}(0, 0) \cdot t^2)) \right\}$$

can equally well be said to approximate M up to order 2 at 0. But we claim that the surfaces P and Q are *exactly the same*. The best way to express this claim is as follows. For each basis $\mathbf{X} = (X_1, X_2)$, let us define a function $\Phi^{\mathbf{X}}: \mathbb{R}^2 \rightarrow \mathbb{R}$ by

$$\Phi^{\mathbf{X}}(sX_1 + tX_2) = \frac{1}{2}(h^{\mathbf{X}}_{11}(0, 0) \cdot s^2 + 2h^{\mathbf{X}}_{12}(0, 0) \cdot st + h^{\mathbf{X}}_{22}(0, 0) \cdot t^2).$$

Then the functions $\Phi^{\mathbf{X}}$ are all the *same* function $\Phi: \mathbb{R}^2 \rightarrow \mathbb{R}$, and we can therefore describe both P and Q simply as the graph of Φ . To check that all $\Phi^{\mathbf{X}}$ are the same, let us use Φ for the function we obtain when \mathbf{X} is the standard basis $(1, 0), (0, 1)$. Then

$$\begin{aligned} \Phi(s^1 X_1 + s^2 X_2) &= \Phi\left(\sum_{i=1}^2 a_{1i}s^i, \sum_{i=1}^2 a_{2i}s^i\right) \\ &= \frac{1}{2} \sum_{j,k=1}^2 h_{jk}(0, 0) \cdot \left(\sum_{i=1}^2 a_{ji}s^i\right) \left(\sum_{i=1}^2 a_{ki}s^i\right) \end{aligned}$$

$$\begin{aligned}
&= \frac{1}{2} \sum_{\alpha, \beta=1}^2 \left(\sum_{j, k=1}^2 h_{jk}(0, 0) a_{j\alpha} a_{k\beta} \right) s^\alpha s^\beta \\
&= \frac{1}{2} \sum_{\alpha, \beta=1}^2 h^{\mathbf{X}}_{\alpha\beta}(0, 0) s^\alpha s^\beta \quad \text{by } (*) \\
&= \Phi^{\mathbf{X}}(s^1 X_1 + s^2 X_2),
\end{aligned}$$

which is what we wanted to prove. It is also easy to see that if we describe M in terms of the “ $X_1, X_2, (0, 0, -1)$ coordinate system”, then Φ becomes $-\Phi$, while the resulting second order approximating surface is unchanged. Thus, for every point p of a surface M in \mathbb{R}^3 , there is a well-defined quadratic surface P which approximates M up to order 2 at p .

Let us for simplicity stick to the case where $p = 0 \in \mathbb{R}^3$, the tangent plane at p is the (x, y) -plane, and M is the graph of $h: \mathbb{R}^2 \rightarrow \mathbb{R}$ (in the standard coordinate system). The surface M is the image of the immersion

$$f(s, t) = (s, t, h(s, t))$$

for which we have

$$\begin{aligned}
N &= N(0, 0) = (0, 0, 1) \\
l &= l(0, 0) = \langle (0, 0, 1), (0, 0, h_{11}(0, 0)) \rangle \\
&= h_{11}(0, 0) \\
m &= m(0, 0) = h_{12}(0, 0) \\
n &= n(0, 0) = h_{22}(0, 0).
\end{aligned}$$

Thus our approximating quadratic surface P at 0 is described explicitly as the graph of

$$\alpha(s, t) = \frac{1}{2}(ls^2 + 2mst + nt^2) = \frac{1}{2} \left\langle (s, t), (s, t) \cdot \begin{pmatrix} l & m \\ m & n \end{pmatrix} \right\rangle.$$

To see just what this graph looks like, we choose two *orthonormal* eigenvectors $X_1, X_2 \in \mathbb{R}^2$ for the symmetric matrix $\begin{pmatrix} l & m \\ m & n \end{pmatrix}$, with corresponding eigenvalues k_1, k_2 . Then

$$\begin{aligned} \alpha(sX_1 + tX_2) &= \frac{1}{2} \left\langle sX_1 + tX_2, sX_1 + tX_2 \cdot \begin{pmatrix} l & m \\ m & n \end{pmatrix} \right\rangle \\ &= \frac{1}{2} \langle sX_1 + tX_2, sk_1X_1 + tk_2X_2 \rangle \\ &= \frac{1}{2} (k_1s^2 + k_2t^2). \end{aligned}$$

In other words, after a rotation of our axes so that they point along X_1, X_2 , the graph of α becomes the graph of $\tilde{\alpha}: \mathbb{R}^2 \rightarrow \mathbb{R}$ defined by

$$\tilde{\alpha}(s, t) = \frac{1}{2} (k_1s^2 + k_2t^2).$$

The shape of this graph depends on the sign of $k_1k_2 = \det \begin{pmatrix} l & m \\ m & n \end{pmatrix} = ln - m^2$, and leads us to classify the points p into four types.

1. *Elliptic point*: $ln - m^2 > 0$. Then k_1, k_2 have the same sign. If $k_1, k_2 > 0$, then the graph of

$$\tilde{\alpha}(s, t) = \frac{s^2}{(\sqrt{2/k_1})^2} + \frac{t^2}{(\sqrt{2/k_2})^2}$$

is an *elliptic paraboloid*; planes parallel to the (x, y) -plane intersect the graph of $\tilde{\alpha}$ in similar ellipses, while planes parallel to the other coordinate planes intersect the graph in parabolas.

In our new coordinate system, the original surface is the graph of \tilde{h} , where

$$\tilde{h}(s, t) = \tilde{\alpha}(s, t) + \tilde{R}(s, t).$$

with $\tilde{R}(s, t)/(s^2 + t^2) \rightarrow 0$. There is clearly a constant $A > 0$ such that $\tilde{\alpha}(s, t) > A(s^2 + t^2)$, so

$$0 = \lim_{(s,t) \rightarrow 0} -\frac{\tilde{R}(s, t)}{s^2 + t^2} = \lim_{(s,t) \rightarrow 0} \left(\frac{\tilde{\alpha}(s, t) - \tilde{h}(s, t)}{s^2 + t^2} \right) \geq A - \lim_{(s,t) \rightarrow 0} \frac{\tilde{h}(s, t)}{s^2 + t^2},$$

and hence

$$\frac{\tilde{h}(s, t)}{s^2 + t^2} \geq A/2 > 0 \quad \text{for sufficiently small } (s, t).$$

Therefore $\tilde{h}(s, t) > 0$ for small (s, t) . Thus points of our surface which are near p lie on the same side of the tangent plane at p as $v(p)$. If $k_1, k_2 < 0$, then the graph of $\tilde{\alpha}$ is an elliptic paraboloid pointing in the other direction, and points of our surface which are near p lie on the other side of the tangent plane at p .

2. *Hyperbolic point:* $ln - m^2 < 0$. Then k_1, k_2 have opposite signs, say $k_1 > 0 > k_2$. The graph of

$$\tilde{\alpha}(s, t) = \frac{s^2}{(\sqrt{2/k_1})^2} - \frac{t^2}{(\sqrt{-2/k_2})^2}$$

is a *hyperbolic paraboloid*; planes parallel to the (x, y) -plane intersect the graph of $\tilde{\alpha}$ in similar hyperbolas [except that the (x, y) -plane itself intersects the graph in two straight lines through $(0, 0)$], while planes parallel to the other coordinate planes intersect the graph in parabolas. It is easy to see that there are points

of the original surface arbitrarily close to p lying on both sides of the tangent plane at p .

3. *Parabolic point:* $ln - m^2 = 0$, but not all of l, m, n are 0. Then exactly one eigenvalue is 0; say $k_1 = 0$ but $k_2 \neq 0$. The graph of

$$\tilde{\alpha}(s, t) = \frac{1}{2}k_2 t^2$$

is a *parabolic cylinder*. If $k_2 > 0$, then our original surface must contain points close to p on the same side of the tangent plane as $v(p)$. But there can also be

points arbitrarily close to p on the other side of the tangent plane. For example, our surface might be the graph of

$$h(s, t) = s^3 + t^2.$$

4. *Planar point*: $l = m = n = 0$. The graph of $\tilde{\alpha}$ is the (x, y) -plane.

In the planar case, nothing at all can be said about which side of the tangent plane our surface lies on. For example, our surface might be the graph of any one of the following functions:

$$h(s, t) = s^4 \quad \text{graph lies above the } (x, y)\text{-plane}$$

$$h(s, t) = -s^4 \quad \text{graph lies below the } (x, y)\text{-plane}$$

$$h(s, t) = s^3 \quad \text{graph lies above and below the } (x, y)\text{-plane.}$$

A more interesting example of a planar point is provided by the “monkey saddle”, the graph of

$$\begin{aligned} h(s, t) &= s^3 - 3st^2 \\ &= \text{real part of } (s + it)^3, \end{aligned}$$

with a planar point at $0 \in \mathbb{R}^3$. I was always very confused by the name of this surface, because I thought it was supposed to be a saddle that you put on a monkey. Actually it's a saddle that a monkey *uses* (to ride a bicycle, say)—there are two depressions for its legs, and an extra one for its tail. The monkey saddle

intersects the (x, y) -plane in the set

$$\{(x, y) : x^3 - 3xy^2 = 0\}$$

which consists of 3 straight lines all making equal angles with each other.

Notice that our classification of points on a surface as elliptic, hyperbolic, parabolic, or planar, does not at all depend on the special parameterization which we introduced; for equation (I) on page 35 shows that

$$\det(-dv : M_p \rightarrow M_p) = \frac{\det(l_{ij})}{\det(g_{ij})} = \frac{ln - m^2}{EG - F^2},$$

which means that the sign of $ln - m^2$ is always the same as the sign of $\det(-dv)$. When we do introduce our special parameterization, we have $E = G = 1$ and $F = 0$ at $(0, 0)$, so equation (I) then gives

$$(l_{ij}) = \text{matrix of } -dv : M_p \rightarrow M_p.$$

Consequently, the numbers k_1, k_2 which we have found can also be described invariantly as the eigenvalues of $-dv$; the orthonormal vectors X_1, X_2 (in \mathbb{R}^2 , which we have identified with M_p) are just the eigenvectors of $-dv$.

The quadratic surface P which approximates M up to order 2 at a point $p \in M$ is called the **osculating paraboloid** at p ; when $p = 0 \in \mathbb{R}^2$, the tangent plane at p is the (x, y) -plane, and X_1, X_2 point along the x - and y -axes, it is the graph of

$$\alpha(s, t) = \tilde{\alpha}(s, t) = \frac{1}{2}(k_1 s^2 + k_2 t^2).$$

For space curves we obtained an analogous osculating curve (pg. II.31), and we used this osculating curve to examine the original curve more closely by projecting it on the coordinate planes. That procedure wouldn't make much sense here, but there is something else we can do. Suppose we first intersect

the osculating paraboloid with the two planes parallel to the (x, y) -plane and at distance d from it, and then project the intersection onto the (x, y) -plane.

We obtain the set

$$J_d = \{(x, y) : k_1 x^2 + k_2 y^2 = \pm 2d\},$$

which is either an ellipse, a pair of hyperbolas, a pair of parallel lines, or nothing. Clearly, the sets

$$\frac{J_d}{\sqrt{2d}} = \left\{ \left(\frac{x}{\sqrt{2d}}, \frac{y}{\sqrt{2d}} \right) : (x, y) \in J_d \right\}$$

are all the same, namely

$$\frac{J_d}{\sqrt{2d}} = J = \{(x, y) : k_1 x^2 + k_2 y^2 = \pm 1\}.$$

(a) k_1, k_2 have same sign

(c) $k_1 = 0, k_2 \neq 0$

(b) k_1, k_2 have opposite signs

(d) $k_1 = k_2 = 0$

Suppose now that we repeat this procedure, except that we intersect the two planes with our original surface instead of with its osculating paraboloid. We would expect the limiting set to be the same, since the surface agrees with its osculating paraboloid up to order 2. Actually, one has to be a little careful in formulating this result, and the corresponding proof is somewhat long, but not very interesting.

1. PROPOSITION. Let $p \in M$ be a point of an imbedded surface $M \subset \mathbb{R}^3$, and let X_1, X_2 be orthonormal eigenvectors of $-dv: M_p \rightarrow M_p$, with corresponding eigenvalues k_1, k_2 . Let $I \subset M_p$ be the set

$$I = \{X \in M_p : k_1 \langle X, X_1 \rangle^2 + k_2 \langle X, X_2 \rangle^2 = \pm 1\},$$

so that I is congruent to

- (a) the ellipse $k_1 x^2 + k_2 y^2 = \pm 1$ p an elliptic point
- (b) the hyperbolas $k_1 x^2 + k_2 y^2 = \pm 1$ p a hyperbolic point
- (c) the parallel lines $k_2 y^2 = \pm 1$ p a parabolic point with $k_2 \neq 0$
- (d) \emptyset p a planar point.

For $d > 0$, let I_d be the projection on M_p of the intersection of M with the two planes parallel to M_p and at distance d from it. Then

$$\lim_{d \rightarrow 0} \frac{I_d}{\sqrt{2d}} = I,$$

where this limit has the following meaning: For every $\varepsilon > 0$, and every compact set $C \subset M_p$, there is some $\delta > 0$ such that if $0 < d < \delta$, then

- (i) every point of $I \cap C$ is within ε of some point of $I_d/\sqrt{2d}$
- (ii) every point of $(I_d/\sqrt{2d}) \cap C$ is within ε of some point of I .

Remark: In case (d), this just means that $I_d/\sqrt{2d}$ eventually lies outside of any compact set. In case (a), we clearly do not have to use the compact set C in condition (i), since I itself is compact. And in condition (ii) the compact set C is needed only to exclude points of I_d coming from extraneous points of M which are not near p .

PROOF. We assume that $p = 0 \in \mathbb{R}^3$, and that M_p is the (x, y) -plane, with the eigenvectors X_1, X_2 of $-dv(p)$ pointing along the x - and y -axes. Then M is locally the graph of a function $h: U \rightarrow \mathbb{R}$ (for $U \subset \mathbb{R}^2$ open), and we can assume that

$$I_d = \{(s, t) \in U : h(s, t) = \pm d\}$$

[there is no need to consider the points (s, t) outside U , since for sufficiently small d , the corresponding points $(s/\sqrt{2d}, t/\sqrt{2d})$ lie outside of any given compact set $C \subset M_p$]. We thus have

$$I_d = \left\{ (s, t) \in U : \frac{k_1 s^2}{2} + \frac{k_2 t^2}{2} + R(s, t) = \pm d \right\},$$

where

$$(1) \quad \frac{R(s, t)}{s^2 + t^2} \rightarrow 0 \quad \text{as } (s, t) \rightarrow 0.$$

Hence

$$\frac{I_d}{\sqrt{2d}} = \left\{ (\sigma, \tau) : \begin{array}{l} (\sqrt{2d}\sigma, \sqrt{2d}\tau) \in U \text{ and} \\ k_1\sigma^2 + k_2\tau^2 + \frac{R(\sqrt{2d}\sigma, \sqrt{2d}\tau)}{d} = \pm 1 \end{array} \right\}.$$

Setting $s = \sqrt{2d}\sigma$ and $t = \sqrt{2d}\tau$ in (1), we see that

$$(2) \quad \frac{R(\sqrt{2d}\sigma, \sqrt{2d}\tau)}{d(\sigma^2 + \tau^2)} \rightarrow 0 \quad \text{as } (\sqrt{2d}\sigma, \sqrt{2d}\tau) \rightarrow 0.$$

Now suppose we are given $\varepsilon > 0$, and a compact set $C \subset M_p$, which we might as well assume is of the form

$$C = \{(\sigma, \tau) : \sqrt{\sigma^2 + \tau^2} \leq A\}.$$

Choose $\varepsilon_0 > 0$ so that

$$(3) \quad |\alpha| < \varepsilon_0 \implies |1 - \sqrt{1 \pm \alpha}| < \varepsilon/A.$$

Let $(\sigma, \tau) \in C \cap I$, so that

$$(4) \quad k_1\sigma^2 + k_2\tau^2 = \pm 1 \quad \text{and} \quad \sqrt{\sigma^2 + \tau^2} \leq A.$$

Consider the function

$$(5) \quad d \mapsto \frac{R(\sqrt{2d}\sigma, \sqrt{2d}\tau)}{d} \quad 0 < d \leq 1.$$

This is continuous in d , and approaches 0 as $d \rightarrow 0^+$, by (2). So there is $\delta > 0$ such that

$$(6) \quad 0 < d < \delta \implies \left| \frac{R(\sqrt{2d}\sigma, \sqrt{2d}\tau)}{d} \right| < \varepsilon_0.$$

Let

$$\alpha = \frac{R(\sqrt{2d}\sigma, \sqrt{2d}\tau)}{d},$$

and consider the point

$$(\sigma\sqrt{1\mp\alpha}, \tau\sqrt{1\mp\alpha}) = \begin{cases} (\sigma\sqrt{1-\alpha}, \tau\sqrt{1-\alpha}) & \text{if } +1 \text{ holds in equation (4)} \\ (\sigma\sqrt{1+\alpha}, \tau\sqrt{1+\alpha}) & \text{if } -1 \text{ holds in equation (4)}. \end{cases}$$

We have

$$\begin{aligned} k_1(\sigma\sqrt{1-\alpha})^2 + k_2(\tau\sqrt{1-\alpha})^2 &= (1-\alpha)[k_1\sigma^2 + k_2\tau^2] = 1-\alpha \\ k_1(\sigma\sqrt{1+\alpha})^2 + k_2(\tau\sqrt{1+\alpha})^2 &= (1+\alpha)[k_1\sigma^2 + k_2\tau^2] = -1-\alpha, \end{aligned}$$

so $(\sigma\sqrt{1\mp\alpha}, \tau\sqrt{1\mp\alpha})$ is in $I_d/\sqrt{2d}$. Its distance from (σ, τ) is

$$\begin{aligned} |1 - \sqrt{1\mp\alpha}| \sqrt{\sigma^2 + \tau^2} &< \frac{\varepsilon}{A} \sqrt{\sigma^2 + \tau^2} && \text{by (3), since } |\alpha| < \varepsilon_0 \quad \text{by (6)} \\ &< \varepsilon && \text{by (4).} \end{aligned}$$

We have thus found a $\delta > 0$ so that the given point $(\sigma, \tau) \in C \cap I$ has distance less than ε from a point of $I_d/\sqrt{2d}$, for all $d < \delta$. To conclude that one δ can be found which works for all $(\sigma, \tau) \in C \cap I$ we need the fact that the function (5) approaches 0 uniformly in (σ, τ) ; this follows from compactness of C .

We will now prove (ii). Given $\varepsilon > 0$ and $A > 0$, pick $\varepsilon_0 > 0$ so that

$$(7) \quad |\alpha| < \varepsilon_0 \implies \left| 1 - \frac{1}{\sqrt{1\pm\alpha}} \right| < \frac{\varepsilon}{A}.$$

Then pick $\delta_0 > 0$ so that

$$s^2 + t^2 < \delta_0 \implies \frac{R(s, t)}{s^2 + t^2} < \frac{\varepsilon_0}{2A^2}.$$

Setting $s = \sqrt{2d}\sigma$ and $t = \sqrt{2d}\tau$, we see that

$$(8) \quad \sigma^2 + \tau^2 < \frac{\delta_0}{2d} \implies \frac{R(\sqrt{2d}\sigma, \sqrt{2d}\tau)}{d} < \frac{\varepsilon_0}{A^2}(\sigma^2 + \tau^2).$$

Let $\delta = \delta_0/2A^2$. Then

$$0 < d < \delta \implies \frac{\delta_0}{2d} > A^2.$$

So if $0 < d < \delta$, then

$$(9) \quad \text{either } \sigma^2 + \tau^2 > A^2 \quad \text{or} \quad \sigma^2 + \tau^2 < A^2 < \frac{\delta_0}{2d}.$$

In the first case, the point $(\sigma, \tau) \in I_d/\sqrt{2d}$ is at distance $> A$ from the origin. In the second case, we have

$$\begin{aligned} \frac{R(\sqrt{2d}\sigma, \sqrt{2d}\tau)}{d} &< \frac{\varepsilon_0}{A^2}(\sigma^2 + \tau^2) && \text{by (8)} \\ &< \varepsilon_0 && \text{by (9),} \end{aligned}$$

so the point $(\sigma, \tau) \in I_d/\sqrt{2d}$ satisfies the equation

$$\begin{aligned} (10) \quad k_1\sigma^2 + k_2\tau^2 &= \pm 1 - \frac{R(\sqrt{2d}\sigma, \sqrt{2d}\tau)}{d} \\ &= \pm 1 - \alpha, \quad \text{where } 0 \leq |\alpha| < \varepsilon_0. \end{aligned}$$

Now the point

$$\left(\frac{\sigma}{\sqrt{1 \mp \alpha}}, \frac{\tau}{\sqrt{1 \mp \alpha}} \right)$$

is in I , and its distance from (σ, τ) is

$$\begin{aligned} \left| 1 - \frac{1}{\sqrt{1 \mp \alpha}} \right| \sqrt{\sigma^2 + \tau^2} &< \frac{\varepsilon}{A} \sqrt{\sigma^2 + \tau^2} && \text{by (7), since } |\alpha| < \varepsilon_0 \text{ by (10)} \\ &< \varepsilon && \text{by (9).} \end{aligned}$$

This completes the proof. \blacklozenge

The limiting set $I \subset M_p$ of Proposition 1 is called the **Dupin indicatrix** at p . In the case of a planar point, we can obtain a more meaningful indicatrix by considering $\lim_{d \rightarrow 0} I_d/\sqrt[3]{d}$ —the adjustment factor $1/\sqrt[3]{d}$ is just what we need in

order that the projection on M_p of the intersections of parallel planes with the osculating *cubic* will be the same. The figure below shows the resulting indicatrix for the monkey saddle; the continuous lines come from intersections with planes

on one side of the tangent plane, and the dashed lines from intersections with planes on the other side. Similarly, if all derivatives of $h: U \rightarrow \mathbb{R}$ up to order $k - 1$ are 0 at $(0, 0)$, then we can look at the generalized indicatrix $\lim_{d \rightarrow 0} I_d / \sqrt[k]{d}$.

Certain geometric terminology concerning conic sections has been taken over, via the Dupin indicatrix, to surfaces. Given a conic section in the plane, the directions which we have chosen as the x - and y - axes are called its **principal axes**. Consequently, the unit vectors $X_1, X_2 \in M_p$ (that is, the unit eigenvectors for $-dv: M_p \rightarrow M_p$) are called the **principal vectors**. They are really defined

only up to sign, so it is often more convenient to speak of the **principal directions**; moreover, if $k_1 = k_2$, then all unit vectors are to be considered to be principal. The eigenvalues k_1 and k_2 are called the **principal curvatures** at p . We have already met these vectors and curvatures in Volume II, and we recall that if $X = (\cos \theta)X_1 + (\sin \theta)X_2$ is any other unit vector, then

$$\begin{aligned} \text{(II)} \quad \langle -dv(X), X \rangle &= \langle k_1(\cos \theta)X_1 + k_2(\sin \theta)X_2, (\cos \theta)X_1 + (\sin \theta)X_2 \rangle \\ &= k_1 \cos^2 \theta + k_2 \sin^2 \theta, \end{aligned}$$

which shows that k_1, k_2 are the minimum and maximum of $\langle -d\nu(X), X \rangle$ for unit vectors $X \in M_p$. Recall also that we defined

$$K(p) = \text{Gaussian curvature at } p = k_1 \cdot k_2$$

$$H(p) = \text{mean curvature at } p = \frac{1}{2}(k_1 + k_2).$$

A surface M is called **flat at** p if $K(p) = 0$. So p is a flat point if and only if p is either parabolic or planar.

For hyperbolas, there are two other important lines, the *asymptotes* (the dashed lines in the previous figure). The unit vectors which point along these lines in the Dupin indicatrix are called the **asymptotic directions**. If the hyperbola has the equation

$$k_1 x^2 + k_2 y^2 = \pm 1 \quad (k_1, k_2 \text{ of different signs}),$$

then the equation of the asymptotic lines $y = mx$ is found by noting that for large x the point (x, mx) is almost on the hyperbola, so

$$k_1 x^2 + k_2 m^2 x^2 \text{ is close to } \pm 1 \implies k_1 + k_2 m^2 \text{ is close to } 0,$$

and hence $m = \pm \sqrt{-k_1/k_2}$. On the other hand, if we consider a unit vector $X = (\cos \theta)X_1 + (\sin \theta)X_2$, then formula (II) gives

$$\langle -d\nu(X), X \rangle = k_1 \cos^2 \theta + k_2 \sin^2 \theta,$$

and this clearly equals 0 precisely when $\tan \theta = \pm \sqrt{-k_1/k_2}$. We therefore see that the vector $X \in M_p$ points along an asymptotic direction if and only if $\langle d\nu(X), X \rangle = 0$, and hence $\text{II}(X, X) = 0$.

Asymptotic directions do not exist at elliptic points, while there are two distinct asymptotic directions at hyperbolic points, and these directions are bisected by the principal directions. At a parabolic point there is only *one* asymptotic

direction—the principal direction with principal curvature 0. At planar points all directions are both principal and asymptotic. It is also clear that the asymptotic directions are perpendicular precisely when $k_1 = -k_2$, or $H = 0$.

Finally, there is one more important term, which describes a point where the Dupin indicatrix is actually a circle, so that the principal curvatures are equal, and all directions are principal directions. A point where all directions are principal is called an **umbilic** or **navel point**. This rather gross anatomical metaphor

is meant to suggest that the surface is very round at the point, like a sphere, on which all points are umbilics. Notice, however, that our definition also makes planar points umbilics, which turns out to be a convenient arrangement. At an umbilic, the map $-dv$ is just multiplication by some number k ; equation (I) therefore shows that

$$l_{ij} = k g_{ij} \quad \text{at an umbilic.}$$

At this stage it seems reasonable to begin asking to what extent the functions l, m, n describe f globally. The simplest question we can ask concerns surfaces f all of whose points are planar. Just as a curve with everywhere 0 curvature is a straight line, so we would expect a surface with $l = m = n = 0$ everywhere to be a plane. This is easy to prove. For, $l_{ij} = 0$ means $\langle -N_i, f_j \rangle = 0$; since N_i is a linear combination of f_1, f_2 , this means that $-N_i = 0$, so N is constant. Therefore $\langle f, N \rangle_i = \langle f_i, N \rangle + \langle f, N_i \rangle = 0 + 0$, and hence $\langle f, N \rangle = b$, where N is a constant vector and b is a constant number. This is just the equation of a plane.

It would next seem reasonable to prove an analogue of the fact that a circle is the only plane curve with constant κ . Here the situation is a little different, however: we cannot expect to characterize a sphere totally in terms of l, m, n , because we have not picked out a preferred parameterization; the functions E, F, G must also play a role. In fact, the simplest criterion to consider is that all points of f be umbilics. This means that

$$l = k E, \quad m = k F, \quad n = k G,$$

for a certain function k . Of course, in the case of a sphere, k is constant, but we do not even have to assume that. Although the following analysis is quite easy, it is worth recording as a theorem, which also includes the result about surfaces with all points planar.

2. THEOREM. If $M \subset \mathbb{R}^3$ is a connected surface such that every point is an umbilic, then M is part of a plane or a sphere.

PROOF. Choose an immersion $f: U \rightarrow M$. By assumption, we have $\langle -N_i, f_j \rangle = \langle k f_i, f_j \rangle$. Since N_i is a linear combination of f_1, f_2 , we thus have

$$(1) \quad N_i = -k f_i.$$

Consequently,

$$N_{ij} = -k_j f_i - k f_{ij}.$$

Since $N_{ij} = N_{ji}$, we obtain

$$-k_j f_i - k f_{ij} = -k_i f_j - k f_{ij},$$

and hence $k_i f_j = k_j f_i$. Setting $i = 1, j = 2$, and using linear independence of f_1, f_2 , we obtain $k_i = 0$, so k is constant. Thus equation (1) gives

$$(2) \quad N = -k f + v_0 \quad \text{for some } v_0 \in \mathbb{R}^3.$$

If $k = 0$, then as we already showed above, f lies in a plane. If $k \neq 0$, we have

$$f - \frac{v_0}{k} = \frac{-N}{k} \implies \left| f - \frac{v_0}{k} \right|^2 = \frac{1}{k^2},$$

so f lies in a sphere of radius $1/|k|$. Simple supplementary considerations then allow one to deduce the stated result. ♦

We now want to carry the analogy with curves still further, and see whether every immersion $f: U \rightarrow \mathbb{R}^3$ is described completely by the corresponding g_{ij} and l_{ij} . Of course, we only expect g_{ij} and l_{ij} to determine f up to proper Euclidean motions (translations followed by rotations [elements of $\text{SO}(3)$]), since g_{ij} and l_{ij} are already “invariant under proper Euclidean motions”—if A is a proper Euclidean motion, then the g_{ij} and l_{ij} for $A \circ f$ are the same as those for f . In the theory of curves we showed that κ and τ formed a complete set of invariants for a curve up to translations and rotations, by showing that they were a complete set of invariants up to rotation for the function

$s \mapsto (\mathbf{t}(s), \mathbf{n}(s), \mathbf{b}(s))$; this was accomplished by using the Serret-Frenet formulas, which are differential equations for $(\mathbf{t}, \mathbf{n}, \mathbf{b})$, involving only κ and τ . In the case of surfaces, we have the three vectors (f_1, f_2, N) , and so we want first to express the derivatives of each of these vectors as linear combinations of these same three vectors.

We begin by considering the f_{ik} , which we want to write as

$$(1) \quad f_{ik} = \sum_{h=1}^2 A_{ik}^h f_h + B_{ik} N.$$

First we will worry about finding the A_{ik}^h , which amounts to finding the $\langle f_{ik}, f_j \rangle$. To do this, we should obviously begin with the definition $\langle f_i, f_j \rangle = g_{ij}$ and differentiate, to get

$$\langle f_{ik}, f_j \rangle + \langle f_i, f_{jk} \rangle = g_{ij,k} \quad [\text{here } g_{ij,1} = D_1 g_{ij} = \frac{\partial g_{ij}}{\partial s}, \text{ etc.}].$$

Now comes the familiar old switcheroo: We also have

$$\begin{aligned} \langle f_{ji}, f_k \rangle + \langle f_j, f_{ki} \rangle &= g_{jk,i} \\ \langle f_{kj}, f_i \rangle + \langle f_k, f_{ij} \rangle &= g_{ki,j}; \end{aligned}$$

adding the first two of these three equations and subtracting the third, we get

$$\begin{aligned} \langle f_{ik}, f_j \rangle &= \frac{1}{2}(g_{ij,k} + g_{jk,i} - g_{ik,j}) \\ &= [ik, j], \end{aligned}$$

where $[ik, j]$ is the Christoffel symbol for the metric $I_f = f^*\langle \ , \ \rangle$ on U with respect to the standard coordinate system (s, t) on \mathbb{R}^2 . Plugging back into (1) we have

$$[ik, j] = \langle f_{ik}, f_j \rangle = \sum_{h=1}^2 A_{ik}^h g_{hj},$$

and, of course, we can solve explicitly for A_{ik}^h , using the g^{ij} :

$$A_{ik}^\rho = \sum_{j=1}^2 g^{\rho j} [ik, j] = \Gamma_{ik}^\rho.$$

There is no problem finding the B_{ik} , since we have already introduced a name for them:

$$B_{ik} = \langle f_{ik}, N \rangle = -\langle N_t, f_k \rangle = l_{ik}.$$

We have thus found that

$$(*) \quad f_{ik} = \sum_{h=1}^2 \Gamma_{ik}^h f_h + l_{ik} N \quad \text{The Gauss Formulas.}$$

The reader can easily check that these equations are indeed precisely the Gauss Formulas on page 4. Of course, in our present derivation, it is unnecessary to use the ∇ operator on the image of f , or even to have it defined; the only ∇ operator one needs to know about is the one for \mathbb{R}^3 , and the Γ 's just appear as weird combinations of the g_{ij} and their derivatives. (It is hard to see why these formulas should be named after Gauss, for he never explicitly solves for the f_{ik} . The closest results he writes down are certain formulas [for m, m', m'', n, n', n'' , on pg. II.91] equivalent to the equations $\langle f_{ik}, f_j \rangle = [ik, j]$.)

We next want to express N_i in terms of f_1, f_2, N , as

$$N_i = \sum_{h=1}^2 C_i^h f_h + 0 \cdot N.$$

Once again, there is no problem here, since we have already introduced a name for the relevant inner products. We have

$$l_{ij} = \langle -N_i, f_j \rangle = - \sum_{h=1}^2 C_i^h g_{hj},$$

and consequently

$$C_i^\rho = - \sum_{j=1}^2 g^{\rho j} l_{ij}.$$

Introducing new symbols l_i^h , we can therefore write

$$(**) \quad N_i = - \sum_{h=1}^2 \left(\sum_{j=1}^2 g^{hj} l_{ij} \right) f_h = - \sum_{h=1}^2 l_i^h f_h \quad \text{The Weingarten Equations.}$$

Of course, equations (**) amount to little more than the definition of l_{ij} and l_i^h , but in the classical literature it is always precisely these equations which are called the Weingarten equations.

The Gauss and Weingarten equations constitute an exact analogue of the Serret-Frenet formulas for a curve—the derivatives of f_1, f_2, N have been

expressed in terms of these same vectors, and only the g_{ij} and l_{ij} enter. We thus seem to be in a good position to produce an immersion f with given g_{ij} and l_{ij} : we should first solve the Gauss and Weingarten equations for f_1, f_2, N , and then solve for f . However, these equations are *partial* differential equations (just 15 in all, for the 9 component functions f_i^j, n^j), and we know that these equations have solutions only if certain compatibility conditions are satisfied. These conditions are given explicitly on pg. I.187, but there is no need to turn back to them: the required conditions are obtained simply by setting mixed partial derivatives equal, and substituting the original equation into the results so obtained. We will now derive these conditions explicitly.

We begin by using (*) to compute

$$\begin{aligned}
 f_{ikj} &= \sum_{h=1}^2 \Gamma_{ik,j}^h f_h + \sum_{h=1}^2 \Gamma_{ik}^h f_{hj} + l_{ik,j} N + l_{ik} N_j \\
 &\quad [\text{here } \Gamma_{ik,1}^h = \partial \Gamma_{ik}^h / \partial s, \text{ etc.}] \\
 &= \sum_{\rho=1}^2 \Gamma_{ik,j}^\rho f_\rho + \sum_{h=1}^2 \Gamma_{ik}^h \left(\sum_{\rho=1}^2 \Gamma_{hj}^\rho f_\rho + l_{hj} N \right) \\
 &\quad + l_{ik,j} N - l_{ik} \left(\sum_{\rho=1}^2 l_j^\rho f_\rho \right), \quad \text{using (*) and (**).}
 \end{aligned}$$

Setting $f_{ikj} = f_{ijk}$, and using linear independence of f_1, f_2, N , we have

$$(A) \quad \Gamma_{ik,j}^\rho - \Gamma_{ij,k}^\rho + \sum_{h=1}^2 (\Gamma_{ik}^h \Gamma_{hj}^\rho - \Gamma_{ij}^h \Gamma_{hk}^\rho) = l_{ik} l_j^\rho - l_{ij} l_k^\rho$$

$$(B) \quad l_{ik,j} - l_{ij,k} + \sum_{h=1}^2 \Gamma_{ik}^h l_{hj} - \sum_{h=1}^2 \Gamma_{ij}^h l_{hk} = 0.$$

In this mess, some things should be looking familiar. Indeed, comparing with pg. II.188, we see that equation (A) says that

$$R^\rho_{kji} = l_{ik} l_j^\rho - l_{ij} l_k^\rho.$$

which is equivalent to

$$\begin{aligned}
 (A') \quad R_{hkji} &= \sum_{\rho=1}^2 g_{h\rho} R^{\rho}_{kji} = \sum_{\rho=1}^2 g_{h\rho} (l_j^{\rho} l_{ik} - l_k^{\rho} l_{ij}) \\
 &= \sum_{\rho=1}^2 g_{h\rho} \left(\sum_{\sigma=1}^2 g^{\rho\sigma} l_{\sigma j} l_{ik} - \sum_{\sigma=1}^2 g^{\rho\sigma} l_{\sigma k} l_{ij} \right) \\
 &\quad \text{by the definition of } l_j^{\rho} \text{ in } (**) \\
 &= l_{hj} l_{ik} - l_{hk} l_{ij}.
 \end{aligned}$$

A special case is

$$R_{1212} = l_{11} l_{22} - l_{12} l_{12} = ln - m^2 \quad \begin{array}{l} \text{Gauss' Equation} \\ \text{(Gauss' Theorema Egregium).} \end{array}$$

This really is equivalent to Gauss' Theorema Egregium, for it says (cf. pg. II.190) that

$$\left\langle R \left(\frac{\partial f}{\partial s}, \frac{\partial f}{\partial t} \right) \frac{\partial f}{\partial t}, \frac{\partial f}{\partial s} \right\rangle = ln - m^2,$$

and hence that the intrinsically defined Gaussian curvature K is given by

$$K = \frac{\left\langle R \left(\frac{\partial f}{\partial s}, \frac{\partial f}{\partial t} \right) \frac{\partial f}{\partial t}, \frac{\partial f}{\partial s} \right\rangle}{\left\langle \frac{\partial f}{\partial s}, \frac{\partial f}{\partial s} \right\rangle \left\langle \frac{\partial f}{\partial t}, \frac{\partial f}{\partial t} \right\rangle - \left\langle \frac{\partial f}{\partial s}, \frac{\partial f}{\partial t} \right\rangle^2} = \frac{ln - m^2}{EG - F^2},$$

the final expression being the Gaussian curvature as originally (extrinsically) defined for a surface in \mathbb{R}^3 . In Volume II we gave a simpler looking proof of this result, but the present proof is philosophically more satisfying, since it relies only on standard techniques for dealing with a system of partial differential equations. Notice that our proof of Theorem I-6 was basically the same, since it used the fact that $R(X, Y)Z$ measures the difference of $\nabla_X \nabla_Y Z$ and $\nabla_Y \nabla_X Z$.

It is easy to see that all other cases of (A') are equivalent to this particular one, or are trivial, because of the identities

$$R_{ijkl} = -R_{jikl} \quad \text{and} \quad R_{klij} = R_{ijkl},$$

which always hold (pp. II.194ff.), and the fact that the right side of (A') has the same symmetry properties.

Now let us take a look at (B). If $j = k$ it says nothing. Moreover, the equation for $j = 2, k = 1$ is equivalent to the one for $j = 1, k = 2$. So we take the latter pair for j and k , and let $i = 1$ or 2 , obtaining

$$(B') \quad \begin{cases} l_{12,1} - l_{11,2} + \sum_{h=1}^2 \Gamma_{12}^h l_{h1} - \sum_{h=1}^2 \Gamma_{11}^h l_{h2} = 0 \\ l_{22,1} - l_{21,2} + \sum_{h=1}^2 \Gamma_{22}^h l_{h1} - \sum_{h=1}^2 \Gamma_{21}^h l_{h2} = 0 \end{cases} \quad \begin{array}{l} \text{The Codazzi-Mainardi} \\ \text{Equations.} \end{array}$$

It is easy to see (Problem 1) that these equations can be derived from the ones given in Corollary 1-12. [Note also that equations (A') and (B') are precisely what the classical tensor analysis equations (11) and (12) on page 16 become in this case.]

There is still one more set of equations which we must consider, obtained by setting $N_{ij} = N_{ji}$. However (Problem 2), it turns out that these reduce to the Codazzi-Mainardi equations. We have thus found altogether three conditions which must be satisfied, and our general theory (Theorem I.6-1) tells us that these are the only conditions we need. We are all ready for a theorem.

3. FUNDAMENTAL THEOREM OF SURFACE THEORY (BONNET; 1867). Let $U \subset \mathbb{R}^2$ be a convex open set containing $(0, 0)$.

(1) Let $f, \bar{f}: U \rightarrow \mathbb{R}^3$ be two immersions, and define

$$\begin{aligned} g_{ij} &= \langle f_i, f_j \rangle & \bar{g}_{ij} &= \langle \bar{f}_i, \bar{f}_j \rangle \\ N &= \frac{f_1 \times f_2}{\sqrt{g_{11}g_{22} - g_{12}^2}} & \bar{N} &= \frac{\bar{f}_1 \times \bar{f}_2}{\sqrt{\bar{g}_{11}\bar{g}_{22} - \bar{g}_{12}^2}} \\ l_{ij} &= \langle -N_i, f_j \rangle = \langle N, f_{ij} \rangle & \bar{l}_{ij} &= \langle -\bar{N}_i, \bar{f}_j \rangle = \langle \bar{N}, \bar{f}_{ij} \rangle. \end{aligned}$$

Suppose that $g_{ij} = \bar{g}_{ij}$ and $l_{ij} = \bar{l}_{ij}$ on U . Then there is a proper Euclidean motion A such that $\bar{f} = A \circ f$.

(2) Let g_{ij} and l_{ij} ($i, j = 1, 2$) be functions on U which satisfy

- (i) $g_{ij} = g_{ji}$ and $l_{ij} = l_{ji}$, and (g_{ij}) is positive definite on U , so that we can define corresponding g^{ij} and Γ_{ij}^k

(ii) Gauss' Equation:

$$\begin{aligned} l_{11}l_{22} - (l_{12})^2 &= R_{1212} \\ &= \sum_{\rho=1}^2 g_{1\rho} \left(\Gamma_{22,1}^\rho - \Gamma_{21,2}^\rho + \sum_{h=1}^2 (\Gamma_{22}^h \Gamma_{h1}^\rho - \Gamma_{21}^h \Gamma_{h2}^\rho) \right) \end{aligned}$$

(iii) The Codazzi-Mainardi Equations:

$$\begin{aligned} l_{12,1} - l_{11,2} + \sum_{h=1}^2 \Gamma_{12}^h l_{h1} - \sum_{h=1}^2 \Gamma_{11}^h l_{h2} &= 0 \\ l_{22,1} - l_{21,2} + \sum_{h=1}^2 \Gamma_{22}^h l_{h1} - \sum_{h=1}^2 \Gamma_{21}^h l_{h2} &= 0. \end{aligned}$$

Then there is an immersion $f: U \rightarrow \mathbb{R}^3$ such that

$$\begin{aligned} g_{ij} &= \langle f_i, f_j \rangle \\ l_{ij} &= \langle -N_i, f_j \rangle = \langle N, f_{ji} \rangle, \quad \text{for } N = \frac{f_1 \times f_2}{\sqrt{g_{11}g_{22} - g_{12}^2}}. \end{aligned}$$

PROOF. Let us adopt the more systematic notation

$$\begin{aligned} \mathbf{v}_1 &= f_1, \quad \mathbf{v}_2 = f_2, \quad \mathbf{v}_3 = N \\ \bar{\mathbf{v}}_1 &= \bar{f}_1, \quad \bar{\mathbf{v}}_2 = \bar{f}_2, \quad \bar{\mathbf{v}}_3 = \bar{N}. \end{aligned}$$

To prove (I), we first choose a rotation $B \in \text{SO}(3)$ such that

$$B(\mathbf{v}_\alpha(0,0)) = \bar{\mathbf{v}}_\alpha(0,0) \quad \alpha = 1, 2, 3.$$

This is possible because $g_{ij}(0) = \bar{g}_{ij}(0)$ for $i, j = 1, 2$, and because the two triples of vectors $(\mathbf{v}_1(0,0), \mathbf{v}_2(0,0), \mathbf{v}_3(0,0))$ and $(\bar{\mathbf{v}}_1(0,0), \bar{\mathbf{v}}_2(0,0), \bar{\mathbf{v}}_3(0,0))$ are both positively oriented, with the third vector perpendicular to the first two. If we let $\tilde{f} = B \circ f$, then it is easy to see that

$$\begin{aligned} \tilde{g}_{ij} &= g_{ij} = \bar{g}_{ij} \\ \tilde{\mathbf{v}}_3 &= B \circ \mathbf{v}_3 \\ \tilde{l}_{ij} &= l_{ij} = \bar{l}_{ij}. \end{aligned}$$

We claim that the maps

$$(\bar{\mathbf{v}}_1, \bar{\mathbf{v}}_2, \bar{\mathbf{v}}_3), (\tilde{\mathbf{v}}_1, \tilde{\mathbf{v}}_2, \tilde{\mathbf{v}}_3): U \rightarrow \mathbb{R}^3,$$

which we know are equal at $(0, 0)$, are actually equal everywhere. To prove this, we recall that the Gauss formulas and the Weingarten equations give

$$(***) \quad \begin{cases} \bar{\mathbf{v}}_{i,k}(s, t) = \sum_{h=1}^2 \bar{\Gamma}_{ik}^h(s, t) \bar{\mathbf{v}}_h(s, t) + \bar{l}_{ik}(s, t) \bar{\mathbf{v}}_3(s, t) & i = 1, 2 \\ \bar{\mathbf{v}}_{3,k}(s, t) = - \sum_{h=1}^2 \left(\sum_{j=1}^2 \bar{g}^{hj}(s, t) \bar{l}_{kj}(s, t) \right) \bar{\mathbf{v}}_h(s, t) \end{cases}$$

for the $\bar{\mathbf{v}}_\alpha$, while for the $\tilde{\mathbf{v}}_\alpha$ we obtain the corresponding equations with $\tilde{\Gamma}_{ik}^h$, \tilde{l}_{ik} and \tilde{g}^{hj} . But $\tilde{l}_{ik} = \bar{l}_{ik}$, and since $\tilde{g}_{ij} = \bar{g}_{ij}$ we also have $\tilde{g}^{hj} = \bar{g}^{hj}$ and $\tilde{\Gamma}_{ik}^h = \bar{\Gamma}_{ik}^h$. So the two maps $(\bar{\mathbf{v}}_1, \bar{\mathbf{v}}_2, \bar{\mathbf{v}}_3)$ and $(\tilde{\mathbf{v}}_1, \tilde{\mathbf{v}}_2, \tilde{\mathbf{v}}_3)$ satisfy the *same* equations (***) and have the same values at $(0, 0)$. Therefore they must be equal on U (Theorem I.6-1). But this means that \tilde{f} and $\bar{f} = B \circ f$ have the same partial derivatives, and therefore differ by a constant vector. Consequently, there is a translation $T: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ with $\tilde{f} = T \circ \bar{f} = (T \circ B) \circ f$.

To prove (2), we use Theorem I.6-1 to conclude that equation (***), written in terms of the given g_{ij} and l_{ij} , has a solution $\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3: U \rightarrow \mathbb{R}^3$ with any desired initial conditions; we have already seen that the required conditions in Theorem I.6-1 amount precisely to Gauss' equation and the Codazzi-Mainardi equations. Moreover, the functions \mathbf{v}_α can be defined on all of U because the equations (***) are linear (compare pg. I.165). Since (g_{ij}) is positive definite at $(0, 0)$, there is a solution for which the following conditions are satisfied at $(s, t) = (0, 0)$:

- (a) $\langle \mathbf{v}_i(s, t), \mathbf{v}_j(s, t) \rangle = g_{ij}(s, t) \quad i, j = 1, 2$
- (b) $\langle \mathbf{v}_i(s, t), \mathbf{v}_3(s, t) \rangle = 0 \quad i = 1, 2$
- (c) $|\mathbf{v}_3(s, t)| = 1$
- (d) $(\mathbf{v}_1(s, t), \mathbf{v}_2(s, t), \mathbf{v}_3(s, t))$ is positively oriented.

We will show that conditions (a)–(d) actually hold at all points of U .

Our equation (***) for $\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3$ gives the equations

$$\begin{aligned} \text{(A)} \quad \langle \mathbf{v}_i, \mathbf{v}_j \rangle_k &= \langle \mathbf{v}_{i,k}, \mathbf{v}_j \rangle + \langle \mathbf{v}_i, \mathbf{v}_{j,k} \rangle \\ &= \sum_{h=1}^2 \Gamma_{ik}^h \langle \mathbf{v}_h, \mathbf{v}_j \rangle + \sum_{h=1}^2 \Gamma_{jk}^h \langle \mathbf{v}_h, \mathbf{v}_i \rangle + l_{ik} \langle \mathbf{v}_3, \mathbf{v}_i \rangle + l_{jk} \langle \mathbf{v}_3, \mathbf{v}_j \rangle \end{aligned}$$

for $i, j = 1, 2$, as well as

$$\begin{aligned}
 \text{(B)} \quad \langle \mathbf{v}_i, \mathbf{v}_3 \rangle_k &= \langle \mathbf{v}_{i,k}, \mathbf{v}_3 \rangle + \langle \mathbf{v}_i, \mathbf{v}_{3,k} \rangle \\
 &= l_{ik} - \sum_{h=1}^2 \left(\sum_{j=1}^2 g^{hj} l_{kj} \right) \langle \mathbf{v}_i, \mathbf{v}_h \rangle
 \end{aligned}$$

and

$$\text{(C)} \quad \langle \mathbf{v}_3, \mathbf{v}_3 \rangle_k = 2 \langle \mathbf{v}_{3,k}, \mathbf{v}_3 \rangle = 0.$$

[Equations (A)–(C) all hold for $k = 1, 2$.]

But we also have

$$\begin{aligned}
 g_{ij,k} &= [ik, j] + [jk, i] \quad (\text{by pg. I.331}) \\
 &= \sum_{h=1}^2 \Gamma_{ik}^h g_{hj} + \sum_{h=1}^2 \Gamma_{jk}^h g_{hi}.
 \end{aligned}$$

This shows that the set of equations (A)–(C) are satisfied both by

the set of functions: $\langle \mathbf{v}_i, \mathbf{v}_j \rangle$ ($j = 1, 2$), $\langle \mathbf{v}_3, \mathbf{v}_1 \rangle$, $\langle \mathbf{v}_3, \mathbf{v}_2 \rangle$, $\langle \mathbf{v}_3, \mathbf{v}_3 \rangle$

and by

the set of functions: g_{ij} ($j = 1, 2$), 0 , 0 , 1 .

Moreover, we chose the \mathbf{v}_i so that these two collections of functions have the same value at $(0, 0)$. It follows that they have the same values on all of U . In other words, equations (a)–(c) hold on all of U . Moreover, (a) and (b) [and non-singularity of (g_{ij})] imply that $(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$ are always linearly independent. So condition (d) at $(0, 0)$ implies condition (d) everywhere.

We now claim that there is a function $f: U \rightarrow \mathbb{R}^3$ satisfying $f_i = \mathbf{v}_i$. In order to prove this, we just have to show that $\mathbf{v}_{i,j} = \mathbf{v}_{j,i}$. But this follows from (**), by symmetry of the Γ_{ik}^h and l_{ik} . We now have $\langle f_i, f_j \rangle = g_{ij}$ by (a). Moreover, (b)–(d) then show that $\mathbf{v}_3 = n$. Consequently,

$$\langle f_{ij}, n \rangle = \langle \mathbf{v}_{i,j}, \mathbf{v}_3 \rangle = l_{ij}$$

by (**), together with (b) and (c). ♦

Theorem 3 is exactly the sort of result we would want if we were primarily interested in immersions $f: U \rightarrow \mathbb{R}^3$. But what we really want to study are submanifolds of \mathbb{R}^3 , without relying on a particular choice of a parameterization. For example, let us consider two surfaces $M, \bar{M} \subset \mathbb{R}^3$ and a diffeomorphism $\phi: M \rightarrow \bar{M}$. We would like to have conditions which insure that ϕ is the restriction to M of some proper Euclidean motion. If we arbitrarily choose some immersion $f: U \rightarrow M \subset \mathbb{R}^3$, and let $\bar{f}: U \rightarrow \bar{M} \subset \mathbb{R}^3$ be $\bar{f} = \phi \circ f$, then Theorem 2 tells us that such a proper Euclidean motion exists if the g_{ij} and l_{ij} for f equal the \bar{g}_{ij} and \bar{l}_{ij} for \bar{f} . Now the individual functions g_{ij} and l_{ij} for f do not have an “invariant meaning”: given a submanifold $M \subset \mathbb{R}^3$, we cannot, for example, find functions γ_{ij} on M so that every $f: U \rightarrow M$ has its g_{ij} ’s given simply by $g_{ij} = \gamma_{ij} \circ f$. Fortunately, however, the tensors

$$\begin{aligned} g_{11} ds \otimes ds + g_{12} ds \otimes dt + g_{21} dt \otimes ds + g_{22} dt \otimes dt \\ l_{11} ds \otimes ds + l_{12} ds \otimes dt + l_{21} dt \otimes ds + l_{22} dt \otimes dt \end{aligned}$$

do have an invariant meaning: they are just f^*I and f^*II . So we can formulate the first part of Theorem 3 for submanifolds:

4. COROLLARY. Let $M, \bar{M} \subset \mathbb{R}^3$ be two connected oriented surfaces imbedded in \mathbb{R}^3 , let $\nu: M \rightarrow S^2 \subset \mathbb{R}^3$ and $\bar{\nu}: \bar{M} \rightarrow S^2 \subset \mathbb{R}^3$ be the unit normal vector fields determined by the orientations, and let I, II and \bar{I}, \bar{II} be the first and second fundamental forms for M and \bar{M} (the forms \bar{I} and \bar{II} being defined with respect to ν and $\bar{\nu}$, respectively). Let $\phi: M \rightarrow \bar{M}$ be an orientation preserving diffeomorphism which preserves the first and second fundamental forms,

$$\begin{aligned} \phi^*\bar{I} &= I \quad (\text{i.e., } \phi \text{ is an isometry}) \\ \phi^*\bar{II} &= II. \end{aligned}$$

Then there is a proper Euclidean motion A such that $\phi = A|_M$ and $A_*\nu = \bar{\nu}$.

PROOF. Let $f: U \rightarrow M \subset \mathbb{R}^3$ be an orientation preserving immersion, and let $\bar{f} = \phi \circ f: U \rightarrow \bar{M} \subset \mathbb{R}^3$; the immersion \bar{f} is also orientation preserving, since ϕ is. The \bar{g}_{ij} for \bar{f} are the coefficients, with respect to the standard coordinate system (s, t) , of

$$\bar{f}^*\bar{I} = (\phi \circ f)^*\bar{I} = f^*\phi^*\bar{I} = f^*I.$$

Consequently, $\bar{g}_{ij} = g_{ij}$. Similarly, since \bar{f} is orientation preserving, the \bar{l}_{ij} are the coefficients of $\bar{f}^*\bar{II} = f^*II$; since f is also orientation preserving, we find that $\bar{l}_{ij} = l_{ij}$. By Theorem 3, there is some proper Euclidean motion A such that $\phi = A$ on $f(U)$. If we choose immersions $\{f_\alpha: U_\alpha \rightarrow M\}$ whose images

cover M , it is easy to see that the corresponding A_α must all be the same proper Euclidean motion A . ♦

We also want to formulate the existence part of Theorem 3 for manifolds, rather than immersions. So we consider an oriented surface M with a Riemannian metric $\langle \cdot, \cdot \rangle$ [corresponding to the g_{ij}] and a symmetric tensor S covariant of order 2 [corresponding to the l_{ij}]. In the previous chapter we have already seen how to give an invariant version of Gauss' equation and the Codazzi-Mainardi equations. This allows us to state

5. COROLLARY. Let $(M, \langle \cdot, \cdot \rangle)$ be an oriented Riemannian 2-manifold, with covariant derivative ∇ and curvature tensor R , and let S be a symmetric tensor on M , covariant of order 2. Suppose that S satisfies

(1) Gauss' Equation:

$$\langle R(X, Y)Y, X \rangle = S(X, X)S(Y, Y) - [S(X, Y)]^2$$

(2) The Codazzi-Mainardi Equations:

$$(\nabla_X S)(Y, Z) = (\nabla_Y S)(X, Z).$$

Then for any $p \in M$ there is a neighborhood U of p and an immersion $f: U \rightarrow \mathbb{R}^3$ such that

$$\begin{aligned} \langle \cdot, \cdot \rangle &= f^* \langle \cdot, \cdot \rangle \\ S &= f^* \text{II}, \end{aligned}$$

where $\langle \cdot, \cdot \rangle$ is the usual Riemannian metric on \mathbb{R}^3 and II is the second fundamental form on $f(U)$ defined in terms of the unit normal field ν which is determined by the orientation that $f(U)$ gets from the orientation on $U \subset M$.

PROOF. Left to the reader. ♦

Unlike Corollary 4, where a global result comes almost automatically, in Corollary 5 we cannot generally choose U to be all of M . As an example, we take the torus $S^1 \times S^1$ with a flat metric $\langle \cdot, \cdot \rangle$ [pg. II.179] and let $S = 0$. The Gauss and Codazzi-Mainardi equations are trivially satisfied. But the only connected submanifolds of \mathbb{R}^3 with $\text{II} = 0$ everywhere are subsets of a plane (Theorem 2), so we certainly cannot find an immersion $f: S^1 \times S^1 \rightarrow \mathbb{R}^3$ with $f^* \text{II} = S = 0$ everywhere. On the other hand (Problem 3), we *can* take U to be all of M in Corollary 5 when M is simply-connected.

Now that we have adequately documented the importance of the second fundamental form in surface theory, we will take this opportunity to slip in something new. The reader has perhaps already surmised with subconscious dread that there is a third fundamental form, and even yet higher numbered monsters, but these hogey men turn out to be very nicely behaved creatures which are in no way to be feared. For a submanifold $M \subset \mathbb{R}^3$, with unit normal $v: M \rightarrow S^2 \subset \mathbb{R}^3$, we define the **third fundamental form** III of M by

$$\begin{aligned} \text{III}(p)(v_p, w_p) &= \langle -dv(v_p), -dv(w_p) \rangle \\ &= \langle dv(v_p), dv(w_p) \rangle \quad v_p, w_p \in M_p. \end{aligned}$$

Similarly, if $f: U \rightarrow \mathbb{R}^3$ is an immersion (for $U \subset \mathbb{R}^2$ open), we define III_f by

$$\begin{aligned} \text{III}_f(s, t)(v, w) &= \langle dN_f(v), dN_f(w) \rangle \\ &= \langle (N_f)_*(v), (N_f)_*(w) \rangle \quad v, w \in \mathbb{R}^2_{(s, t)}. \end{aligned}$$

This is equivalent to defining $\text{III}_f = f^*\text{III}$, where III is the third fundamental form for image f . Remembering that $dv: M_p \rightarrow M_p$ is self-adjoint (Theorem 1-8 or Theorem II.3-1), we see that

$$\text{III}(p)(v_p, w_p) = \langle (dv)^2(v_p), w_p \rangle.$$

This suggests defining

$$\text{IV}(p)(v_p, w_p) = \langle (dv)^3(v_p), w_p \rangle,$$

and so forth. There is no notational way to write down the general definition, since no one has ever addressed the burning question of how we should indicate the n^{th} Roman numeral (come to think of it, no one even knows how to write down arbitrarily large Roman numerals). But that doesn't matter very much, especially as all these forms are expressible in terms of I and II anyway:

6. PROPOSITION. For a surface $M \subset \mathbb{R}^3$ we have

$$\text{III} - 2H \cdot \text{II} + K \cdot \text{I} = 0.$$

(Similarly, for an immersion $f: U \rightarrow \mathbb{R}^3$, we have

$$\text{III}_f - 2H \cdot \text{II}_f + K \cdot \text{I}_f = 0.$$

where $H(s, t)$ is the mean curvature of image f at $f(s, t)$, etc.)

PROOF. Remember the Cayley-Hamilton Theorem! The map $-dv: M_p \rightarrow M_p$ satisfies its characteristic polynomial $\chi(\lambda)$, which is given by

$$\chi(\lambda) = \lambda^2 - [\text{trace}(-dv)]\lambda + \det(-dv) = \lambda^2 - 2H\lambda + K.$$

Consequently,

$$(-dv)^2 - 2H(-dv) + K \cdot \text{identity} = 0 \quad \text{on } M_p.$$

Applying this equation to v_p , and taking the inner product with w_p , we obtain the desired result. ♦

It is clear that we can also express IV in terms of III and II, etc. Proposition 6 does not necessarily mean that III is not worth considering, for it is still a useful tool for expressing certain quantities. Suppose, for example, that we have an immersion $f: U \rightarrow \mathbb{R}^3$, with normal map $N_f (= v \circ f$ for the unit normal map v on image f). Since the normal map N_f plays such a vital role in describing the geometry of f , it is not at all unreasonable to ask what the first and second fundamental forms of N_f look like. Notice that in this instance we certainly want to explicitly consider the forms I_{N_f} and II_{N_f} for the map N_f : the image of N_f is just part of S^2 , so its first and second fundamental forms aren't very interesting.

7. PROPOSITION. Let $f: U \rightarrow \mathbb{R}^3$ be an immersion with normal map $N_f = v \circ f$. Then the third fundamental form of f is both the first fundamental form of N_f and the negative of the second fundamental form of N_f :

$$III_f = I_{N_f} = -II_{N_f}.$$

PROOF. Our original definition,

$$III_f(s, t)(v, w) = \langle (N_f)_*(v), (N_f)_*(w) \rangle,$$

shows that $III_f = I_{N_f}$. Since the unit normal vector at any point $p \in S^2$ is just p itself, it is also clear that the normal map of N_f is just N_f itself, so we have $N_{N_f} = N_f$. Thus

$$\begin{aligned} II_{N_f}(s, t)(v, w) &= \langle -(N_{N_f})_*(v), (N_f)_*(w) \rangle \\ &= \langle -(N_f)_*(v), (N_f)_*(w) \rangle. \quad \diamond \end{aligned}$$

This result will come in handy at one point in Chapter 9, but we have no more to say about III at present. Following the route set forth in the first chapter of Volume II, we will now briefly look at some global properties of surfaces which are related to positive curvature. At the very outset we note one respect in which the situation for surfaces in \mathbb{R}^3 is different from that of curves in \mathbb{R}^2 : Although

we are able to define a signed curvature κ for a curve c in \mathbb{R}^2 , the sign of κ depends on the “orientation” of c , and is reversed when we traverse c in the opposite direction; but for a surface $M \subset \mathbb{R}^3$, the Gaussian curvature K , which may also be positive or negative, does not depend on the orientation of M . We begin with a simple, but sometimes useful, observation.

8. PROPOSITION. If M is a compact surface immersed in \mathbb{R}^3 , then there is at least one point $p \in M$ where $K(p) > 0$.

PROOF. The trick is to choose a point $p \in M$ whose distance from 0 is a maximum. Then M is even more curved at p than the sphere of radius $|p|$ —in fact, each principal curvature is $> 1/|p|$, by Proposition II.3-0, and the corresponding result for curves in \mathbb{R}^2 . Details are left as an exercise. ♦

This result gives us another way of seeing that the flat torus cannot be immersed in \mathbb{R}^3 (no matter what tensor S we choose on it).

We now want to consider surfaces M with $K(p) > 0$ for *all* $p \in M$. We naturally hope to relate this condition to convexity, so a brief discussion of that concept is in order. We define an imbedded surface $M \subset \mathbb{R}^3$ to be **convex** if it lies on one side of each of its tangent planes. As in the case of curves, we would first like to relate this definition to the more common one.

Any subset A of \mathbb{R}^3 is called **convex** if the line segment \overline{pq} from p to q is contained in A whenever $p, q \in A$. Suppose A is convex and p is a point in the boundary of A . A plane P containing p is called a **support plane** of A if A lies completely in one of the closed half-spaces into which P divides \mathbb{R}^3 .

9. PROPOSITION. If A is convex, and p is in the boundary of A , then there is at least one support plane P containing p .

PROOF. If A has no interior points, it lies in a plane, and the Theorem follows easily from the corresponding result, Proposition II.1-3, for subsets of \mathbb{R}^2 . If A has an interior point q , let Q be a plane containing q and p , and let L be a support line for $A \cap Q$ through p . This line L divides Q into two closed half-planes; let Q' be the one such that $Q' - L$ contains no points of $Q \cap A$.

Now we will consider the various closed half-planes having L as their edge. Choose one side of Q' and consider angles θ such that the half-plane with L as its edge which makes an angle of θ with Q' on this side does not intersect A except along L (it may be that $\theta = 0$ is the only possibility). Let θ_1 be the least upper bound of all such θ , and let Q_1 be the half-plane with L as edge which makes an angle of θ_1 . Let Q_2 be the corresponding half-plane on the other side of Q' .

To prove the theorem, it clearly suffices to prove that the angle between Q_1 and Q_2 is $\geq \pi$. We note that there are points of A on planes arbitrarily close to Q_1 and Q_2 . If the angle between Q_1 and Q_2 were $< \pi$, then we could consider a suitable pair of such points, together with points of A in a whole neighborhood of q , and find that A must contain some point of L in its interior, which is impossible. ♦

We now want to show that a compact connected 2-dimensional submanifold M of \mathbb{R}^3 is convex if and only if the set A consisting of all points on M or inside M is a convex subset of \mathbb{R}^3 . Once again, we are assuming Corollary I.11-15, and the following easy consequence:

Suppose $M \subset \mathbb{R}^3$ is a compact connected surface, and l is a ray from p which intersects M at just one point $q \neq p$. Suppose, moreover, that l does *not* lie along the tangent plane of M at q . Then p is inside M .

10. PROPOSITION. Let $M \subset \mathbb{R}^3$ be a compact connected surface, and let A be the set of all points on or inside M . Then M is convex (that is, M lies on one side of each of its tangent planes) if and only if A is convex.

PROOF. Exactly like the proof of Proposition II.1-4. ♦

We are finally ready to relate convexity and curvature. If you have found yourself nodding drowsily at the rather obvious generalizations of old material which occupied the last few pages, it is time to wake up now, because our result for surfaces is *not* just an analogue of the result for curves.

11. THEOREM (HADAMARD). (1) If M is a convex surface in \mathbb{R}^3 , then $K(p) \geq 0$ for all $p \in M$.

(2) Let M be a compact connected 2-manifold, and $f: M \rightarrow \mathbb{R}^3$ an immersion with $K(p) > 0$ for all $p \in M$. Then

- (i) The manifold M is orientable, and the normal map $N: M \rightarrow S^2 \subset \mathbb{R}^3$ is a diffeomorphism,
- (ii) The map $f: M \rightarrow \mathbb{R}^3$ is an imbedding, and $f(M)$ is convex.

PROOF. The first part is immediate, for we have already seen that if $K(p) < 0$, then M lies on both sides of M_p .

To prove (2), we first recall that since $K(p) > 0$, points of M near p all lie on one side of M_p . We choose N so that it always points on this side. Since this

gives us a continuous choice of N , it also gives us an orientation of M . To show that $N: M \rightarrow S^2$ is a diffeomorphism, we note first that N_* is always one-one, since $K = \det N_*$. So $N(M) \subset S^2$ is open. It is also closed, since M is compact; so $N(M) = S^2$. Now we need to use a few properties of covering spaces. The fact that $N: M \rightarrow S^2$ is onto and locally one-one does not immediately imply that N is a covering space map; however it is an easy exercise (Problem 4) to show that this follows from the fact that M is compact. But S^2 is simply-connected, and therefore has no non-trivial covering spaces. So $N: M \rightarrow S^2$ is a diffeomorphism, and we have proved (i).

To prove (ii), we consider a point $p \in M$ and the tangent space $M_p \subset \mathbb{R}^3_{f(p)}$. At least some points of $f(M)$ lie on the same side of M_p as $N(p)$. Let $f(q)$ be

a point on this side which is furthest from M_p . Then clearly $N(q) = -N(p)$. Suppose that $f(p) = f(p')$ for some other $p' \in M$. Since $N: M \rightarrow \mathbb{R}^3$ is one-one, $N(p')$ cannot be either $N(p)$ or $-N(p) = N(q)$. So the tangent plane $M_{p'}$ must cross the tangent plane M_p . It is then easy to see that $f(M)$ must

contain points on both sides of M_p . Let $f(r)$ be a point of M furthest from M_p on the *other* side from q . Then $N(r)$ must equal $N(p)$, contradicting the fact that N is one-one. Thus we have shown that f is an embedding.

To show that $f(M)$ is convex, we use a similar argument. Given $p \in M$, we just have to show that all of $f(M)$ lies on the same side of $M_p \subset \mathbb{R}^3_{f(p)}$ as $N(p)$ does. If there were points on the opposite side, and $f(q)$ were a point on the opposite side which is furthest from M_p , then $N(q)$ would have to equal $N(p)$, again a contradiction. ♦

This result naturally invites comparison with Theorem II.1-8, which states that a simple closed curve c in \mathbb{R}^2 is convex if and only if it satisfies $\kappa \geq 0$ or $\kappa \leq 0$ (depending on the direction in which c is traversed). The proof of part (1) of Theorem 11 is much simpler than the proof of the corresponding part of Theorem II.1-8. This is because the sign of the Gaussian curvature K has a local geometric meaning, while the sign of κ has none; the only meaningful assertion about κ is the *global* statement that it is ≥ 0 or ≤ 0 everywhere. In part (2) of Theorem 11 we have the significant circumstance that we do not have to assume that M is imbedded—this comes out as part of the conclusion. The analogous assertion is *false* in the case of curves: the figure below shows an immersed, but not imbedded, curve with $\kappa \geq 0$ everywhere. In one respect

our result does not improve on Theorem II.1-8, for in order to prove part (2), we needed to assume the strict inequality $K(p) > 0$. Actually the result holds even when we assume only that $K \geq 0$, but the proof in this case is much more difficult (for further discussion, and references, see pp. IV. 82–83).

Our approach to surface theory has so far been very classical, but we are now ready to jazz it up a bit. First we want to examine the moving frame approach again, and write out explicitly all the equations (which in the case of surfaces in \mathbb{R}^3 boil down to almost nothing). In addition to their importance in the remainder of this chapter, some of these formulas will be crucial in Chapter 6 (and the equations in the general case will be even more crucial in Chapter 7).

If X_1, X_2 is a positively oriented orthonormal moving frame on an oriented surface $M \subset \mathbb{R}^3$, and we let $X_3 = \nu$, then X_1, X_2, X_3 is a positively oriented adapted orthonormal moving frame on M . There are just the following forms to consider:

$$\begin{array}{ll} \theta^1, \theta^2 & \text{the dual 1-forms} \\ \omega_1^2 = -\omega_2^1 & \text{the connection form} \\ \psi_1^3, \psi_2^3. & \end{array}$$

We want to relate these forms to the tensors and functions on M already considered. Notice first that \mathbf{I} is given by

$$\mathbf{I} = \theta^1 \otimes \theta^1 + \theta^2 \otimes \theta^2.$$

We also have

$$dA = \theta^1 \wedge \theta^2,$$

where dA is the volume element determined by the metric \mathbf{I} on M and the given orientation. Since we have (see page 19ff.)

$$\begin{aligned}\psi_1^3 &= s_{11}^3 \theta^1 + s_{21}^3 \theta^2 = \Pi(X_1, X_1) \theta^1 + \Pi(X_2, X_1) \theta^2 \\ \psi_2^3 &= s_{12}^3 \theta^1 + s_{22}^3 \theta^2 = \Pi(X_1, X_2) \theta^1 + \Pi(X_2, X_2) \theta^2,\end{aligned}$$

we can write

$$\Pi = \psi_1^3 \otimes \theta^1 + \psi_2^3 \otimes \theta^2.$$

It is also easy to see that the Gaussian and mean curvatures

$$\begin{aligned}K &= \Pi(X_1, X_1) \cdot \Pi(X_2, X_2) - [\Pi(X_1, X_2)]^2 \\ H &= \frac{1}{2} \{ \Pi(X_1, X_1) + \Pi(X_2, X_2) \}\end{aligned}$$

are given by

$$\begin{aligned}\psi_1^3 \wedge \psi_2^3 &= K \theta^1 \wedge \theta^2 \\ \psi_1^3 \wedge \theta^2 - \psi_2^3 \wedge \theta^1 &= 2H \theta^1 \wedge \theta^2.\end{aligned}$$

On the other hand, we have a much more important expression for K , in terms of the connection form ω_1^2 . We note first that equation (3) on page 16 now reduces to

$$d\omega_1^2 = \Omega_1^2.$$

Then Gauss' equation (page 20) becomes simply

$$0 = d\omega_1^2 - \psi_2^3 \wedge \psi_1^3 = d\omega_1^2 + K \theta^1 \wedge \theta^2,$$

so that

$$d\omega_1^2 = -K \theta^1 \wedge \theta^2.$$

Since this equation is equivalent to Gauss' equation, it must somehow demonstrate the Theorema Egregium, and it surely does, since the form ω_1^2 does not depend on the imbedding (it is the unique form with $d\theta^1 = \omega_1^2 \wedge \theta^2$ and $d\theta^2 = -\omega_1^2 \wedge \theta^1$). Some elementary treatments of surface theory proceed to

use this equation to *define* the Gaussian curvature of an arbitrary 2-dimensional Riemannian manifold—it is only necessary to check that K does not depend on the choice of the orthonormal moving frame; this is a special case of the moving frame definition of the curvature tensor given in Chapter II.7. Finally, we mention that the Codazzi-Mainardi equations (page 20) now become

$$\begin{aligned} d\psi_1^3 &= \omega_1^2 \wedge \psi_2^3 \\ d\psi_2^3 &= -\omega_1^2 \wedge \psi_1^3. \end{aligned}$$

An introduction to surface theory carried out purely in terms of this moving frame and structural equation approach can be very frustrating. Instead of dealing with geometrically tangible things like dN and Π , one has only the 1-forms $\omega_1^2, \psi_1^3, \psi_2^3$ to play with, and the simplicity of the Gauss and Codazzi-Mainardi equations as given above seems vitiated by their lack of intuitive geometric content. But this simplicity is a great advantage in proving theorems, and can be attributed, in large measure, to the fact that they express integrability conditions so neatly in terms of d . For example, they allow us to give a proof of the fundamental theorem of surface theory which uses the differential form version of the Frobenius integrability theorem (Proposition I.7-14), instead of mucking around with the classical integrability conditions; we will present this proof, in a more general situation, in Chapter 7. The truly overwhelming advantage of the moving frame approach becomes apparent when one is seriously investigating questions about the shape of surfaces in space; any information one can hope to get has to come out of the three simple equations

$$d\omega_1^2 = -\psi_1^3 \wedge \psi_2^3, \quad d\psi_1^3 = \omega_1^2 \wedge \psi_2^3, \quad d\psi_2^3 = -\omega_1^2 \wedge \psi_1^3.$$

Usually one just picks a frame suited to the problem and reads off the information from these equations. As a very simple example, we consider an all-umbilic surface $M \subset \mathbb{R}^3$. In this situation any adapted orthonormal moving frame X_1, X_2, X_3 on M is suitable (the hypothesis that p is an umbilic essentially says that all orthonormal frames at p are indistinguishable from one another), and we have

$$\psi_i^3 = \lambda \theta^i \quad i = 1, 2$$

for some function λ on M . Thus

$$\begin{aligned} d\lambda \wedge \theta^1 + \lambda d\theta^1 &= d\psi_1^3 = \omega_1^2 \wedge \psi_2^3 = \lambda \omega_1^2 \wedge \theta^2 \\ d\lambda \wedge \theta^2 + \lambda d\theta^2 &= -\lambda \omega_1^2 \wedge \theta^1, \end{aligned}$$

while

$$\begin{aligned} d\theta^1 &= \omega_1^2 \wedge \theta^2 \\ d\theta^2 &= -\omega_1^2 \wedge \theta^1. \end{aligned}$$

So we find that

$$d\lambda \wedge \theta^i = 0 \quad i = 1, 2.$$

But this implies that the 1-form $d\lambda$ is 0, so we find, once again, that λ is constant. More interesting examples will occur in later chapters.

The moving frame approach was brought in at this point not to launch an extended investigation into the geometry of surfaces—that occurs in later chapters—but with a completely different goal in mind. We want to show that the Gauss and Codazzi-Mainardi equations for surfaces in \mathbb{R}^3 are, from the proper point of view, nothing more than the “equations of structure” of the Lie group $SO(3)$, and that the Fundamental Theorem of Surface Theory reduces to Theorems I.10-17 and I.10-18 about Lie groups. After doing this, we will then proceed to bring another group into the picture by examining properties of surfaces in \mathbb{R}^3 which are invariant under the group of maps $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ of the form $A = T \circ B$ for T a translation and $B \in SL(3) =$ group of 3×3 matrices with $\det = 1$.

We begin with some preliminaries about notation. Nowadays, an “affine” map $A: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is usually defined to be one of the form $A = T \circ B$ for T a translation and $B \in GL(n, \mathbb{R})$. Thus the proper Euclidean motions, $A = T \circ B$ for $B \in SO(n)$, might be described as “special orthogonal affine” maps, while maps $A = T \circ B$ for $B \in SL(n)$ might best be described as “special linear affine” maps. We will employ this terminology regularly for maps $A: \mathbb{R}^n \rightarrow \mathbb{R}^n$, but we will also find it convenient to abbreviate the phrase “special linear affine” to “special affine” when we speak of such concepts as “special affine curvature”. Thus when we speak of the “special affine geometry of surfaces” in \mathbb{R}^3 , we mean properties of surfaces invariant under special linear affine maps. On those occasions when we want to consider properties of surfaces invariant under all affine maps, we will emphasize this fact by speaking of “general affine” invariants.

We will also include a brief review of the relevant facts about Lie groups (pp. II.36–37), since we are going to make a slight change of notation. If G is a Lie group with Lie algebra \mathfrak{g} , then we define the natural \mathfrak{g} -valued 1-form* ω on G by $\omega(a)(\tilde{X}(a)) = X$, where \tilde{X} is the left invariant vector field with $\tilde{X}(e) = X$. If X_1, \dots, X_n is a basis of \mathfrak{g} , then we have $\omega = \sum_{i=1}^n \omega^i X_i$ for ordinary (\mathbb{R} -valued) left invariant 1-forms ω^i , and these forms ω^i are a basis for the left invariant 1-forms. These forms are important because two maps

*We are now using ω to distinguish this form on G from the forms ω_1^2 for a moving frame on a surface. This wasn't important in Volume II, where we considered only curves.

$f, g: M \rightarrow G$ differ by a left translation [$f = L_a \circ g$ for some $a \in G$] if and only if $f^*(\omega^i) = g^*(\omega^i)$ for all i (Theorem I.10-18). When G is a subgroup of $GL(n, \mathbb{R})$, with $P: G \rightarrow GL(n, \mathbb{R}) \subset \mathbb{R}^{n^2}$ the inclusion map, then we can form $P^{-1} \cdot dP$, where P^{-1} denotes (somewhat confusingly) the map $A \mapsto A^{-1}$, and the differential dP of P can be considered either as an \mathbb{R}^{n^2} -valued 1-form on G , or as the matrix of 1-forms $dP = (dx^{ij})$, where dx^{ij} denotes the differential of $x^{ij}|_G$. Then (pp. II.36–37) $P^{-1} \cdot dP$ is the natural \mathfrak{g} -valued 1-form ω on G . Among the entries of this matrix will be a basis for the left invariant 1-forms on G (the entries are generally not linearly independent, since the forms dx^{ij} are not linearly independent on G). So if $f: M \rightarrow GL(n, \mathbb{R})$ is a C^∞ map, and we want to look at the forms $f^*(\omega^i)$ for a basis $\{\omega^i\}$ of left invariant 1-forms on G , it suffices to look at the entries of the matrix

$$f^*(P^{-1} \cdot dP) = f^{-1} \cdot df.$$

To study properties of immersions $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ which are invariant under special orthogonal affine maps of \mathbb{R}^3 , we need to define an associated map $\alpha_f: \mathbb{R}^2 \rightarrow SO(3)$. This can be done in the following way. Let $X_3 = N$ be the normal map of f , and let X_1, X_2 be the result of applying the Gram-Schmidt orthonormalization process to the vectors f_1, f_2 . We then have an adapted orthonormal moving frame X_1, X_2, X_3 on \mathbb{R}^2 , and if we also consider X_i as a column vector, then $\alpha_f = (X_1, X_2, X_3): \mathbb{R}^2 \rightarrow SO(3)$ is the desired map. Notice that we can reconstruct f_1, f_2 from X_1, X_2 when we are also given the functions g_{ij} .

To find $\alpha_f^*(\omega^i)$, where the ω^i are a basis for the left invariant 1-forms on $SO(3)$, we look at the entries of the matrix of 1-forms

$$a = \alpha_f^{-1} \cdot d\alpha_f, \quad \text{with} \quad d\alpha_f = \alpha_f \cdot a.$$

This equation means that

$$(dX_1, dX_2, dX_3) = (X_1, X_2, X_3) \begin{pmatrix} 0 & -a_{21} & -a_{31} \\ a_{21} & 0 & -a_{32} \\ a_{31} & a_{32} & 0 \end{pmatrix},$$

where the a_{ij} are 1-forms, and the X_i and dX_i are considered as column vectors; the latter equation stands for

$$dX_1 = a_{21}X_2 + a_{31}X_3, \quad \text{etc.}$$

Thus, if ∇' denotes the covariant differentiation in \mathbb{R}^3 , we have

$$\nabla'_X X_1 = dX_1(X) = a_{21}(X)X_2 + a_{31}(X)X_3, \quad \text{etc.}$$

But

$$\nabla'_X X_1 = \omega_1^2(X) \cdot X_2 + \psi_1^3(X) \cdot X_3, \quad \text{etc.}$$

(where $\omega_1^2, \psi_1^3, \psi_2^3$ really denote f^* of the corresponding forms on image f). Thus we see that

The forms $\omega_1^2, \psi_1^3, \psi_2^3$ are precisely $\alpha_f^(\omega^i)$ for ω^i a basis of the left invariant 1-forms on $\text{SO}(3)$.*

Theorem I.10-18 then tells us that for two immersions $f, \bar{f}: \mathbb{R}^2 \rightarrow \mathbb{R}^3$, the maps $\alpha_f, \alpha_{\bar{f}}: \mathbb{R}^2 \rightarrow \text{SO}(3)$ differ by an element of $\text{SO}(3)$ if and only if

$$\bar{\omega}_1^2 = \omega_1^2, \quad \bar{\psi}_1^3 = \psi_1^3, \quad \bar{\psi}_2^3 = \psi_2^3;$$

here the forms $\omega_1^2, \psi_1^3, \psi_2^3$ are formed for the moving frame $X_1, X_2, X_3 = N$, where X_1, X_2 are obtained by applying the Gram-Schmidt orthonormalization process to f_1, f_2 , while the forms $\bar{\omega}_1^2, \bar{\psi}_1^3, \bar{\psi}_2^3$ are formed for the moving frame $\bar{X}_1, \bar{X}_2, \bar{X}_3 = \bar{N}$, where \bar{X}_1, \bar{X}_2 are obtained by applying the Gram-Schmidt orthonormalization process to \bar{f}_1, \bar{f}_2 .

From this fact we can easily derive the first part of the Fundamental Theorem of Surface Theory. For if $\bar{g}_{ij} = g_{ij}$, then \bar{X}_1, \bar{X}_2 are the same linear combination of \bar{f}_1, \bar{f}_2 as X_1, X_2 are of f_1, f_2 . Consequently, if we are also given that $\bar{l}_{ij} = l_{ij} \implies \bar{\Pi}(\bar{f}_i, \bar{f}_j) = \Pi(f_i, f_j)$, then we conclude that $\bar{\Pi}(\bar{X}_i, \bar{X}_j) = \Pi(X_i, X_j)$. The formulas on page 69 then show that $\bar{\psi}_1^3 = \psi_1^3$ and $\bar{\psi}_2^3 = \psi_2^3$, while the equation $\bar{\omega}_1^2 = \omega_1^2$ follows from $\bar{g}_{ij} = g_{ij}$. Thus $\alpha_f, \alpha_{\bar{f}}: \mathbb{R}^2 \rightarrow \text{SO}(3)$ differ by an element of $\text{SO}(3)$; this implies that $(f_1, f_2, N), (\bar{f}_1, \bar{f}_2, \bar{N})$ differ by an element of $\text{SO}(3)$, and hence that f, \bar{f} differ by a special orthogonal affine map of \mathbb{R}^3 .

In the case of curves, the equations of structure of $\text{SO}(n)$ or $\text{SL}(n, \mathbb{R})$ could not give any interesting information, since there are no non-zero 2-forms on \mathbb{R} . But they do give information for surfaces. To figure out the equations of structure of $\text{SO}(3)$, we proceed as follows. Since the Lie algebra

$$\mathfrak{o}(3) = \{\text{tangent space of } \text{SO}(3) \text{ at } I\}$$

is just the set of skew-symmetric 3×3 matrices, the matrices

$$X_1 = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad X_2 = \begin{pmatrix} 0 & 0 & -1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \quad X_3 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}$$

are a basis for $\mathfrak{o}(3)$. The bracket operation in $\mathfrak{o}(3)$ is (pp. I.378–379)

$$[M, N] = MN - NM.$$

In particular, we compute that

$$[X_1, X_2] = X_3, \quad [X_1, X_3] = -X_2, \quad [X_2, X_3] = X_1,$$

so that if we write

$$[X_i, X_j] = \sum_{k=1}^3 C_{ij}^k X_k,$$

then the “constants of structure” C_{ij}^k are

$$\begin{array}{lll} C_{12}^1 = 0 & C_{12}^2 = 0 & C_{12}^3 = 1 \\ C_{13}^1 = 0 & C_{13}^2 = -1 & C_{13}^3 = 0 \\ C_{23}^1 = 1 & C_{23}^2 = 0 & C_{23}^3 = 0. \end{array}$$

Now let ω^i be the left invariant 1-forms on $\mathfrak{o}(3)$ with $\omega^1(I)$, $\omega^2(I)$, $\omega^3(I)$ dual to X_1 , X_2 , X_3 . The equation on pg. I.396 (which is equivalent to the “equations of structure” on pg. I.404) then gives

$$\begin{aligned} d\omega^1 &= -\omega^2 \wedge \omega^3 \\ d\omega^2 &= \omega^1 \wedge \omega^3 \\ d\omega^3 &= -\omega^1 \wedge \omega^2. \end{aligned}$$

Now we have seen that if $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ is an immersion, then the forms ω_1^2 , ψ_1^3 , ψ_2^3 for f are given by

$$\begin{aligned} \omega_1^2 &= \alpha_f^*(\omega^1) \\ \psi_1^3 &= \alpha_f^*(\omega^2) \\ \psi_2^3 &= \alpha_f^*(\omega^3). \end{aligned}$$

Therefore

$$\begin{aligned} d\omega_1^2 &= \alpha_f^*(d\omega^1) = -\alpha_f^*(\omega^2 \wedge \omega^3) = -\psi_1^3 \wedge \psi_2^3 \\ d\psi_1^3 &= \alpha_f^*(d\omega^2) = -\alpha_f^*(\omega^1 \wedge \omega^3) = \omega_1^2 \wedge \psi_2^3 \\ d\psi_2^3 &= \alpha_f^*(d\omega^3) = -\alpha_f^*(\omega^1 \wedge \omega^2) = -\omega_1^2 \wedge \psi_1^3. \end{aligned}$$

As promised, these are precisely the Gauss Equation and Codazzi-Mainardi Equations, in the form given on pages 69–70. The reader can now easily see that the second part of the Fundamental Theorem of Surface Theory follows immediately from Theorem I.10-17.

For the remainder of this chapter* we will be considering the special affine theory of surfaces $M \subset \mathbb{R}^3$. If we try to follow the approach used for ordinary surface theory, then instead of working with an adapted moving frame X_1, X_2, ν on M which is orthonormal, we want to work with an adapted moving frame X_1, X_2, X_3 on M with $\det(X_1, X_2, X_3) = 1$. If $f: U \rightarrow M$ is an immersion (for $U \subset \mathbb{R}^2$ open), then you might think that we should use the moving frame

$$(af_1, af_2, aN), \quad \text{where} \quad a = \frac{1}{\sqrt[3]{\det(f_1, f_2, N)}}.$$

But this moving frame has no significance for special affine geometry, for it is not a “special affine invariant”: if $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is special linear affine, then the normal $N_{A \circ f}$ for $A \circ f$ is not necessarily the image $A_*(N_f)$ of the normal N_f for f . As a matter of fact, not only the length, but even the direction of $A_*(N_f)$ will be wrong; the whole concept of “orthogonality” has no meaning in special affine geometry. Our first problem, therefore, is to pick out a “special affine normal” for M which is a special affine invariant. This is going to take quite a bit of doing.

In ordinary surface theory, the normal $\nu(p)$ is defined in terms of the tangent plane M_p of M , which is the first order surface which approximates M up to order 1 at p . Since special affine geometry always seems to involve higher order approximations to our given geometric object, we might expect to find a reasonable candidate for the special affine normal by looking at the second order approximation to our surface. As before, let us assume that $p = 0 \in \mathbb{R}^3$ and that the tangent plane at p is the (x, y) -plane, so that M is the graph of a function $h: \mathbb{R}^2 \rightarrow \mathbb{R}$ with $h(0, 0) = h_1(0, 0) = h_2(0, 0) = 0$. The quadratic surface approximating M up to order 2 at 0 is

$$P = \left\{ (s, t, \frac{1}{2}(h_{11}(0, 0) \cdot s^2 + 2h_{12}(0, 0) \cdot st + h_{22}(0, 0) \cdot t^2)) \right\}.$$

We have already seen that this surface does not depend on the particular choice of a basis in \mathbb{R}^2 : if $\mathbf{X} = X_1, X_2$ is any basis of \mathbb{R}^2 and $h^{\mathbf{X}}(s, t)$ is the third coordinate of the point of M lying above $sX_1 + tX_2$, then the surface

$$Q = \left\{ (sX_1 + tX_2, \frac{1}{2}(h^{\mathbf{X}}_{11}(0, 0) \cdot s^2 + 2h^{\mathbf{X}}_{12}(0, 0) \cdot st + h^{\mathbf{X}}_{22}(0, 0) \cdot t^2)) \right\}$$

is exactly the same as P . We also noted that we still have $Q = P$ when we change the direction of the z -axis; it is just as easy to see that $Q = P$ even when we change the *unit* on the z -axis, so that we are describing M in terms of the “ $X_1, X_2, (0, 0, c)$ coordinate system”.

*This material will not be needed later, except in Problem 4-16. Problems for this chapter are on page 134.

In all this arbitrariness, however, one essential prejudice of ordinary geometry remains: we have always picked the third axis perpendicular to the plane of the first two. Suppose now that we choose X_1, X_2 in \mathbb{R}^2 and a linearly independent vector X_3 which does not necessarily point along the z -axis. We can

still describe M as a graph in terms of the “ (X_1, X_2, X_3) coordinate system”: we let $\tilde{h}(s, t)$ be the X_3 component of the point of M with $s = X_1$ component and $t = X_2$ component. Now we look at the surface

$$Q = \{sX_1 + tX_2 + \frac{1}{2}(\tilde{h}_{11}(0, 0) \cdot s^2 + 2\tilde{h}_{12}(0, 0) \cdot st + \tilde{h}_{22}(0, 0) \cdot t^2)X_3\}.$$

This surface is *not* the same surface as P . In fact, consider the case where $X_3 = (0, 0, 1) + \lambda X_1 + \mu X_2$ for certain numbers λ, μ . To say that M is the graph of h in the $X_1, X_2, (0, 0, 1)$ system means that

$$(1) \quad M = \{sX_1 + tX_2 + h(s, t) \cdot (0, 0, 1)\} \quad [h_\alpha(0, 0) = 0];$$

similarly, if M is the graph of \tilde{h} in the X_1, X_2, X_3 system, then

$$(2) \quad \begin{aligned} M &= \{sX_1 + tX_2 + \tilde{h}(s, t)X_3\} \\ &= \{[s + \lambda\tilde{h}(s, t)]X_1 + [t + \mu\tilde{h}(s, t)]X_2 + \tilde{h}(s, t) \cdot (0, 0, 1)\} \\ &\quad [\tilde{h}_\alpha(0, 0) = 0]. \end{aligned}$$

Comparing (1) and (2) we find that

$$\tilde{h}(s, t) = h(s + \lambda\tilde{h}(s, t), t + \mu\tilde{h}(s, t)).$$

From this we easily compute that $\tilde{h}_{\alpha\beta}(0, 0) = h_{\alpha\beta}(0, 0)$, so that the approximating functions of s and t

$$\begin{aligned} &\tilde{h}_{11}(0, 0)s^2 + 2\tilde{h}_{12}(0, 0)st + \tilde{h}_{22}(0, 0)t^2 \\ &h_{11}(0, 0)s^2 + 2h_{12}(0, 0)st + h_{22}(0, 0)t^2 \end{aligned}$$

are the same; this means that the approximating *surfaces*

$$\begin{aligned} P &= \{(sX_1 + tX_2, \tfrac{1}{2}(h_{11}(0,0)s^2 + 2h_{12}(0,0)st + h_{22}(0,0)t^2))\} \\ Q &= \{sX_1 + tX_2 + \tfrac{1}{2}(\tilde{h}_{11}(0,0)s^2 + 2\tilde{h}_{12}(0,0)st + \tilde{h}_{22}(0,0)t^2)X_3\} \\ &= \{sX_1 + tX_2 + \tfrac{1}{2}(h_{11}(0,0)s^2 + 2h_{12}(0,0)st + h_{22}(0,0)t^2)X_3\} \end{aligned}$$

are definitely different. In fact, we clearly have

$$Q = A(P),$$

where $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is the affine map which keeps M_p fixed and takes $(0, 0, 1)$ to X_3 . All we can say is that Q does not change when we multiply X_3 by a constant, just as P does not change when we multiply $(0, 0, 1)$ by a constant; we can merely speak of the osculating paraboloid corresponding to any given line through p which does not lie in M_p .

Thus we see that we do not get a special affine invariant osculating paraboloid simply by looking at M up to order 2. There are some things that we do get, however. Consider first a fixed basis X_1, X_2 for $M_p = (x, y)$ -plane. We have just seen that the matrices

$$S = \begin{pmatrix} h_{11}(0,0) & h_{12}(0,0) \\ h_{21}(0,0) & h_{22}(0,0) \end{pmatrix} \quad \text{and} \quad S' = \begin{pmatrix} \tilde{h}_{11}(0,0) & \tilde{h}_{12}(0,0) \\ \tilde{h}_{21}(0,0) & \tilde{h}_{22}(0,0) \end{pmatrix},$$

defined in terms of the third axes $(0, 0, 1)$ and $X_3 = (0, 0, 1) + \lambda X_1 + \mu X_2$, respectively, are exactly the same; if we had picked X_3 to be the most general possible choice, $X_3 = (0, 0, c) + \lambda X_1 + \mu X_2$, then S' would clearly be

$$S' = \frac{1}{c} \cdot S.$$

On the other hand, suppose we consider the coordinate system

$$a_{11}X_1 + a_{21}X_2, \quad a_{12}X_1 + a_{22}X_2, \quad (0, 0, 1).$$

Equation (*) on page 37 shows that the matrix S' in this case is related to the matrix S by

$$S' = A^t S A, \quad A = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix},$$

where t denotes the transpose. In general, if we are given any two bases (X_1, X_2, X_3) and (X'_1, X'_2, X'_3) of \mathbb{R}^3_p , with X_1, X_2 and X'_1, X'_2 bases for M_p , and

$$X'_3 = cX_3 + \lambda X_1 + \mu X_2,$$

then the matrices S and S' are related by

$$(1) \quad S' = \frac{1}{c} \cdot A^t S A,$$

where $A = (a_{ij})$ is given by

$$(2) \quad X'_i = \sum_{j=1}^2 a_{ji} X_j.$$

From equation (1) we see that

$$\det S' \gtrless 0 \iff \det S \gtrless 0 \quad \text{and} \quad S' = 0 \iff S = 0.$$

Thus we can determine whether p is an elliptic, hyperbolic, parabolic, or planar, point of M by means of an arbitrary basis (X_1, X_2, X_3) of \mathbb{R}^3_p with $X_1, X_2 \in M_p$. This clearly implies that the “type” of a point (elliptic, hyperbolic, parabolic, or planar) is a “general affine invariant”: If $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is any affine map and $M \subset \mathbb{R}^3$ is a surface, then $A(p)$ is the same type of point on $A(M)$ as p is on M .

Consider, for the time being, an elliptic point $p \in M$. As we observed in the proof of Theorem 11, there is a natural orientation for M_p , the one that makes an ordered basis (X_1, X_2) of M_p positively oriented whenever (X_1, X_2, X_3) is positively oriented in \mathbb{R}^3_p for any $X_3 \in \mathbb{R}^3_p$ which points “inward” (that is, in the direction of the osculating paraboloid). Now any basis $X_1, X_2, X_3 \in \mathbb{R}^3_p$ with $X_1, X_2 \in M_p$ determines a matrix $S = (s_{ij})$, and we can use S to define an inner product on M_p by

$$\langle X_i, X_j \rangle = s_{ij};$$

this inner product is positive definite if and only if X_3 is inward pointing. If X_1, X_2, X_3 happens to be orthonormal, then the inner product is just the second fundamental form II of ordinary surface theory. Now consider another basis X'_1, X'_2, X'_3 , with X'_3 inward pointing. This determines a matrix S' , and hence another positive definite inner product $\langle \cdot, \cdot \rangle'$ on M_p by

$$\langle X'_i, X'_j \rangle' = s'_{ij}.$$

Equation (1) shows that the inner products $\langle \cdot, \cdot \rangle$ and $\langle \cdot, \cdot \rangle'$ are closely related. Indeed,

$$\begin{aligned} \langle X'_i, X'_j \rangle' &= s'_{ij} = (\text{constant}) \cdot \sum_{k,l} a_{ki} s_{kl} a_{lj} \\ &= (\text{constant}) \cdot \sum_{k,l} a_{ki} a_{lj} \langle X_k, X_l \rangle \\ &= (\text{constant}) \cdot \left\langle \sum_k a_{ki} X_k, \sum_l a_{lj} X_l \right\rangle \\ &= (\text{constant}) \cdot \langle X'_i, X'_j \rangle \quad \text{by (2),} \end{aligned}$$

so that we have

$$\langle \cdot, \cdot \rangle' = (\text{constant}) \cdot \langle \cdot, \cdot \rangle.$$

By restricting our attention to inward pointing X_3 , we thus obtain a class of positive definite inner products on M_p , any one being a (positive) constant multiple of any other. We can express this by saying that we have defined a “conformal structure” on M_p (compare pg. II.296). This conformal structure is invariant under all affine maps, provided only that they are orientation preserving: If $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is any orientation preserving affine map and $p \in M \subset \mathbb{R}^3$ is an elliptic point, then the class of inner products defined on M_p is precisely A^* of the class of inner products defined on the tangent space $A(M)_{A(p)}$ of $A(M)$ at $A(p)$.

A conformal structure on M_p does not allow us to pick out orthonormal bases, but it does make sense to consider bases X_1, X_2 of M_p with

$$\langle X_i, X_j \rangle = (\text{constant} > 0) \cdot \delta_{ij},$$

since this condition does not depend on the choice of the inner product $\langle \cdot, \cdot \rangle$ in our conformal structure. Such bases may be called “quasi-orthonormal”. They can clearly be characterized quite simply as follows: for any inward pointing vector $X_3 \in \mathbb{R}^3_p$, the corresponding osculating paraboloid P is given by

$$P = \{sX_1 + tX_2 + (\text{constant} > 0) \cdot (s^2 + t^2) \cdot X_3\}.$$

These considerations can be made in a less geometric way, but with the calculations going through more smoothly, by using moving frames. For an adapted moving frame X_1, X_2, X_3 on a surface $M \subset \mathbb{R}^3$ we will still use the dual and connection forms ϕ^α and ψ^α_β for moving frames in \mathbb{R}^3 , and we again let θ^1, θ^2

be the dual forms determined by the moving frame X_1, X_2 on M . As in ordinary surface theory, we have

$$\begin{aligned}\phi^i &= \theta^i & \text{on } TM & \quad i = 1, 2 \\ \phi^3 &= 0 & \text{on } TM;\end{aligned}$$

moreover the first structural equation,

$$d\phi^3 = - \sum_{\gamma=1}^3 \psi_\gamma^3 \wedge \phi^\gamma,$$

still implies that

$$0 = \sum_{k=1}^2 \theta^k \wedge \psi_k^3 \quad \text{on } TM,$$

so that by Cartan's Lemma there is a matrix $S = (s_{ij})$ with

$$\begin{aligned}\text{(a)} \quad \psi_j^3 &= \sum_{i=1}^2 s_{ij} \theta^i & \text{on } TM \\ s_{ij} &= s_{ji}.\end{aligned}$$

We will soon be able to compare this matrix S with the one defined previously. First we want to consider another adapted moving frame X'_1, X'_2, X'_3 on M . The matrix a with $X'_\alpha = \sum_\beta a_{\beta\alpha} X_\beta$ must be of the form

$$a = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ 0 & 0 & a_{33} \end{pmatrix},$$

and we easily find that

$$\text{(b)} \quad (a^{-1})_{3i} = 0 \quad i = 1, 2; \quad (a^{-1})_{33} = \frac{1}{a_{33}}.$$

The dual forms ϕ'^α for the X'_α are given by (see pg. II. 282)

$$\begin{aligned}\text{(c)} \quad \phi' &= a^{-1} \phi \implies \phi = a \cdot \phi' \\ &\implies \theta^i = \sum_{j=1}^2 a_{ij} \theta'^j,\end{aligned}$$

while the connection forms ψ'^α_β are related to the ψ^α_β by (pg. II.280)

$$(d) \quad \psi' = a^{-1} da + a^{-1} \psi a.$$

In particular,

$$\begin{aligned} \psi'^3_i &= (a^{-1} da)_{3i} + (a^{-1} \psi a)_{3i} \\ &= \sum_{\alpha=1}^3 (a^{-1})_{3\alpha} da_{\alpha i} + \sum_{\alpha, \beta=1}^3 (a^{-1})_{3\alpha} \psi^\alpha_\beta a_{\beta i} \\ &= 0 + \sum_{j=1}^2 \frac{1}{a_{33}} \psi^3_j a_{ji} \quad \text{by (b).} \end{aligned}$$

Hence

$$\begin{aligned} \psi'^3_i &= \frac{1}{a_{33}} \sum_{j,k} a_{ji} s_{jk} \theta^k \\ &= \frac{1}{a_{33}} \sum_{j,k,l} a_{ji} s_{jk} a_{kl} \theta'^l. \end{aligned}$$

So if we also write

$$\psi'^3_j = \sum_{i=1}^2 s'_{ij} \theta'^i, \quad s'_{ij} = s'_{ji},$$

then the matrix S' is related to the matrix S by

$$(e) \quad S' = \frac{1}{a_{33}} A^t S A,$$

where A is the 2×2 matrix $A = (a_{ij})$.

As a first consequence of this equation we see, what is not *a priori* clear, that

The matrix $S(p)$ depends only on the vectors $X_1(p), X_2(p), X_3(p)$.

Taking X_3 to be a parallel vector field in \mathbb{R}^3 , we easily see that $S(p)$ is, in fact, the same as the matrix S on page 77, for the basis $X_1(p), X_2(p), X_3(p)$ of \mathbb{R}^3_p . Then equation (e) is just equation (l) on page 78. As before, we then see from equation (e) that if p is an elliptic point, then the inner product

$$\sum_{i,j} s_{ij}(p) \cdot \theta^i(p) \otimes \theta^j(p)$$

on M_p is well-defined up to constant multiple, and hence, by considering only the case where $X_3(p)$ is inward pointing, we again obtain the (general orientation preserving affine invariant) conformal structure on M_p . Clearly the basis X_1, X_2 of M_p is quasi-orthonormal [that is, $\langle X_i(p), X_j(p) \rangle = (\text{constant} > 0) \cdot \delta_{ij}$] if and only if

$$S(p) = (\text{constant} > 0) \cdot \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \text{or} \quad \psi_i^3(p) = (\text{constant} > 0) \cdot \theta^i(p).$$

Now from among our class of inner products on M_p we can distinguish a particular one $\langle \cdot, \cdot \rangle_p$, which will be a special affine invariant. We do this by defining $X_1, X_2 \in M_p$ to be **orthonormal with respect to** $\langle \cdot, \cdot \rangle_p$ if and only if

$$(*) \quad S(p) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \text{for all inward pointing } X_3 \in \mathbb{R}^3_p \text{ with } \det(X_1, X_2, X_3) = \pm 1$$

(the sign depending on whether or not (X_1, X_2) is positively oriented). To check that this is well-defined, note first that if we also have

$$\det(X_1, X_2, X'_3) = \pm 1$$

for an inward pointing X'_3 , then clearly $a_{33}(p) = 1$, so equation (e) shows that $S'(p) = S(p)$; consequently, condition (*) does not depend on the choice of X_3 . Moreover, for fixed $X_3 \in \mathbb{R}^3_p$, and different $X'_1, X'_2 \in M_p$, equation (e) shows that $S' = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ if and only if $A^t A = I$, which means that X'_1, X'_2 is related to X_1, X_2 by the orthogonal transformation A ; hence the inner product which makes X_1, X_2 orthonormal also makes X'_1, X'_2 orthonormal. It should be clear, from the very definition, that $\langle \cdot, \cdot \rangle_p$ is a special affine invariant: If $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is special linear affine, and $p \in M$ is an elliptic point, then the inner product $\langle \cdot, \cdot \rangle_p$ on M_p is A^* of the inner product $\langle \cdot, \cdot \rangle_{A(p)}$ on the tangent space $A(M)_{A(p)}$ of $A(M)$ at $A(p)$. Clearly a basis $X_1, X_2 \in M_p$ is orthonormal with respect to $\langle \cdot, \cdot \rangle_p$ if and only if

$$\psi_i^3(p) = \theta^i(p) \quad \text{or} \quad P = \{sX_1 + tX_2 + \frac{1}{2}(s^2 + t^2)X_3\}$$

for every inward pointing $X_3 \in \mathbb{R}^3_p$ with $\det(X_1, X_2, X_3) = \pm 1$.

On a surface M with all points elliptic, we now have an inner product $\langle \cdot, \cdot \rangle_p$ defined on each M_p , and thus we have a Riemannian metric $\langle \cdot, \cdot \rangle$ on M . This Riemannian metric will also be denoted by \mathbb{I} , and called the **special affine first fundamental form** of M . If it seems strange that we can find a special affine invariant metric on elliptically curved surfaces in \mathbb{R}^3 even though there is clearly

no special affine invariant metric on \mathbb{R}^3 itself, it might help to observe that we have essentially the same situation for 1-dimensional manifolds M in \mathbb{R}^3 , for we can define the unit tangent vectors of M to be those of the form $c'(\sigma)$, where $c: [0, 1] \rightarrow M$ is a curve parameterized by special affine arclength. Once again the manifold M cannot be too flat (and in fact the requisite condition is more stringent, since it involves third derivatives). Naturally, if $f: M \rightarrow \mathbb{R}^3$ is an immersion with all points of the image elliptic, then we define the **special affine first fundamental form** \mathcal{I}_f of f to be the tensor $\mathcal{I}_f = f^*(\langle \cdot, \cdot \rangle)$ on M , where $\langle \cdot, \cdot \rangle$ is the special affine first fundamental form on $f(M)$. Notice that this is not completely analogous to the definition in ordinary surface theory, where we can simply define $\mathcal{I}_f = f^*\langle \cdot, \cdot \rangle$ for $\langle \cdot, \cdot \rangle$ the usual Riemannian metric on \mathbb{R}^3 ; it is much closer to the definition of \mathcal{II}_f . In fact, we have already noted that $\langle \cdot, \cdot \rangle_p$ is a multiple of $\mathcal{II}(p)$; just which multiple will soon be determined.

When $f: U \rightarrow \mathbb{R}^3$ for $U \subset \mathbb{R}^2$ open, and all points of $f(U)$ are elliptic, we define the functions $g_{ij}: U \rightarrow \mathbb{R}$ to be the components of \mathcal{I}_f with respect to the standard coordinate system (s, t) on \mathbb{R}^2 , so that

$$\mathcal{I}_f = g_{11} ds \otimes ds + g_{12} ds \otimes dt + g_{21} dt \otimes ds + g_{22} dt \otimes dt.$$

We would naturally like to be able to compute the g_{ij} in terms of f . We first take the case where f is simply

$$f(s, t) = (s, t, h(s, t)), \quad h(0, 0) = h_1(0, 0) = h_2(0, 0) = 0,$$

with $p = f(0, 0) = 0 \in \mathbb{R}^3$. If $X_1, X_2, X_3 \in \mathbb{R}^3_0$ is the standard basis, then the corresponding osculating paraboloid P is the graph of

$$(s, t) \mapsto \frac{1}{2}(\alpha s^2 + 2\beta st + \gamma t^2) \quad \text{for} \quad \begin{cases} \alpha = h_{11}(0, 0) \\ \beta = h_{12}(0, 0) \\ \gamma = h_{22}(0, 0). \end{cases}$$

If p is an elliptic point, then $\alpha\gamma - \beta^2 > 0$. For the sake of concreteness, suppose also that P lies above the (x, y) -plane, so that X_3 is inward pointing. There is another basis $X'_j = \sum_{i=1}^2 a_{ij} X_i$ of \mathbb{R}^2 such that P is the graph of

$$(s, t) \mapsto \frac{1}{2}(s^2 + t^2)$$

in the X'_1, X'_2, X_3 system. Equation (l) on page 78 (or equation (e) on page 81) shows that the matrix $A = (a_{ij})$ satisfies

$$\begin{aligned} (1) \quad A^t \cdot \frac{1}{2} \begin{pmatrix} \alpha & \beta \\ \beta & \gamma \end{pmatrix} \cdot A &= \frac{1}{2} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \implies \begin{pmatrix} \alpha & \beta \\ \beta & \gamma \end{pmatrix} = (A^t)^{-1} A^{-1} \\ &\implies \det A = (\alpha\gamma - \beta^2)^{-1/2}. \end{aligned}$$

Now P is also the graph of $(s, t) \mapsto \frac{1}{2}(s^2 + t^2)$ in the $(\lambda X'_1, \lambda X'_2, \lambda^2 X_3)$ coordinate system. In order to have

$$\begin{aligned} 1 &= \det(\lambda X'_1, \lambda X'_2, \lambda^2 X_3) = \lambda^4 \det(X'_1, X'_2, X_3) \\ &= \lambda^4 \cdot \det A = \lambda^4 (\alpha\gamma - \beta^2)^{-1/2}, \end{aligned}$$

we must take

$$\lambda = \sqrt[8]{\alpha\gamma - \beta^2}.$$

So the vectors

$$X''_1 = (\sqrt[8]{\alpha\gamma - \beta^2}) X'_1, \quad X''_2 = (\sqrt[8]{\alpha\gamma - \beta^2}) X'_2$$

are orthonormal with respect to $\langle \cdot, \cdot \rangle_0$. To figure out the numbers $g_{ij}(0, 0)$, we note that if $B = (b_{ij})$ is the inverse of the matrix A , then

$$X_i = \sum_{j=1}^2 b_{ji} X'_j = \frac{1}{\sqrt[8]{\alpha\gamma - \beta^2}} \sum_{j=1}^2 b_{ji} X''_j,$$

and consequently

$$\begin{aligned} g_{ij}(0, 0) &= \langle X_i, X_j \rangle_0 = \frac{1}{\sqrt[4]{\alpha\gamma - \beta^2}} \left\langle \sum_{k=1}^2 b_{ki} X''_k, \sum_{k=1}^2 b_{kj} X''_k \right\rangle_0 \\ &= \frac{1}{\sqrt[4]{\alpha\gamma - \beta^2}} \sum_{k=1}^2 b_{ki} b_{kj} \\ &= \frac{1}{\sqrt[4]{\alpha\gamma - \beta^2}} (B^t B)_{ij} = \frac{1}{\sqrt[4]{\alpha\gamma - \beta^2}} ((A^t)^{-1} A^{-1})_{ij}. \end{aligned}$$

Using (1), we see that

$$(2) \quad g_{ij}(0, 0) = \frac{h_{ij}(0, 0)}{\sqrt[4]{\det(h_{ij}(0, 0))}}.$$

This can also be written

$$(3) \quad g_{ij}(0, 0) = \frac{d_{ij}}{\sqrt[4]{\det(d_{ij})}}(0, 0),$$

where $d_{ij} = \det(f_1, f_2, f_{ij})$.

These calculations were all carried out for the case where f is of the form $f(s, t) = (s, t, h(s, t))$, with $h(0, 0) = h_1(0, 0) = h_2(0, 0) = 0$. We could try to

deal with the general map $f: U \rightarrow \mathbb{R}^3$ by reducing it to this case. For example, if $f_1(0,0)$ and $f_2(0,0)$ both lie in the (x, y) -plane, we could first determine a function h by the condition

$$\begin{aligned} \{(f^1(s, t), f^2(s, t), f^3(s, t))\} &= f(U) = \{(s, t, h(s, t))\} \\ \implies h(f^1(s, t), f^2(s, t)) &= f^3(s, t), \end{aligned}$$

use this equation to relate the $h_{ij}(0,0)$ to the $f_i(0,0)$ and $f_{ij}(0,0)$, and then use (2) to find $g_{ij}(0,0)$ in terms of these numbers (we would still have to take care of the general case when $f_1(0,0)$ and $f_2(0,0)$ do not lie in \mathbb{R}^2). A much simpler course of action is to guess from (3) that the answer should be

$$\begin{aligned} \mathfrak{I}_f &= \frac{d_{11} ds \otimes ds + d_{12} ds \otimes dt + d_{21} dt \otimes ds + d_{22} dt \otimes dt}{\sqrt[4]{\det(d_{ij})}} \\ &= \frac{1}{\sqrt[4]{\det(d_{ij})}} \sum_{i,j=1}^2 d_{ij} ds^i \otimes ds^j, \quad \text{using } (s^1, s^2) \text{ for } (s, t). \end{aligned}$$

Now this guess cannot be precisely correct, for if we define $\tilde{f}(s^1, s^2) = f(s^2, s^1)$, then we have $\tilde{d}_{ij}(s^1, s^2) = \det(\tilde{f}_1, \tilde{f}_2, \tilde{f}_{12})(s^1, s^2) = \det(f_2, f_1, f_{12})(s^2, s^1) = -d_{ij}(s^2, s^1)$, so our formula changes sign. The problem, of course, is that \tilde{f} is orientation reversing if f is orientation preserving. The right guess is that the above formula holds whenever $f: U \rightarrow M$ is orientation preserving. To prove this, we note first that the right side is clearly a special affine invariant, since it involves only determinants d_{ij} ; consequently, there is no loss of generality in assuming that the tangent plane at the point in question is the (x, y) -plane. We still based our calculations on a very special parameterization, so we want to check that the right side is “invariant under orientation preserving change of parameter”: if $f: U \rightarrow \mathbb{R}^3$ is any immersion (for $U \subset \mathbb{R}^2$ open), and $p = (p^1, p^2): V \rightarrow U$ is an orientation preserving diffeomorphism (for $V \subset \mathbb{R}^2$ open), then we want to check that

$$(4) \quad p^* \left(\frac{1}{\sqrt[4]{\det(d_{ij})}} \sum_{i,j=1}^2 d_{ij} ds^i \otimes ds^j \right) = \frac{1}{\sqrt[4]{\det(\tilde{d}_{ij})}} \sum_{i,j=1}^2 \tilde{d}_{ij} ds^i \otimes ds^j,$$

where the \tilde{d}_{ij} are the d_{ij} for $\tilde{f} = f \circ p$.

Now

$$\begin{aligned}
 (5) \quad p^* \left(\sum_{i,j=1}^2 d_{ij} ds^i \otimes ds^j \right) &= \sum_{i,j=1}^2 (d_{ij} \circ p) \left(\sum_{\rho=1}^2 p^i_{\rho} ds^{\rho} \right) \otimes \left(\sum_{\sigma=1}^2 p^j_{\sigma} ds^{\sigma} \right) \\
 &= \sum_{i,j=1}^2 \sum_{\rho,\sigma=1}^2 p^i_{\rho} p^j_{\sigma} (d_{ij} \circ p) ds^{\rho} \otimes ds^{\sigma} \\
 &= \sum_{i,j=1}^2 \left(\sum_{\rho,\sigma=1}^2 p^{\rho}_i p^{\sigma}_j (d_{\rho\sigma} \circ p) \right) ds^i \otimes ds^j.
 \end{aligned}$$

On the other hand, since

$$\begin{aligned}
 \tilde{f}_i &= D_i(f \circ p) = \sum_{\rho=1}^2 p^{\rho}_i (f_{\rho} \circ p) \\
 \tilde{f}_{ij} &= \sum_{\rho=1}^2 p^{\rho}_{ij} (f_{\rho} \circ p) + \sum_{\rho,\sigma=1}^2 p^{\rho}_i p^{\sigma}_j (f_{\rho\sigma} \circ p),
 \end{aligned}$$

we have

$$\begin{aligned}
 (6) \quad \tilde{d}_{ij} &= \det(\tilde{f}_1, \tilde{f}_2, \tilde{f}_{ij}) \\
 &= \det \left(\sum_{\mu=1}^2 (f_{\mu} \circ p) \cdot p^{\mu}_1, \sum_{v=1}^2 (f_v \circ p) \cdot p^v_2, \right. \\
 &\quad \left. \sum_{\rho,\sigma=1}^2 p^{\rho}_i p^{\sigma}_j (f_{\rho\sigma} \circ p) + \sum_{\rho=1}^2 p^{\rho}_{ij} (f_{\rho} \circ p) \right) \\
 &= \det \left(\sum_{\mu=1}^2 (f_{\mu} \circ p) \cdot p^{\mu}_1, \sum_{v=1}^2 (f_v \circ p) \cdot p^v_2, \sum_{\rho,\sigma=1}^2 p^{\rho}_i p^{\sigma}_j (f_{\rho\sigma} \circ p) \right) \\
 &= \sum_{\mu,v=1}^2 p^{\mu}_1 p^v_2 \sum_{\rho,\sigma=1}^2 p^{\rho}_i p^{\sigma}_j \det(f_{\mu} \circ p, f_v \circ p, f_{\rho\sigma} \circ p) \\
 &= (\det p') \cdot \left[\sum_{\rho,\sigma=1}^2 p^{\rho}_i p^{\sigma}_j (d_{\rho\sigma} \circ p) \right],
 \end{aligned}$$

and consequently

$$(7) \quad \sum_{i,j=1}^2 \tilde{d}_{ij} ds^i \otimes ds^j = (\det p') \sum_{i,j=1}^2 \left(\sum_{\rho,\sigma=1}^2 p^{\rho}_i p^{\sigma}_j (d_{\rho\sigma} \circ p) \right) ds^i \otimes ds^j.$$

If it weren't for the factor $(\det p')$, the tensors in (5) and (7) would already be the same. From (6) we easily see that

$$(8) \quad \begin{aligned} \det(\tilde{d}_{ij}) &= (\det p')^4 \cdot \det(d_{ij} \circ p) \\ \implies \sqrt[4]{\det(\tilde{d}_{ij})} &= (\det p') \cdot \sqrt[4]{\det(d_{ij} \circ p)} \quad \text{for } \det p' > 0. \end{aligned}$$

Together with (7), this gives exactly the equation (4) which we want. We have thus shown that for orientation preserving $f: U \rightarrow M$ we always have

$$\begin{aligned} \mathfrak{I}_f &= \sum_{i,j=1}^2 g_{ij} ds^i \otimes ds^j \\ \text{for } g_{ij} &= \frac{d_{ij}}{\sqrt[4]{\det(d_{ij})}}, \quad d_{ij} = \det(f_1, f_2, f_{ij}). \end{aligned}$$

This formula allows us to compare the special affine first fundamental form \mathfrak{I}_f with the ordinary *second* fundamental form \mathbf{II}_f , whose coefficients l_{ij} are

$$\begin{aligned} l_{ij} &= \langle n, f_{ij} \rangle = \left\langle \frac{f_1 \times f_2}{|f_1 \times f_2|}, f_{ij} \right\rangle \\ &= \frac{\det(f_1, f_2, f_{ij})}{|f_1 \times f_2|} = \frac{d_{ij}}{\det(g_{ij})}. \end{aligned}$$

In the classical literature, the tensor \mathfrak{I}_f is introduced a little differently. One simply notes that $\sum_{i,j} d_{ij} ds^i \otimes ds^j$ is a nice tensor to consider, because it is a special affine invariant. Then one asks whether it is also an invariant under change of parameter. After deriving equation (7) one sees that it isn't, but upon noticing (8), one realizes that dividing by $\sqrt[4]{\det(d_{ij})}$ will give a tensor that is invariant under orientation preserving change of parameter, yet still a special affine invariant.

Now consider a hyperbolic point $p \in M$, and a basis $X_1, X_2, X_3 \in \mathbb{R}^3_p$ with $X_1, X_2 \in M_p$. This again determines a matrix $S = (s_{ij})$, and we can still define an inner product on M_p by

$$\langle X_i, X_j \rangle = s_{ij},$$

but now the inner product is merely non-degenerate, and neither positive definite nor negative definite. Any other such inner product, defined for a different basis, is a constant multiple of this one. If we want these constant multiples all to be positive, then we will have to have a way of selecting a permissible direction

for the vectors X_3 . So we have to choose, arbitrarily, an orientation for M_p , and then *define* X_3 to “point inward” if and only if (X_1, X_2, X_3) is positively oriented in \mathbb{R}^3_p whenever (X_1, X_2) is positively oriented in M_p . By considering only inward pointing X_3 we obtain a class of non-degenerate inner products on M_p , any one being a positive constant multiple of any other. If $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is any affine map and we give the tangent space $A(M)_{A(p)}$ the orientation which makes $A_*: M_p \rightarrow A(M)_{A(p)}$ orientation preserving, then the class of inner products on M_p is precisely A^* of the class of inner products on $A(M)_{A(p)}$.

In the present set-up it makes sense to consider ordered bases X_1, X_2 of M_p with

$$\begin{aligned}\langle X_1, X_1 \rangle &= -\langle X_2, X_2 \rangle = \text{constant} > 0 \\ \langle X_1, X_2 \rangle &= 0.\end{aligned}$$

These ordered bases will again be called “quasi-orthonormal”. For any such ordered basis, and any inward pointing $X_3 \in \mathbb{R}^3_p$, the corresponding osculating paraboloid P is given by

$$P = \{sX_1 + tX_2 + (\text{constant} > 0) \cdot (s^2 - t^2)X_3\}.$$

In terms of moving frames we have

$$S(p) = (\text{constant} > 0) \cdot \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad \text{or} \quad \begin{cases} \psi_1^3(p) = (\text{constant} > 0) \cdot \theta^1(p) \\ \psi_2^3(p) = -(\text{constant} > 0) \cdot \theta^2(p). \end{cases}$$

From among our class of inner products on M_p we can again distinguish a particular one $\langle \cdot, \cdot \rangle_p$. We define an ordered basis X_1, X_2 to be “orthonormal”,

$$\begin{aligned}\langle X_1, X_1 \rangle_p &= -\langle X_2, X_2 \rangle_p = 1 \\ \langle X_1, X_2 \rangle_p &= 0,\end{aligned}$$

if and only if $S(p) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ for all inward pointing $X_3 \in \mathbb{R}^3_p$ satisfying $\det(X_1, X_2, X_3) = 1$. The verification that this is well-defined is similar to the case of an elliptic point. If $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is a map of the form $A = T \circ B$, where T is a translation and $B: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is a linear map of determinant ± 1 , and we give the tangent space $A(M)_{A(p)}$ the orientation which makes $A_*: M_p \rightarrow A(M)_{A(p)}$ orientation preserving, then $\langle \cdot, \cdot \rangle_p$ is A^* of the inner product $\langle \cdot, \cdot \rangle_{A(p)}$ on $A(M)_{A(p)}$. Clearly an ordered basis (X_1, X_2) of M_p is orthonormal if and only if

$$\left. \begin{aligned} \psi_1^3(p) &= \theta^1(p) \\ \psi_2^3(p) &= -\theta^2(p) \end{aligned} \right\} \quad \text{or} \quad P = \left\{ sX_1 + tX_2 + \frac{1}{2}(s^2 - t^2)X_3 \right\}$$

for all inward pointing $X_3 \in \mathbb{R}^3_p$ with $\det(X_1, X_2, X_3) = 1$.

On an oriented surface M with all points hyperbolic, we now have an inner product $\langle \cdot, \cdot \rangle_p$ defined on each M_p , and hence an “indefinite Riemannian metric” $\langle \cdot, \cdot \rangle$ on M . Once again we also denote $\langle \cdot, \cdot \rangle$ by \mathfrak{I} , and call it the **special affine first fundamental form** of M . If $f: M \rightarrow \mathbb{R}^3$ is an immersion of an oriented surface with all points of the image hyperbolic, then we define the **special affine first fundamental form** \mathfrak{I}_f of f to be the tensor $\mathfrak{I}_f = f^*(\langle \cdot, \cdot \rangle)$ on M , where $\langle \cdot, \cdot \rangle$ is the special affine first fundamental form on $f(M)$, when $f(M)$ is given the orientation that makes f orientation preserving.

When $f: U \rightarrow \mathbb{R}^3$, for $U \subset \mathbb{R}^2$ open (with the usual orientation), and all points of $f(U)$ are hyperbolic, we again define functions $g_{ij}: U \rightarrow \mathbb{R}$ by

$$\mathfrak{I}_f = g_{11} ds \otimes ds + g_{12} ds \otimes dt + g_{21} dt \otimes ds + g_{22} dt \otimes dt.$$

Again take the case where $f(s, t) = (s, t, h(s, t))$, with $p = f(0, 0) = 0 \in \mathbb{R}^3$ and $M_p = (x, y)$ -plane. If $X'_j = \sum_{i=1}^2 a_{ij} X_i$ is a new basis of \mathbb{R}^2 such that P is the graph of

$$(s, t) \mapsto \frac{1}{2}(s^2 - t^2)$$

in the X'_1, X'_2, X_3 system, then we have

$$\begin{aligned} (I') \quad A^t \cdot \frac{1}{2} \begin{pmatrix} \alpha & \beta \\ \beta & \gamma \end{pmatrix} \cdot A &= \frac{1}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \\ \implies \begin{pmatrix} \alpha & \beta \\ \beta & \gamma \end{pmatrix} &= (A^t)^{-1} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} A^{-1} \\ \implies \det A &= (\beta^2 - \alpha\gamma)^{-1/2}. \end{aligned}$$

As before, we see that the vectors

$$X''_1 = (\sqrt[8]{\beta^2 - \alpha\gamma}) X'_1, \quad X''_2 = (\sqrt[8]{\beta^2 - \alpha\gamma}) X'_2$$

satisfy

$$\begin{aligned} \langle X''_1, X''_1 \rangle_0 &= -\langle X''_2, X''_2 \rangle_0 = 1 \\ \langle X''_1, X''_2 \rangle_0 &= 0. \end{aligned}$$

So, introducing the matrix B as before, we have

$$\begin{aligned}
 g(0,0) = \langle X_i, X_j \rangle_0 &= \frac{1}{\sqrt[4]{\beta^2 - \alpha\gamma}} \left\langle \sum_{k=1}^2 b_{ki} X''_k, \sum_{k=1}^2 b_{kj} X''_k \right\rangle_0 \\
 &= \frac{1}{\sqrt[4]{\beta^2 - \alpha\gamma}} \cdot (b_{1i}b_{1j} - b_{2i}b_{2j}) \\
 &= \frac{1}{\sqrt[4]{\beta^2 - \alpha\gamma}} \left[B^t \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} B \right]_{ij} \\
 &= \frac{1}{\sqrt[4]{\beta^2 - \alpha\gamma}} \left[(A^t)^{-1} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} A^{-1} \right]_{ij}.
 \end{aligned}$$

Thus (I') gives

$$g_{ij}(0,0) = \frac{d_{ij}}{\sqrt[4]{-\det(d_{ij})}}(0,0).$$

The same calculations as before show that this formula holds for any $f: U \rightarrow \mathbb{R}^3$. We can refer to the elliptic and hyperbolic cases jointly by means of equation

$$\begin{aligned}
 \text{(I)} \quad \mathfrak{I}_f &= \sum_{i,j=1}^2 g_{ij} ds^i \otimes ds^j \\
 \text{for } g_{ij} &= \frac{d_{ij}}{\sqrt[4]{|\det(d_{ij})|}}, \quad d_{ij} = \det(f_1, f_2, f_{ij}).
 \end{aligned}$$

If M consists entirely of elliptic points, then the map $f: U \rightarrow M$ must be orientation preserving when M is given its natural orientation, and if M consists entirely of hyperbolic points, then M must be given the orientation which makes f orientation preserving. (Henceforth we will not bother to mention the subsidiary conditions on orientation which must be added to all our considerations.)

Finally, what do we do at points $p \in M$ which are flat (parabolic or planar)? The answer is, we don't do anything. We do not define $\langle \cdot, \cdot \rangle$ and *we cannot expect to*. To see that this must be so, just consider the surface $\mathbb{R}^2 \subset \mathbb{R}^3$, consisting entirely of flat points. If we could define a metric $\langle \cdot, \cdot \rangle$ on \mathbb{R}^2 which was a special affine invariant, then we would have to have $A^* \langle \cdot, \cdot \rangle = \langle \cdot, \cdot \rangle$ for every special linear affine map A from \mathbb{R}^2 to \mathbb{R}^2 , since such an A can always be extended to a special linear affine map $A': \mathbb{R}^3 \rightarrow \mathbb{R}^3$. But of course, there is no metric on \mathbb{R}^2 which is invariant under all special linear affine maps. In affine geometry we will simply always assume, without explicitly mentioning it again,

that all surfaces have no flat points. Thus connected surfaces will consist either entirely of elliptic points, or entirely of hyperbolic points.

After all this work, we are hardly any closer to the problem of picking out a “special affine normal”. In order to do this we will have to consider *third* order approximations to M . We will still assume that $p = 0 \in \mathbb{R}^3$ and that M_p is the (x, y) -plane. Choose some vector $X_3 \in \mathbb{R}^3$ which is not in $\mathbb{R}^2 = (x, y)$ -plane. For every basis $\mathbf{X} = (X_1, X_2)$ of \mathbb{R}^2 , we can then consider the function $h^{\mathbf{X}}$ which describes M in the X_1, X_2, X_3 coordinate system, and we can look at the quadratic and cubic polynomials

$$\begin{aligned} & \frac{1}{2}(h^{\mathbf{X}}_{11}(0,0) \cdot s^2 + 2h^{\mathbf{X}}_{12}(0,0) \cdot st + h^{\mathbf{X}}_{22}(0,0) \cdot t^2) \\ & \frac{1}{6}(h^{\mathbf{X}}_{111}(0,0) \cdot s^3 + 3h^{\mathbf{X}}_{112}(0,0) \cdot s^2t + 3h^{\mathbf{X}}_{122}(0,0) \cdot st^2 + h^{\mathbf{X}}_{222}(0,0) \cdot t^3) \end{aligned}$$

which appear in the Taylor series for $h^{\mathbf{X}}$. As on page 37, we can also define functions $\Phi^{\mathbf{X}}, \Psi^{\mathbf{X}}: \mathbb{R}^2 \rightarrow \mathbb{R}$ by

$$\begin{aligned} \Phi^{\mathbf{X}}(sX_1 + tX_2) &= \frac{1}{2}(h^{\mathbf{X}}_{11}(0,0) \cdot s^2 + 2h^{\mathbf{X}}_{12}(0,0) \cdot st + h^{\mathbf{X}}_{22}(0,0) \cdot t^2) \\ \Psi^{\mathbf{X}}(sX_1 + tX_2) &= \frac{1}{6}(h^{\mathbf{X}}_{111}(0,0) \cdot s^3 + 3h^{\mathbf{X}}_{112}(0,0) \cdot s^2t \\ & \quad + 3h^{\mathbf{X}}_{122}(0,0) \cdot st^2 + h^{\mathbf{X}}_{222}(0,0) \cdot t^3). \end{aligned}$$

All the $\Phi^{\mathbf{X}}$ are really the same function $\Phi: \mathbb{R}^2 \rightarrow \mathbb{R}$, and all the $\Psi^{\mathbf{X}}$ are really the same function $\Psi: \mathbb{R}^2 \rightarrow \mathbb{R}$. We have already checked this for the $\Phi^{\mathbf{X}}$'s, using the relation

$$(1) \quad h^{\mathbf{X}}_{\alpha\beta}(0,0) = \sum_{j,k=1}^2 a_{j\alpha}a_{k\beta}h_{jk}(0,0);$$

the check for the $\Psi^{\mathbf{X}}$'s is similar, using the easily derived relation

$$(2) \quad h^{\mathbf{X}}_{\alpha\beta\gamma}(0,0) = \sum_{j,k,l=1}^2 a_{j\alpha}a_{k\beta}a_{l\gamma}h_{jkl}(0,0).$$

Remember that these functions Φ and Ψ *do* depend on the original choice of X_3 . We would now like to ask if there is a particular choice for the direction of X_3 which will make the functions Φ and Ψ be related to each other in some especially nice way; so the real problem here is to formulate a definite question, by deciding on a suitable criterion for declaring that Φ and Ψ are nicely related.

We now find ourselves placed in a purely algebraic situation, which we can formulate as follows. A function $\Phi: \mathbb{R}^2 \rightarrow \mathbb{R}$ will be called **quadratic** if for a basis X_1, X_2 of \mathbb{R}^2 we have

$$\Phi(sX_1 + tX_2) = \Phi_{11}s^2 + 2\Phi_{12}st + \Phi_{22}t^2,$$

for some numbers Φ_{jk} . More generally, for an n -dimensional vector space V , a function $\Phi: V \rightarrow \mathbb{R}$ will be called **quadratic** if for a basis X_1, \dots, X_n of V we have

$$\Phi\left(\sum_{i=1}^n s^i X_i\right) = \sum_{j,k=1}^n \Phi_{jk} s^j s^k$$

for certain numbers Φ_{jk} , which it will be convenient to assume are symmetric with respect to the indices j and k . It is easy to see that if Φ has this form for one basis, then it has this form for any other basis. Indeed, if $\bar{X}_1, \dots, \bar{X}_n$ is another basis, with $\bar{X}_j = \sum_i a_{ij} X_i$, then

$$\begin{aligned} \Phi\left(\sum_{i=1}^n s^i \bar{X}_i\right) &= \Phi\left(\sum_{i=1}^n \sum_{\rho=1}^n s^i a_{\rho i} X_\rho\right) = \Phi\left(\sum_{\rho=1}^n \left(\sum_{i=1}^n s^i a_{\rho i}\right) X_\rho\right) \\ &= \sum_{j,k=1}^n \Phi_{jk} \left(\sum_{i=1}^n s^i a_{ji}\right) \left(\sum_{i=1}^n s^i a_{ki}\right) \\ &= \sum_{\alpha,\beta=1}^n \left(\sum_{j,k=1}^n \Phi_{jk} a_{j\alpha} a_{k\beta}\right) s^\alpha s^\beta = \sum_{\alpha,\beta=1}^n \bar{\Phi}_{\alpha\beta} s^\alpha s^\beta, \end{aligned}$$

where the $\bar{\Phi}_{\alpha\beta}$ are given by

$$(3) \quad \bar{\Phi}_{\alpha\beta} = \sum_{j,k=1}^n \Phi_{jk} a_{j\alpha} a_{k\beta}.$$

Naturally, (3) is just the n -dimensional analogue of the equations (1) which gave us a well-defined Φ in the first place. Notice that in terms of the matrix $A = (a_{ij})$ and the matrices $[\Phi] = (\Phi_{jk})$ and $[\bar{\Phi}] = (\bar{\Phi}_{\alpha\beta})$ we can write (3) as

$$(4) \quad [\bar{\Phi}] = A^t \cdot [\Phi] \cdot A.$$

We will define a function $\Psi: V \rightarrow \mathbb{R}$ to be **cubic** if for a basis X_1, \dots, X_n of V we have

$$\Psi\left(\sum_{i=1}^n s^i X_i\right) = \sum_{j,k,l=1}^n \Psi_{jkl} s^j s^k s^l,$$

for certain numbers Ψ_{jkl} , which we can assume are symmetric in the indices. For the basis \bar{X} we easily find that

$$\Psi\left(\sum_{i=1}^n s^i \bar{X}_i\right) = \sum_{\alpha, \beta, \gamma=1}^n \bar{\Psi}_{\alpha\beta\gamma} s^\alpha s^\beta s^\gamma,$$

where

$$(5) \quad \bar{\Psi}_{\alpha\beta\gamma} = \sum_{j,k,l=1}^n \Psi_{jkl} a_{j\alpha} a_{k\beta} a_{l\gamma};$$

this equation, of course, is just the analogue of (2). It is not hard to see that we could also define a quadratic function $\Phi: V \rightarrow \mathbb{R}$ to be one of the form $\Phi(X) = B(X, X)$ for a symmetric bilinear function $B: V \times V \rightarrow \mathbb{R}$. Similarly, a cubic function $\Psi: V \rightarrow \mathbb{R}$ is one of the form $\Psi(X) = T(X, X, X)$ for a symmetric trilinear function $T: V \times V \times V \rightarrow \mathbb{R}$.

Now we would like to find some quantity depending on Φ and Ψ , but *not* on the choice of basis, and hence not on the particular coefficients Φ_{jk} and Ψ_{jkl} for this basis. As a warm-up, let's first take the case of two *quadratic* forms Φ and Θ . We will assume that the first quadratic form Φ is non-degenerate, by which we mean that the corresponding symmetric bilinear form is non-degenerate. More concretely, this means that if we choose a basis X_1, \dots, X_n for V , then the matrix $[\Phi] = (\Phi_{jk})$ is non-singular, and therefore has an inverse matrix $[\Phi]^{-1} = (\Phi^{jk})$ with

$$\sum_{k=1}^n \Phi_{jk} \Phi^{kl} = \delta_j^l.$$

Now consider the number

$$\sum_{j,k=1}^n \Phi^{jk} \Theta_{jk}.$$

If $\bar{X}_j = \sum_i a_{ij} X_i$ is a new basis, and $B = (b_{ij})$ is the inverse of $A = (a_{ij})$, then (4) shows that the matrix $[\bar{\Phi}] = (\bar{\Phi}_{\alpha\beta})$ satisfies

$$[\bar{\Phi}] = A^t [\Phi] A \implies [\bar{\Phi}]^{-1} = B [\Phi]^{-1} B^t$$

and hence

$$(6) \quad \bar{\Phi}^{\alpha\beta} = \sum_{j,k=1}^n \Phi^{jk} b_{\alpha j} b_{\beta k}.$$

Applying (3) to Θ , we thus find that

$$\begin{aligned}
 \sum_{\alpha, \beta=1}^n \bar{\Phi}^{\alpha\beta} \bar{\Theta}_{\alpha\beta} &= \sum_{\alpha, \beta=1}^n \sum_{j, k=1}^n \Phi^{jk} b_{\alpha j} b_{\beta k} \sum_{l, m=1}^n \Theta_{lm} a_{l\alpha} a_{m\beta} \\
 &= \sum_{j, k=1}^n \sum_{l, m=1}^n \Phi^{jk} \Theta_{lm} \delta_{lj} \delta_{mk} \\
 &= \sum_{j, k=1}^n \Phi^{jk} \Theta_{jk}.
 \end{aligned}$$

We thus have a well-defined number (Φ, Θ) , which for any basis $\{X_i\}$ is given by

$$(\Phi, \Theta) = \sum_{j, k=1}^n \Phi^{jk} \Theta_{jk}.$$

Naturally, there must also be some invariant definition of (Φ, Θ) lurking around. Indeed, the bilinear function corresponding to Φ is just what we usually call an inner product $\langle \cdot, \cdot \rangle$ on V . This gives rise to inner products on just about every other vector space in sight which is related to V . In particular, we could define an inner product $\langle \cdot, \cdot \rangle$ on the set of all bilinear functions $C: V \times V \rightarrow \mathbb{R}$; the quadratic function Θ corresponds to such a C , and (Φ, Θ) is just $\langle C, C \rangle$. But in this case I don't think it's worth all the linear algebra which this involves; it's easier to just do the calculation.

To get a little more feeling for what the number (Φ, Θ) is, take the case where the inner product corresponding to Φ is actually positive definite. Then there is a basis X_1, \dots, X_n of V such that $\Phi_{ij} = \delta_{ij}$ and also $\Theta_{ij} = 0$ for $i \neq j$ (compare Proposition II.4-14). So (Φ, Θ) is just the sum of the "diagonal terms", $(\Phi, \Theta) = \sum_i \Theta_{ii}$. When $(\Phi, \Theta) = 0$, the forms Φ and Θ are said to be **apolar**, a term that comes from the old invariant theory. We can give a very concrete geometric meaning to apolarity when V is 2-dimensional. For our special choice of basis, we see that Θ is apolar to Φ if and only if the graph of $\Theta: V \rightarrow \mathbb{R}$ is a hyperbolic paraboloid,

$$\begin{aligned}
 \Theta(sX_1 + tX_2) &= \Theta_{11}s^2 + \Theta_{22}t^2 \\
 &= \Theta_{11}s^2 - \Theta_{11}t^2,
 \end{aligned}$$

for which the set $\Theta^{-1}(0) \subset V$ is a pair of straight lines making angles of $\pi/4$ with the lines spanned by X_1 and X_2 (we measure angles in V by using the inner product on V corresponding to Φ , so that X_1 and X_2 are orthonormal).

We can also express the apolarity of Φ and Θ in a way that does not involve the special choice of basis: Φ and Θ are apolar if and only if $\Theta^{-1}(0)$ is the union of two straight lines which are perpendicular to each other in the inner product on V corresponding to Φ .

Now consider a quadratic function Φ , which we will still assume is non-degenerate, and a cubic function Ψ . Instead of constructing a number from Φ and Ψ , we will construct an element of V^* , namely

$$X_i \mapsto \sum_{j,k=1}^n \Phi^{jk} \Psi_{ijk}.$$

Suppose we have a new basis $\bar{X}_j = \sum_i a_{ij} X_i$, and that we let $B = (b_{ij})$ be the inverse matrix of $A = (a_{ij})$, as before. Consider the map

$$\bar{X}_\alpha \mapsto \sum_{\beta,\gamma=1}^n \bar{\Phi}^{\beta\gamma} \bar{\Psi}_{\alpha\beta\gamma}.$$

This map takes $X_i = \sum_\alpha b_{\alpha i} \bar{X}_\alpha$ to

$$\begin{aligned} \sum_{\alpha=1}^n b_{\alpha i} \sum_{\beta,\gamma=1}^n \bar{\Phi}^{\beta\gamma} \bar{\Psi}_{\alpha\beta\gamma} &= \sum_{\alpha=1}^n b_{\alpha i} \sum_{\beta,\gamma=1}^n \sum_{j,k=1}^n \Phi^{jk} b_{\beta j} b_{\gamma k} \sum_{l,p,q=1}^n \Psi_{lpq} a_{l\alpha} a_{p\beta} a_{q\gamma} \\ &\quad \text{by (5) and (6)} \\ &= \sum_{j,k=1}^n \Phi^{jk} \Psi_{ijk}. \end{aligned}$$

Thus we have a well-defined map $(\Phi, \Psi): V \rightarrow \mathbb{R}$, which for any basis $\{X_i\}$ is given by

$$(\Phi, \Psi)(X_i) = \sum_{j,k=1}^n \Phi^{jk} \Psi_{ijk};$$

industrious readers can supply their own invariant definition. As before, we say that Φ and Ψ are **apolar** if $(\Phi, \Psi) = 0$. Suppose that V is 2-dimensional, with a basis X_1, X_2 . Since

$$\begin{pmatrix} \Phi^{11} & \Phi^{12} \\ \Phi^{21} & \Phi^{22} \end{pmatrix} = \frac{1}{\det[\Phi]} \begin{pmatrix} \Phi_{22} & -\Phi_{21} \\ -\Phi_{12} & \Phi_{11} \end{pmatrix},$$

and the Φ_{jk} and Ψ_{jkl} are symmetric in the indices, we see that Φ and Ψ are apolar if and only if they satisfy the **apolarity conditions**

$$(*) \quad \begin{cases} \Phi_{22} \Psi_{111} - 2\Phi_{12} \Psi_{112} + \Phi_{11} \Psi_{122} = 0 \\ \Phi_{22} \Psi_{112} - 2\Phi_{12} \Psi_{122} + \Phi_{11} \Psi_{222} = 0. \end{cases}$$

Later on we will give a geometric interpretation of apolarity when V is 2-dimensional, but for the moment, we content ourselves with the observation that apolarity is clearly just about the simplest well-defined relationship that one can posit between a quadratic and a cubic function. It also happens to do the trick:

12. PROPOSITION. Let M be a surface in \mathbb{R}^3 and $p \in M$ a point which is elliptic or hyperbolic. For each tangent vector $X_3 \in \mathbb{R}^3_p$ which is not in M_p , define a quadratic function $\Phi: M_p \rightarrow \mathbb{R}$ and a cubic function $\Psi: M_p \rightarrow \mathbb{R}$ by looking at the second and third order terms in the Taylor series for the function which describes M in terms of the X_1, X_2, X_3 coordinate system, for any basis X_1, X_2 of M_p . Then there is a unique direction for X_3 which makes Φ and Ψ apolar.

PROOF. For simplicity we will assume that $p = 0 \in \mathbb{R}^3$ and that M_p is the (x, y) -plane. We can choose a basis X_1, X_2 for \mathbb{R}^2 so that if

$$(1) \quad M = \{sX_1 + tX_2 + h(s, t) \cdot (0, 0, 1)\},$$

then h has the form

$$(2) \quad h(s, t) = \frac{A}{2}(s^2 \pm t^2) + \frac{1}{6}(Bs^3 + 3Cs^2t + 3Dst^2 + Et^3) + R(s, t),$$

where $R(s, t)/|(s, t)|^3 \rightarrow 0$ as $(s, t) \rightarrow 0$.

Now consider the basis $X_1, X_2, X_3 = (0, 0, 1) + \lambda X_1 + \mu X_2$, for two constants λ, μ . Let k be the function describing M in the X_1, X_2, X_3 coordinate system, so that

$$(3) \quad \begin{aligned} M &= \{sX_1 + tX_2 + k(s, t) \cdot [(0, 0, 1) + \lambda X_1 + \mu X_2]\} \\ &= \{[s + \lambda \cdot k(s, t)]X_1 + [t + \mu \cdot k(s, t)]X_2 + k(s, t) \cdot (0, 0, 1)\}. \end{aligned}$$

Comparing with (1), we see that

$$k(s, t) = h(s + \lambda \cdot k(s, t), t + \mu \cdot k(s, t)).$$

Using (2), and noting that we have $k(s, t)/|(s, t)| \rightarrow 0$, we find that

$$\begin{aligned} k(s, t) &= \frac{A}{2}(s^2 \pm t^2) + \frac{1}{6}(Bs^3 + 3Cs^2t + 3Dst^2 + Et^3) \\ &\quad + Ak(s, t)(\lambda \cdot s \pm \mu \cdot t) + R'(s, t). \end{aligned}$$

where $R'(s, t)/|(s, t)|^3 \rightarrow 0$ as $(s, t) \rightarrow 0$. If we plug the whole right side of this equation into the term $k(s, t)$ on the right, we then find that

$$k(s, t) = \frac{A}{2}(s^2 \pm t^2) + \frac{1}{6}(Bs^3 + 3Cs^2t + 3Dst^2 + Et^3) \\ + \frac{1}{2}(s^2 \pm t^2)(\lambda \cdot s \pm \mu \cdot t) + R''(s, t),$$

where $R''(s, t)/|(s, t)|^3 \rightarrow 0$. Therefore the Φ and Ψ for the basis X_1, X_2, X_3 are given by

$$\Phi(sX_1 + tX_2) = \frac{A}{2}(s^2 \pm t^2) \\ \Psi(sX_1 + tX_2) = \frac{1}{6}([B + 3\lambda]s^3 + 3[C \pm \mu]s^2t + 3[D \pm \lambda]st^2 + [E + 3\mu]t^3).$$

The apolarity conditions $(*)$ for this Φ and Ψ are

$$\pm(B + 3\lambda) + (D \pm \lambda) = 0 \\ \pm(C \pm \mu) + (E + 3\mu) = 0.$$

There are clearly unique λ and μ for which these equations hold. It is also clear that if the apolarity conditions hold for some X_3 , then they also hold for any multiple of X_3 . So there is a unique direction for X_3 which will make Φ and Ψ apolar. \diamond

For an elliptic or hyperbolic point $p \in M$, the unique direction through p which is given by Proposition 12 is called the **affine normal direction** at p . It is clearly a general affine invariant: If $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is any affine map, then the affine normal direction through the point $A(p) \in A(M)$ is the image under A of the affine normal direction through $p \in M$.

The affine normal direction can also be characterized in terms of moving frames. For simplicity we first assume that $p = 0 \in \mathbb{R}^3$ and that $M_p = (x, y)$ -plane. If the vector v points along the affine normal direction through p , then M is the graph, in the $(1, 0, 0), (0, 1, 0), v$ coordinate system, of a function h satisfying the apolarity conditions $(*)$:

$$0 = h_{22}h_{111} - 2h_{12}h_{112} + h_{11}h_{122} = \frac{\partial}{\partial s} \det h_{ij} \\ 0 = h_{22}h_{112} - 2h_{12}h_{122} + h_{11}h_{222} = \frac{\partial}{\partial t} \det h_{ij} \quad \text{at } (0, 0).$$

We can write these two equations together simply as

$$(1) \quad 0 = d \det(h_{ij}) \quad \text{at } (0, 0).$$

Locally M is the image of the map $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ defined by

$$f(s, t) = (s, t, 0) + h(s, t) \cdot v.$$

First take the particularly simple moving frame

$$\overset{\circ}{X}_1 = f_1 = (1, 0, 0) + h_1 v, \quad \overset{\circ}{X}_2 = f_2 = (0, 1, 0) + h_2 v, \quad \overset{\circ}{X}_3 = v$$

and let $\overset{\circ}{\psi}_\beta^\alpha$ be the corresponding connection forms. Then

$$\begin{aligned} 0 \overset{\circ}{X}_1 + 0 \overset{\circ}{X}_2 + h_{ik} \overset{\circ}{X}_3 &= \nabla'_{\overset{\circ}{X}_k} \overset{\circ}{X}_i = \sum_{\alpha=1}^3 \overset{\circ}{\psi}_i^\alpha(\overset{\circ}{X}_k) \cdot \overset{\circ}{X}_\alpha \quad i, k = 1, 2 \\ 0 &= \nabla'_{\overset{\circ}{X}_k} \overset{\circ}{X}_3 = \sum_{\alpha=1}^3 \overset{\circ}{\psi}_3^\alpha(\overset{\circ}{X}_k) \cdot \overset{\circ}{X}_\alpha \quad k = 1, 2, \end{aligned}$$

which implies, among other things, that

$$(2) \quad \begin{aligned} \overset{\circ}{\psi}_i^j &= 0 \quad \text{on } TM \quad i, j = 1, 2 \\ \overset{\circ}{\psi}_3^\alpha &= 0 \quad \text{on } TM \quad \alpha = 1, 2, 3. \end{aligned}$$

Now consider an arbitrary adapted moving frame X_1, X_2, X_3 subject only to the condition that

$$X_3 = \overset{\circ}{X}_3 \quad \text{at } p.$$

This condition implies that the matrix a on page 80 relating the two frames also satisfies

$$(3) \quad \begin{aligned} a_{i3}(p) &= 0 \quad i = 1, 2; & a_{33}(p) &= 1 \\ \implies (a^{-1})_{i3}(p) &= 0 \quad i = 1, 2; & (a^{-1})_{33}(p) &= 1. \end{aligned}$$

From the general equation (d) on page 81 we have

$$\begin{aligned} \psi_i^j &= (a^{-1} da)_i^j + (a^{-1} \overset{\circ}{\psi} a)_i^j \\ &= \sum_{\alpha=1}^3 (a^{-1})_{j\alpha} da_{\alpha i} + \sum_{\alpha, \beta=1}^3 (a^{-1})_{j\alpha} \overset{\circ}{\psi}_\beta^\alpha a_{\beta i} \quad i, j = 1, 2 \\ \psi_3^3 &= (a^{-1} da)_3^3 + (a^{-1} \overset{\circ}{\psi} a)_3^3 \\ &= \sum_{\alpha=1}^3 (a^{-1})_{3\alpha} da_{\alpha 3} + \sum_{\alpha, \beta=1}^3 (a^{-1})_{3\alpha} \overset{\circ}{\psi}_\beta^\alpha a_{\beta 3}. \end{aligned}$$

Taking into account equations (2) and (3), as well as equation (b) on page 80, we obtain

$$(4) \quad \psi_3^3 = da_{33} \quad \text{on } TM, \text{ at } p$$

and

$$\psi_i^j = \sum_{k=1}^2 (a^{-1})_{jk} da_{ki} \quad \text{on } TM, \text{ at } p \quad i, j = 1, 2;$$

since our matrix a has the form

$$\begin{pmatrix} a_{11} & a_{12} & 0 \\ a_{21} & a_{22} & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad \text{at } p,$$

we can write the latter equation as

$$(5) \quad \psi_i^j = \sum_{k=1}^2 (A^{-1})_{jk} dA_{ki} \quad \text{on } TM, \text{ at } p \quad i, j = 1, 2,$$

where A is the 2×2 matrix $A = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}$. But we can compute da_{33} in terms of the matrix S for the moving frame X_1, X_2, X_3 . For equation (e) on page 81 relates S to $\overset{\circ}{S} = (h_{ij})$ by

$$\begin{aligned} a_{33} \cdot S &= A^t \overset{\circ}{S} A \implies (a_{33})^2 \cdot (\det S) = (\det A)^2 \cdot (\det \overset{\circ}{S}) \\ &\implies 2 \log |a_{33}| + \log |\det S| = 2 \log |\det A| + \log |\det \overset{\circ}{S}|. \end{aligned}$$

Since $a_{33}(p) = 1$, at p we have

$$\begin{aligned} 2 da_{33} + d \log |\det S| &= 2d \log |\det A| + d \log |\det \overset{\circ}{S}| \\ &= 2d \log |\det A|, \quad \text{by (I)}. \end{aligned}$$

Hence (4) becomes

$$(6) \quad \psi_3^3 = d \log |\det A| - \frac{1}{2} d \log |\det S| \quad \text{on } TM, \text{ at } p.$$

Now note that

$$\begin{aligned} d \log |\det A| &= \frac{d \det A}{\det A} = \frac{d(A_{11}A_{22} - A_{12}A_{21})}{\det A} \\ &= \frac{(A_{22} dA_{11} - A_{12} dA_{21}) + (-A_{21} dA_{12} + A_{11} dA_{22})}{\det A}. \end{aligned}$$

Since

$$A^{-1} = \frac{\begin{pmatrix} a_{22} & -a_{12} \\ -a_{21} & a_{11} \end{pmatrix}}{\det A},$$

this becomes

$$\begin{aligned} d \log |\det A| &= \sum_{k=1}^2 (A^{-1})_{1k} dA_{k1} + \sum_{k=1}^2 (A^{-1})_{2k} dA_{k2} \\ &= \psi_1^1 + \psi_2^2 \quad \text{on } TM, \text{ at } p \quad \text{by (5).} \end{aligned}$$

Substituting into (6) we see that

An adapted moving frame X_1, X_2, X_3 on $M \subset \mathbb{R}^3$ has $X_3(p)$ pointing in the affine normal direction at p if and only if

$$\psi_3^3 = \psi_1^1 + \psi_2^2 - \frac{1}{2} d \log |\det S| \quad \text{on } TM, \text{ at } p.$$

From this fact we see, what is by no means *a priori* clear, that the condition $\psi_3^3 = \psi_1^1 + \psi_2^2 - \frac{1}{2} d \log |\det S|$ on TM at p depends only on the direction of X_3 at p . It is also possible to check this by a direct, quite unpleasant, calculation. If we had somehow independently observed this fact, we could have used this equation to *define* the affine normal direction. Of course, it is hard to see how one would ever be led to such an “observation”, but there is at least a way to simplify the equation. We have already observed that the condition

$$S(p) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \text{or} \quad \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad \text{or} \quad \begin{cases} \psi_1^3 = \theta^1 \\ \psi_2^3 = \pm \theta^2 \end{cases}$$

depends only on the value of the moving frame X_1, X_2, X_3 at p , so it is reasonable to restrict our attention to frames satisfying this condition at all points. It is clear that

An adapted moving frame X_1, X_2, X_3 on $M \subset \mathbb{R}^3$ with $S = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ or $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ everywhere, has $X_3(p)$ pointing in the affine normal direction at p if and only if

$$\psi_3^3 = \psi_1^1 + \psi_2^2 \quad \text{on } TM, \text{ at } p.$$

The direct verification that for such frames the condition $\psi_3^3 = \psi_1^1 + \psi_2^2$ on TM at p depends only on the direction of X_3 at p is a little easier, and gives a nice

criterion for the direction of the affine normal; of course, as a definition it still leaves a lot to be desired in terms of motivation.

Now that we have picked out an affine normal direction which is a general affine invariant, it is a simple matter to define a special affine normal vector which is a special affine invariant. We define the **special affine normal** ν_p of M at p to be the unique vector $\nu_p \in \mathbb{R}^3_p$ such that

- (1) ν_p points along the affine normal direction at p
- (2) $\det(X_1, X_2, \nu_p) = 1$ for every positively oriented basis X_1, X_2 of M_p which is orthonormal for the metric $\langle \cdot, \cdot \rangle_p$.

If $f: M \rightarrow \mathbb{R}^3$ is an immersion, we let \mathcal{N} be the vector field along f such that $\mathcal{N}(p)_{f(p)} \in \mathbb{R}^3_{f(p)}$ is the special affine normal to $f(M)$ at $f(p)$. We will not try to derive a formula for \mathcal{N} right away, since it will come out very naturally later on.

Suppose now that we have an adapted moving frame X_1, X_2, X_3 on M such that $\det(X_1, X_2, X_3) = 1$. Then for all tangent vectors X to M we have

$$\begin{aligned} 0 &= X(\det(X_1, X_2, X_3)) \\ &= \det(\nabla'_X X_1, X_2, X_3) + \det(X_1, \nabla'_X X_2, X_3) + \det(X_1, X_2, \nabla'_X X_3) \\ &= \det\left(\sum_{\alpha=1}^3 \psi_1^\alpha(X) \cdot X_\alpha, X_2, X_3\right) + \cdots \\ &= \psi_1^1(X) + \psi_2^2(X) + \psi_3^3(X). \end{aligned}$$

Thus we have

$$\psi_1^1 + \psi_2^2 + \psi_3^3 = 0 \quad \text{on } TM.$$

Suppose, moreover, that (X_1, X_2) is positively oriented and orthonormal with respect to the metric $\langle \cdot, \cdot \rangle$ on M ; in other words, suppose that $S = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ or $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ everywhere. We have seen that in this case $X_3(p)$ points in the affine normal direction if and only if

$$\psi_3^3 = \psi_1^1 + \psi_2^2 \quad \text{on } TM, \text{ at } p.$$

Since we also have $\psi_1^1 + \psi_2^2 + \psi_3^3 = 0$ everywhere on TM , we find that

An adapted moving frame X_1, X_2, X_3 on $M \subset \mathbb{R}^3$ with (X_1, X_2) positively oriented, $\det(X_1, X_2, X_3) = 1$, and $S = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ or $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ everywhere, has $X_3(p) = \nu_p$ if and only if

$$\psi_3^3 = 0 \quad \text{on } TM, \text{ at } p.$$

Now the condition $\psi_3^3(p) = 0$ on M_p means that

$$\nabla'_{X_p} X_3 \in M_p \quad \text{for all } X_p \in M_p.$$

So we see, in particular, that we always have

$$\nabla'_{X_p} \nu \in M_p \quad \text{for } X_p \in M_p,$$

just as we always have $\nabla'_{X_p} \nu \in M_p$ in ordinary surface theory. (Verifying this fact directly from the definition of ν involves a rather hideous computation, and in general all the formulas and computations for affine surface theory are considerably more complicated than those in ordinary surface theory; that is why we have brought in moving frames, with their attendant computational simplifications, so early in the game.) We will denote the map $X_p \mapsto \nabla'_{X_p} \nu$ from M_p to M_p by $d\nu: M_p \rightarrow M_p$. The reason for this notation is the same as in ordinary surface theory: since we have a vector $\nu_p \in \mathbb{R}^3_p$ for each $p \in M$, we have a map $\nu: M \rightarrow \mathbb{R}^3$, and $\nabla'_{X_p} \nu$ is the same as $[d\nu(X_p)]_p$. In the present case, the map ν doesn't go into any special subset of \mathbb{R}^3 , but $\nu(M) \subset \mathbb{R}^3$ will be some surface, at least near the points where $d\nu: M_p \rightarrow M_p$ is non-singular. The relation $\nabla'_{X_p} \nu \in M_p$ tells us that the tangent plane M_p is parallel to the tangent plane $\nu(M)_{\nu(p)}$. So we could also denote $d\nu: M_p \rightarrow M_p$ by $\nu_*: M_p \rightarrow M_p$, as in the case of ordinary surface theory.

Before proceeding with the development of special affine surface theory, we pause briefly to describe the procedure usually found in those papers and books which present the theory totally from the moving frame point of view, and ignore the question of general affine invariants, like the affine normal direction. One works, first of all, only with adapted frames X_1, X_2, X_3 satisfying $\det(X_1, X_2, X_3) = 1$, and hence $\psi_1^1 + \psi_2^2 + \psi_3^3 = 0$ on TM . Equation (e) is first derived, except that now a_{33} must = 1; it shows that S is determined only up to a transformation $S \mapsto A^t S A$. The canonical forms for symmetric matrices under this equivalence relation are precisely $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ and $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$; so one "normalizes" the frame by requiring that S be everywhere of this form. Then one further normalizes the frame by requiring that $\psi_3^3(p) = 0$ for all p , noting that the condition $\psi_3^3(p) = 0$ now uniquely determines $X_3(p)$; indeed if $\{X_\alpha\}$ and $\{X'_\alpha\}$ are two adapted frames with $\det(X_1, X_2, X_3) = \det(X'_1, X'_2, X'_3) = 1$ and $S = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ or $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ everywhere, so that

$$\begin{aligned} \psi_1^3 &= \theta^1 \\ \psi_2^3 &= \pm \theta^2, \end{aligned}$$

then the matrix a relating the X'_α to the X_α must be of the form

$$a = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ 0 & 0 & 1 \end{pmatrix}$$

and equation (d) on page 81 yields

$$\begin{aligned} \psi'_3 &= \psi_1^3 a_{13} + \psi_2^3 a_{23} + \psi_3^3 \\ &= a_{13} \theta^1 + a_{23} \theta^2 + \psi_3^3, \end{aligned}$$

so that $\psi_3^3(p) = \psi'_3(p) = 0 \implies a_{13}(p) = a_{23}(p) = 0 \implies X'_3(p) = X_3(p)$. The uniquely determined X_3 is now dubbed the special affine normal, and any basis X_1, X_2 with $S = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ or $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ is called orthonormal, thereby defining the special affine first fundamental form. These normalizations are usually carried out with hardly a word of motivation, as if they are so natural that any idiot would immediately think of doing them—in reality, of course, the authors already knew what results they wanted, since they were simply reformulating a classical theory.

Now that we have finally determined the special affine normal v_p at $p \in M$, we can imitate a basic construction from ordinary surface theory. First we introduce the unique projections

$$\begin{aligned} \mathsf{T}: \mathbb{R}^3_p &\rightarrow M_p \\ \mathsf{L}: \mathbb{R}^3_p &\rightarrow \mathbb{R} \cdot v_p = \text{all multiples of } v_p \end{aligned}$$

such that

$$X = \mathsf{T}X + \mathsf{L}X \quad \text{for all } X \in M_p.$$

Notice that $\mathsf{T}: \mathbb{R}^3_p \rightarrow M_p$ is generally different from the tangential projection $\mathsf{T}: \mathbb{R}^3_p \rightarrow M$ of ordinary surface theory. Given vector fields X, Y tangent along M , we would like to find $\mathsf{T}\nabla'_X Y$ and $\mathsf{L}\nabla'_X Y$, where $\nabla'_X Y$ is the ordinary covariant differentiation in \mathbb{R}^3 . Now in ordinary surface theory, $\mathsf{L}\nabla'_X Y$ involved the second fundamental form II . Since II is so closely related to the affine first fundamental form I , we might expect I to be involved in $\mathsf{L}\nabla'_X Y$. As a matter of fact,

13. PROPOSITION. If X, Y are tangent along $M \subset \mathbb{R}^3$, then

$$\mathsf{L}\nabla'_X Y = \langle X, Y \rangle \cdot v = \mathsf{I}(X, Y) \cdot v.$$

PROOF. Note first that, as in the case of $\mathcal{L}\nabla'_X Y$, we have

$$\mathcal{L}\nabla'_{X_p} fY = \mathcal{L}(X_p(f) \cdot Y_p + f(p) \cdot \nabla'_{X_p} Y) = f(p) \cdot \mathcal{L}\nabla'_{X_p} Y,$$

so $\mathcal{L}\nabla'_{X_p} Y$ actually depends only on the value of Y at p . Now let (X_1, X_2) be a positively oriented moving frame on M which is orthonormal for $\langle \cdot, \cdot \rangle$; this means (taking the elliptic case for simplicity) that for the moving frame $(X_1, X_2, X_3) = (X_1, X_2, \nu)$ we have

$$\psi_i^3 = \theta^i \quad \text{on } TM.$$

But then

$$\mathcal{L}\nabla'_{X_p} X_i = \psi_i^3(X) \cdot \nu = \theta^i(X) \cdot \nu = \langle X, X_i \rangle \cdot \nu. \quad \blacklozenge$$

Now let's consider $\mathcal{T}\nabla'_X Y$. In ordinary surface theory this is $\nabla_X Y$, where ∇ is the connection on M determined by the metric $i^*\langle \cdot, \cdot \rangle$. In affine surface theory, we can consider the connection ∇ on M determined by the metric $\langle \cdot, \cdot \rangle$ (this exists even if $\langle \cdot, \cdot \rangle$ is not positive definite; compare pg. II.342). Now one can ask whether $\mathcal{T}\nabla'_X Y = \nabla_X Y$ for vector fields X and Y tangent along M . This simply isn't true, and we therefore define a map $\mathfrak{s}: M_p \times M_p \rightarrow M_p$ by

$$\mathcal{T}\nabla'_{X_p} Y = \nabla_{X_p} Y + \mathfrak{s}(X_p, Y_p),$$

where Y is a vector field tangent along M which extends Y_p . The notation $\mathfrak{s}(X_p, Y_p)$ is justified, since

$$\begin{aligned} \mathcal{T}\nabla'_{X_p} fY - \nabla_{X_p} fY &= \mathcal{T}(X_p(f) \cdot Y_p + f(p) \cdot \nabla'_{X_p} Y) \\ &\quad - [X_p(f) \cdot Y_p + f(p) \cdot \nabla_{X_p} Y] \\ &= f(p) \cdot [\mathcal{T}\nabla'_{X_p} Y - \nabla_{X_p} Y]. \end{aligned}$$

14. PROPOSITION. The tensor \mathfrak{s} is symmetric.

PROOF. If X and Y are extensions of $X_p, Y_p \in M_p$ to vector fields which are tangent to M at all points of M , then

$$\begin{aligned} \mathfrak{s}(X_p, Y_p) - \mathfrak{s}(Y_p, X_p) &= \mathcal{T}(\nabla'_{X_p} Y - \nabla'_{Y_p} X) - (\nabla_{X_p} Y - \nabla_{Y_p} X) \\ &= [X, Y](p) - [X, Y](p) = 0. \quad \blacklozenge \end{aligned}$$

We can now write the decomposition

$$\nabla'_X Y = \Upsilon \nabla'_X Y + \mathcal{L} \nabla'_X Y$$

in the following form:

The Special Affine Gauss Formulas:
 $\nabla'_X Y = \nabla_X Y + \mathcal{L}(X, Y) + \langle X, Y \rangle \nu$
 for vector fields X, Y tangent along M .

In ordinary surface theory we often found that the second fundamental form $\mathbb{I}(X, Y) = \langle s(X, Y), \nu \rangle$ was easier to work with than the map $s: M_p \times M_p \rightarrow M_p^\perp$ itself. Since \mathcal{L} now goes into M_p , we have to adopt a slightly different strategy. We define the **special affine second fundamental form** \mathbb{I} of M to be the *tri*-linear map

$$\mathbb{I}(X, Y, Z) = \langle \mathcal{L}(X, Y), Z \rangle.$$

Naturally, when $f: M \rightarrow \mathbb{R}^3$ is an immersion, we define the **special affine second fundamental form** \mathbb{I}_f of f to be $f^* \mathbb{I}$, where \mathbb{I} is the special affine second fundamental form of $f(M)$. For $f: U \rightarrow \mathbb{R}^3$ (with $U \subset \mathbb{R}^2$ open), we write the form \mathbb{I}_f as

$$\mathbb{I}_f = \sum_{i,j,k=1}^2 \ell_{ijk} ds^i \otimes ds^j \otimes ds^k.$$

Since the components of \mathbb{I}_f have three indices, there is no possibility of confusing the ℓ_{ijk} with the l_{ij} (if things hadn't worked out like this, I think I would have committed suicide at this point). We also write

$$\mathcal{L}(f_i, f_j) = \sum_{k=1}^2 \ell_{ij}^k f_k,$$

so that

$$\begin{aligned} \ell_{ijk} &= \langle \mathcal{L}(f_i, f_j), f_k \rangle = \left\langle \sum_{\rho=1}^2 \ell_{ij}^\rho f_\rho, f_k \right\rangle \\ &= \sum_{\rho=1}^2 g_{k\rho} \ell_{ij}^\rho; \end{aligned}$$

equivalently,

$$\ell_{ij}^k = \sum_{\rho=1}^2 g^{k\rho} \ell_{ij\rho}.$$

Suppose that (X_1, X_2) is a positively oriented moving frame on M which is orthonormal for $\langle \cdot, \cdot \rangle$, and let $X_3 = \nu$. For the moment consider the case where all points of M are elliptic. We set

$$c_{ijk} = \mathfrak{T}(X_i, X_j, X_k) = \langle \mathfrak{A}(X_i, X_j), X_k \rangle,$$

so that we have

$$\begin{aligned} \mathfrak{A}(X, Y) &= \sum_{k=1}^2 c_{ijk} \theta^i(X) \theta^j(Y) \cdot X_k \\ c_{ijk} &= c_{jik}. \end{aligned}$$

We also let ω_i^j be the connection forms for the frame X_1, X_2 which are determined by the metric $\langle \cdot, \cdot \rangle$; thus ω_i^j are the unique 1-forms on M satisfying

$$\begin{aligned} d\theta^i &= - \sum_{j=1}^2 \omega_j^i \wedge \theta^j \\ \omega_j^i &= -\omega_i^j. \end{aligned}$$

Since

$$\nabla' X_i = \nabla_X X_i + \mathfrak{A}(X_i, X),$$

we have

$$\psi_i^k(X) = \omega_i^k(X) + \sum_{j=1}^2 c_{ijk} \theta^j(X)$$

and hence

$$(1) \quad \psi_i^k = \omega_i^k + \sum_{j=1}^2 c_{ijk} \theta^j.$$

Since $\omega_i^k = -\omega_k^i$, we obtain

$$(2) \quad \psi_i^k + \psi_k^i = \sum_{j=1}^2 (c_{ijk} + c_{kji}) \theta^j.$$

(As usual, these formulas are understood as formulas on TM). From this we immediately deduce

15. PROPOSITION. The tensor \mathfrak{s} satisfies the “apolarity condition”

$$\text{trace}(X \mapsto \mathfrak{s}(X, Y)) = 0.$$

In terms of a map $f: U \rightarrow \mathbb{R}^3$ we have

$$0 = \sum_{i,k=1}^2 g^{ik} \ell_{ijk} = \sum_{i,k=1}^2 g^{ik} \ell_{jik};$$

in other words, the quadratic form determined by $\langle \cdot, \cdot \rangle_p$ is apolar to the cubic form determined by $\mathfrak{I}(p)$.

PROOF. For our moving frame (X_1, X_2, X_3) we have $\psi_1^1 + \psi_2^2 + \psi_3^3 = 0$, and also $\psi_3^3 = 0$, so $\psi_1^1 + \psi_2^2 = 0$. Using equation (2), this gives

$$\begin{aligned} 0 = \sum_{j=1}^2 \left(\sum_{i=1}^2 c_{iji} \right) \theta^j &\implies 0 = \sum_{i=1}^2 c_{iji} \\ &= \sum_{i=1}^2 \langle \mathfrak{s}(X_i, X_j), X_i \rangle \\ &= \text{trace}(X \mapsto \mathfrak{s}(X, X_j)). \end{aligned}$$

Similar, but slightly more involved, computations give the same result in the hyperbolic case. The second part of the Proposition is merely a restatement of the first, as we easily compute by using Fact 0. ♦

By bringing in the structural equations, we obtain one other important piece of information.

16. PROPOSITION. The tensor \mathfrak{I} is symmetric in all three arguments; equivalently,

$$\langle \mathfrak{s}(X, Y), Z \rangle = \langle \mathfrak{s}(X, Z), Y \rangle.$$

In terms of a map $f: U \rightarrow \mathbb{R}^3$ we have

$$\ell_{ijk} = \ell_{ikj}.$$

PROOF. Again we consider only the elliptic case, and leave the hyperbolic case to the reader. From equation (2) on page 106 we obtain

$$(1) \quad \sum_{k=1}^2 \psi_i^k \wedge \theta^k + \sum_{k=1}^2 \psi_k^i \wedge \theta^k = \sum_{j,k=1}^2 (c_{ijk} + c_{kji}) \theta^j \wedge \theta^k.$$

Now

$$(2) \quad \sum_{k=1}^2 \psi_k^i \wedge \theta^k = -d\theta^i$$

by the first structural equation. But we also have $\psi_i^3 = \theta^i$, so we also get

$$(3) \quad \begin{aligned} d\theta^i &= d\psi_i^3 = -\sum_{k=1}^2 \psi_k^3 \wedge \psi_i^k \quad (\text{since } \psi_3^3 = 0) \\ &= -\sum_{k=1}^2 \theta^k \wedge \psi_i^k = \sum_{k=1}^2 \psi_i^k \wedge \theta^k. \end{aligned}$$

From (1), (2), (3) we have

$$0 = \sum_{j,k=1}^2 (c_{ijk} + c_{kji}) \theta^j \wedge \theta^k,$$

so for each i, j, k we have

$$\begin{aligned} 0 &= c_{ijk} + c_{kji} - c_{ikj} - c_{jki} \\ &= c_{ijk} - c_{ikj}. \quad \spadesuit \end{aligned}$$

From the apolarity conditions we can now easily obtain an explicit formula for the vector field \mathcal{N} along a map $f: U \rightarrow \mathbb{R}^3$. We write the special affine Gauss formulas as

$$\begin{aligned} f_{ij} &= \nabla_{f_i} f_j + \mathfrak{s}(f_i, f_j) + g_{ij} \mathcal{N} \\ &= \sum_{k=1}^2 \Gamma_{ij}^k f_k + \sum_{k=1}^2 \ell_{ij}^k f_k + g_{ij} \mathcal{N}, \end{aligned}$$

where the Γ_{ij}^k are the Christoffel symbols for the metric $\langle \cdot, \cdot \rangle$, and hence computable in terms of the g_{ij} . Now

$$\sum_{i,j=1}^2 g^{ij} g_{ij} = 2,$$

so we have

$$\begin{aligned}\mathcal{N} &= \frac{1}{2} \sum_{i,j=1}^2 g^{ij} \left(f_{ij} - \sum_{k=1}^2 \Gamma_{ij}^k f_k - \sum_{k=1}^2 \ell_{ij}^k f_k \right) \\ &= \frac{1}{2} \sum_{i,j=1}^2 g^{ij} \left(f_{ij} - \sum_{k=1}^2 \Gamma_{ij}^k f_k \right) - \frac{1}{2} \sum_{i,j=1}^2 \sum_{k,\rho=1}^2 g^{ij} g^{k\rho} \ell_{ij\rho} \\ &= \frac{1}{2} \sum_{i,j=1}^2 g^{ij} \left(f_{ij} - \sum_{k=1}^2 \Gamma_{ij}^k f_k \right),\end{aligned}$$

using Proposition 15 and the fact that $\ell_{ij\rho} = \ell_{\rho ij}$, by Proposition 16. This equation means that each component \mathcal{N}^α of \mathcal{N} is given by

$$(II) \quad \mathcal{N}^\alpha = \frac{1}{2} \sum_{i,j=1}^2 g^{ij} \left(f_{ij}^\alpha - \sum_{k=1}^2 \Gamma_{ij}^k f_k^\alpha \right) \quad \alpha = 1, 2, 3.$$

Notice that the partial derivatives f_i^α are the components of the vector field df^α on U . So the tensor $\nabla(df^\alpha)$ of type $\binom{2}{0}$ has components (pg. II.210)

$$f_{i;j}^\alpha = f_{ij}^\alpha - \sum_{k=1}^2 \Gamma_{ij}^k f_k^\alpha.$$

[In Chapter 1 we wrote $f_{;i}$ instead of f_i for $\partial f / \partial x^i$, but when we are dealing with the standard coordinate system on \mathbb{R}^2 we will revert to the standard subscript notation for partial derivatives; we use $;$ rather than $'$ to emphasize that we are using the covariant derivative ∇ .] We can therefore also write

$$(II') \quad \mathcal{N}^\alpha = \frac{1}{2} \sum_{i,j=1}^2 g^{ij} f_{i;j}^\alpha.$$

Our formula is rather complicated, but it involves only quantities computable in terms of the g_{ij} 's, and hence ultimately in terms of f : in Addendum 1 to Chapter 7 we will have a little more to say about it.

With our present proof of Proposition 15, the fact that our fundamental forms \mathbf{I}, \mathbf{II} satisfy the same apolarity conditions which we used to *define* \mathbf{II} works out as some sort of miracle. So it will perhaps be reassuring to see this fact demonstrated by a computation, which will also be useful later. We will assume that $p = 0 \in \mathbb{R}^3$, the tangent plane M_p is the (x, y) -plane, and the z -axis is the affine

normal direction at p . Then M is the image of an immersion $f(s, t) = (s, t, h(s, t))$ with $h(0, 0) = h_1(0, 0) = h_2(0, 0) = 0$, and h satisfies the apolarity conditions

$$(1) \quad 0 = d(\det h_{ij}) \quad \text{at } (0, 0).$$

Now $\nabla'_{f_i} f_j = (0, 0, h_{ij})$, and the tangential projection \mathfrak{T} at 0 is just the ordinary projection on the (x, y) -plane, so $\mathfrak{T}\nabla'_{f_i} f_j = 0$ at p . Consequently, $\mathfrak{A}(f_i, f_j) = -\nabla_{f_i} f_j$ at $(0, 0)$, which gives

$$\begin{aligned} (2) \quad \ell_{ijk} &= \langle \mathfrak{A}(f_i, f_j), f_k \rangle = -\langle \nabla_{f_i} f_j, f_k \rangle && \text{at } (0, 0) \\ &= -\sum_{\rho=1}^2 \Gamma_{ij}^{\rho} \langle f_{\rho}, f_k \rangle = -\sum_{\rho=1}^2 g_{\rho k} \Gamma_{ij}^{\rho} && \text{at } (0, 0) \\ &= -[ij, k] && \text{at } (0, 0) \end{aligned}$$

where $[ij, k]$ are Christoffel symbols for \mathfrak{I}_f . To compute them, we note that

$$\begin{aligned} \frac{\partial g_{ij}}{\partial s^k} &= \frac{\partial}{\partial s^k} [d_{ij} \cdot (\det(d_{ij}))^{-1/4}] && \text{at } (0, 0) \\ &= (\det(d_{ij}))^{-1/4} \frac{\partial d_{ij}}{\partial s^k} && \text{at } (0, 0) \text{ by (1)} \\ &= (\det(d_{ij}))^{-1/4} \frac{\partial}{\partial s^k} \det(f_1, f_2, f_{ij}) && \text{at } (0, 0) \\ &= (\det(d_{ij}))^{-1/4} [\det(f_{1k}, f_2, f_{ij}) + \det(f_1, f_{2k}, f_{ij}) \\ &\quad + \det(f_1, f_2, f_{ijk})] && \text{at } (0, 0) \\ &= (\det(d_{ij}(0, 0)))^{-1/4} [0 + 0 + h_{ijk}(0, 0)], \end{aligned}$$

since each f_{ij} has its first 2 components equal 0 at $(0, 0)$. Thus

$$\begin{aligned} [ij, k](0, 0) &= \frac{1}{2} \left(\frac{\partial g_{ik}}{\partial s^j} + \frac{\partial g_{jk}}{\partial s^i} - \frac{\partial g_{ij}}{\partial s^k} \right) (0, 0) \\ &= \frac{(h_{ikj} + h_{jki} - h_{ijk})}{2 \cdot \sqrt[4]{\det(d_{ij})}} (0, 0), \end{aligned}$$

and (2) becomes

$$(3) \quad \ell_{ijk}(0, 0) = -\frac{h_{ijk}(0, 0)}{2 \cdot \sqrt[4]{\det(d_{ij}(0, 0))}}.$$

This demonstrates Propositions 15 and 16 (since we can always make the z -axis the direction of the affine normal direction by a suitable special affine linear map, and the assertions in question are invariant under such maps).

In ordinary surface theory we used $\mathbf{I}(p)$ and $\mathbf{II}(p)$ to define two numerical invariants, the principal curvatures $k_1(p), k_2(p)$ [or equivalently $K(p)$ and $H(p)$]. These invariants arise quite naturally from an algebraic point of view, as the invariants of a 2×2 symmetric matrix S under the map $S \mapsto A^{-1}SA$, for 2×2 orthogonal matrices A . Geometrically, these invariants arise when we describe the osculating paraboloid of M (using the ordinary normal ν_p as the third axis)—for $p \in M \subset \mathbb{R}^3$ and $p' \in M' \subset \mathbb{R}^3$ we have $\{k_1(p), k_2(p)\} = \{k_1(p'), k_2(p')\}$ if and only if there is a special orthogonal affine map $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ which takes the osculating paraboloid P at p onto the osculating paraboloid P' at p' . In special affine surface theory we now want to use $\mathbf{I}(p)$ and $\mathbf{II}(p)$ to determine numerical invariants. Algebraically, we are asking for invariants of a cubic form Ψ under the map $\Psi \mapsto \bar{\Psi}$, where

$$\bar{\Psi}_{\alpha\beta\gamma} = \sum_{j,k,l=1}^2 \Psi_{jkl} a_{j\alpha} a_{k\beta} a_{l\gamma}$$

for 2×2 matrices A which preserve a certain quadratic form Φ . In the olden days when mighty invariant theory held sway over most of the domains of mathematics, this question was as natural to consider as the first, and one could probably preface the answer with the standard refrain “As every undergraduate knows . . .”. Nowadays, of course, not even graduate students know, or care, what the invariants for cubic forms are. Instead of describing them algebraically, we pass immediately to the (equivalent) geometric problem. For each $p \in M$ we have the function $\Phi + \Psi: M_p \rightarrow \mathbb{R}$ obtained by looking at the second and third order terms in the Taylor series for the function which describes M in the X_1, X_2, ν_p coordinate system, for any basis X_1, X_2 of M_p (which one doesn't matter). We will call the graph S of $\Phi + \Psi$ in the X_1, X_2, ν_p coordinate system the **osculating cubic** at p , and we want to classify these osculating cubics up to special linear affine maps.

17. PROPOSITION. Let S be the osculating cubic at a point p of a surface $M \subset \mathbb{R}^3$. If p is an elliptic point, then there is a special linear affine map $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ such that $A(S) \subset \mathbb{R}^3$ is the graph (in the ordinary coordinate system for \mathbb{R}^3) of the function

$$(a) \quad (s, t) \mapsto \frac{1}{2}(s^2 + t^2) + \frac{C}{6}(s^3 - 3st^2), \quad \text{for some } C.$$

If p is a hyperbolic point, then we can choose A so that $A(S)$ is the graph of one of the three functions

$$(b1) \quad (s, t) \mapsto \frac{1}{2}(s^2 - t^2) + \frac{C}{6}(s^3 + 3st^2)$$

$$(b2) \quad (s, t) \mapsto \frac{1}{2}(s^2 - t^2) + \frac{C}{6}(t^3 + 3ts^2)$$

$$(c) \quad (s, t) \mapsto \frac{1}{2}(s^2 - t^2) + \frac{1}{6}(s + t)^3;$$

we can also choose A so that $A(S)$ is the graph of one of the two functions

$$(b') \quad (s, t) \mapsto st + \frac{D}{6}(s^3 + t^3)$$

$$(c') \quad (s, t) \mapsto st + \frac{1}{6}s^3.$$

Remark: Changing from (b1) to (b2) involves interchanging the first two axes of \mathbb{R}^3 while leaving the third axis fixed, so we need both forms unless we allow maps $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ of the form $A = T \circ B$ with T a translation and $\det B = \pm 1$. Alternatively, we can make do with only one of these forms if we allow ourselves to change the orientation of M , and hence the direction of ν_p .

PROOF. We might as well assume that $p = 0 \in \mathbb{R}^3$, the tangent plane M_p is the (x, y) -plane, the affine normal ν_p is $(0, 0, 1)$, and the vectors $(1, 0)$ and $(0, 1)$ are an orthonormal basis of M_p ; for it is clear that the image of M under a suitable special linear affine map will have this property. Then M is the image of an immersion $f(s, t) = (s, t, h(s, t))$ with $h(0, 0) = h_1(0, 0) = h_2(0, 0) = 0$; since the z -axis is the affine normal direction, the apolarity conditions become

$$(*) \quad \begin{cases} h_{22}h_{111} - 2h_{12}h_{112} + h_{11}h_{122} = 0 \\ h_{22}h_{112} - 2h_{12}h_{122} + h_{11}h_{222} = 0 \end{cases} \quad \text{at } (0, 0).$$

Suppose that p is an elliptic point. The fact that $\nu_p = (0, 0, 1)$ and the basis $(1, 0, 0), (0, 1, 0)$ is orthonormal, means that $h_{ij}(0, 0) = \delta_{ij}$. So $(*)$ becomes

$$h_{111} + h_{122} = 0 \quad \text{and} \quad h_{112} + h_{222} = 0 \quad \text{at } (0, 0),$$

and S is the graph of a function of the form

$$(s, t) \mapsto \frac{1}{2}(s^2 + t^2) + \frac{1}{6}(as^3 + 3bs^2t - 3ast^2 - bt^3).$$

Now suppose we apply one more special linear (in fact, special orthogonal) transformation

$$(1) \quad (\sigma, \tau, z) \mapsto (\sigma \cos \theta - \tau \sin \theta, \sigma \sin \theta + \tau \cos \theta, z).$$

The image of S under this map is the graph of

$$(s, t) \mapsto \frac{1}{2}([s \cos \theta - t \sin \theta]^2 + [s \sin \theta + t \cos \theta]^2) \\ + \frac{1}{6}(a[s \cos \theta - t \sin \theta]^3 + \cdots),$$

which works out to be

$$(2) \quad (s, t) \mapsto \frac{1}{2}(s^2 + t^2) + \frac{1}{6}(a^*s^3 + 3b^*s^2t - 3a^*st^2 - b^*t^3),$$

where

$$(3) \quad \begin{cases} a^* = a \cos^3 \theta + 3b \cos^2 \theta \sin \theta - 3a \cos \theta \sin^2 \theta - b \sin^3 \theta \\ b^* = b \cos^3 \theta - 3a \cos^2 \theta \sin \theta - 3b \cos \theta \sin^2 \theta + a \sin^3 \theta. \end{cases}$$

To obtain the desired form (a), we just have to choose θ so that $b^* = 0$, which can be done by choosing θ so that $\cot \theta$ is a solution of the equation

$$b(\cot \theta)^3 - 3a(\cot \theta)^2 - 3b(\cot \theta) + a = 0.$$

Now suppose that p is a hyperbolic point. Then $h_{11}(0, 0) = -h_{22}(0, 0) = 1$ and $h_{12}(0, 0) = 0$. So (*) becomes

$$h_{122} = h_{111} \quad \text{and} \quad h_{222} = h_{112} \quad \text{at } (0, 0),$$

and S is the graph of a function of the form

$$(4) \quad (s, t) \mapsto \frac{1}{2}(s^2 - t^2) + \frac{1}{6}(as^3 + 3bs^2t + 3ast^2 + bt^3).$$

We might as well assume that $a, b \neq 0$, for otherwise we already have the form (b1) or (b2). We apply one more special linear transformation

$$(5) \quad (\sigma, \tau, z) \mapsto (\sigma \cosh u + \tau \sinh u, \sigma \sinh u + \tau \cosh u, z).$$

The image of S under this map works out to be the graph of

$$(s, t) \mapsto \frac{1}{2}(s^2 - t^2) + \frac{1}{6}(a^*s^3 + 3b^*s^2t + 3a^*st^2 + b^*t^3),$$

where

$$(6) \quad \begin{cases} a^* = a \cosh^3 u + 3b \cosh^2 u \sinh u + 3a \cosh u \sinh^2 u + b \sinh^3 u \\ b^* = b \cosh^3 u + 3a \cosh^2 u \sinh u + 3b \cosh u \sinh^2 u + a \sinh^3 u. \end{cases}$$

To obtain the form (b1), we have to find u so that $v = \coth u = (\cosh u)/(\sinh u)$ satisfies the equation

$$(7) \quad bv^3 + 3av^2 + 3bv + a = 0.$$

Now \coth does not take on all values, for the odd function

$$\coth u = \frac{\cosh u}{\sinh u} = \frac{e^u + e^{-u}}{e^u - e^{-u}} = \frac{e^{2u} + 1}{e^{2u} - 1}$$

is clearly > 1 for $u > 0$, and hence < -1 for $u < 0$. It is easy to see that \coth actually takes on all values except those in $[-1, 1]$. So we can obtain the

form (b1) if equation (7) has a real root which is not in $[-1, 1]$. This certainly happens if the values of $bv^3 + 3av^2 + 3bv + a$ are either both positive or both negative at $v = 1$ and $v = -1$. So we can obtain (b1) if

$$(8) \quad 4a + 4b \text{ and } 4a - 4b \text{ are both } > 0 \text{ or both } < 0.$$

But similarly, we can obtain (b2) if the values of $av^3 + 3bv^2 + 3av + b$ are both positive or both negative at $v = 1$ and $v = -1$, i.e., if

$$(9) \quad 4a + 4b \text{ and } 4b - 4a \text{ are both } > 0 \text{ or both } < 0.$$

Clearly, either (8) or (9) must hold if $a \neq \pm b$. Thus (b1) or (b2) can be obtained when $a \neq \pm b$. We note right away that (b') is obtained from (b1) by considering the special linear transformation

$$(10) \quad (\sigma, \tau, z) \mapsto \left(\frac{\sigma + \tau}{\sqrt{2}}, \frac{-(\sigma - \tau)}{\sqrt{2}}, z \right),$$

the constant D being $-C\sqrt{2}$. Similarly, (b') is obtained from (b2) by considering the special linear transformation

$$(11) \quad (\sigma, \tau, z) \mapsto \left(\frac{\sigma - \tau}{\sqrt{2}}, \frac{\sigma + \tau}{\sqrt{2}}, z \right),$$

the constant D being $+C\sqrt{2}$.

When we have $a = \pm b$, then our original function (4) is

$$(s, t) \mapsto \frac{1}{2}(s^2 - t^2) + \frac{a}{6}(s \pm t)^3.$$

The transformation (11) or (10) will change this to

$$(s, t) \mapsto st + \frac{a'}{6}s^3.$$

If $a' = 0$, this is a special case of (b'). Otherwise, we can make $a' = 1$, and thus achieve (c'), by a transformation which changes s to $s/\sqrt[3]{a'}$, and t to $\sqrt[3]{a'}t$. Since we can achieve (c'), we can now achieve (c) by using the inverse of the transformation (11). ♦

Notice that in case (a), the cubic part of S is just (a multiple of) the monkey saddle. Implicit in the previous Proposition is a geometric interpretation of apolarity when $\Phi: V \rightarrow \mathbb{R}$ corresponds to a positive definite inner product on a 2-dimensional vector space V . The cubic form $\Psi: V \rightarrow \mathbb{R}$ is apolar to Φ when the set $\Psi^{-1}(0)$ consists of three lines that make angles of $\pi/3$ with each other (in the inner product on V corresponding to Φ). It is clear that if we apply a rotation around the z -axis through an angle of $\pi/3$ or $2\pi/3$, then $A(S)$ will go into itself, so in case (a) the affine linear map A is not unique. We can also change C to $-C$ in (a) by rotation through an angle of π , which changes s to $-s$ and t to $-t$; the same change occurs if we rotate through an angle of $\pi + \pi/3$ or $\pi + 2\pi/3$. If $C = 0$, then we can apply any rotation around the z -axis. However, from equations (3) it is easy to see that this is the only extent to which A and C are not unique.

In the hyperbolic case, if we can obtain (b1) or (b2) with one constant $C \neq 0$, then we can also achieve this form with $-C$ by applying the rotation $(\sigma, \tau, z) \mapsto (-\sigma, -\tau, z)$. On the other hand, it is easy to see that this is the only other constant we can obtain, and that there is precisely one A which will make $A(S)$ have each of these forms. When $C = 0$, then we can always compose A with any transformation of the form

$$(\sigma, \tau, z) \mapsto (\pm[\sigma \cosh u + \tau \sinh u], \pm[\sigma \sinh u + \tau \cosh u], z).$$

Bearing these remarks in mind, we see that Proposition 17 allows us to define a single new invariant: If p is a point of M for which the osculating cubic S has the form (a), (b1), or (b2) for some number C (unique up to sign), we define the **Pick invariant** J at p by

$$J = \frac{C^2}{2};$$

if the osculating cubic has the form (c), we define J to be 0.

It would be nice to have a straightforward invariant description of J in terms of the forms \mathbf{I} , \mathbf{II} , and it can be obtained as follows. Given an inner product $\langle \cdot, \cdot \rangle$ on a vector space V , we can use it to define an inner product $\langle \cdot, \cdot \rangle$ on the vector space of all trilinear maps $\alpha: V \times V \times V \rightarrow \mathbb{R}$. Instead of describing this completely invariantly, let us consider a basis v_1, \dots, v_n of V and let $\gamma_{ij} = \langle v_i, v_j \rangle$. The matrix (γ_{ij}) is non-singular, and has an inverse matrix (γ^{ij}) . Given two trilinear maps $\alpha, \beta: V \times V \times V \rightarrow \mathbb{R}$, let $\alpha_{ijk} = \alpha(v_i, v_j, v_k)$ and $\beta_{ijk} = \beta(v_i, v_j, v_k)$. Then

$$\langle \alpha, \beta \rangle = \sum_{i,j,k=1}^n \sum_{\rho,\sigma,\tau=1}^n \alpha_{ijk} \beta_{\rho\sigma\tau} \gamma^{i\rho} \gamma^{j\sigma} \gamma^{k\tau}.$$

If v_1, \dots, v_n is orthonormal with respect to $\langle \cdot, \cdot \rangle$, then we have simply

$$\langle \alpha, \beta \rangle = \sum_{i,j,k=1}^n \alpha_{ijk} \beta_{ijk}.$$

The reader may easily check that this definition does not depend on the choice of basis, or else fashion an invariant definition.

18. PROPOSITION. For a point p of a surface $M \subset \mathbb{R}^3$, the Pick invariant $J(p)$ is

$$J(p) = \frac{1}{2} \langle \mathbf{II}(p), \mathbf{II}(p) \rangle_p,$$

where $\langle \cdot, \cdot \rangle_p$ is the inner product on all trilinear maps on M_p determined by the inner product $\langle \cdot, \cdot \rangle_p$ on M_p .

If $f: U \rightarrow \mathbb{R}^3$ is an immersion, then

$$J = \frac{1}{2} \sum_{i,j,k=1}^2 \sum_{\rho,\sigma,\tau=1}^2 f_{ijk} f_{\rho\sigma\tau} g^{i\rho} g^{j\sigma} g^{k\tau}.$$

PROOF. It suffices to consider the case where $M = \{(s, t, h(s, t))\}$, the point p is $0 \in \mathbb{R}^3$, and the osculating cubic S has one of the forms (a)–(c) in Proposition 17. In case (a) we thus have

$$\begin{aligned} h(0, 0) &= h_i(0, 0) = 0, \\ h_{ij}(0, 0) &= \delta_{ij}, \\ h_{111}(0, 0) &= C, \\ h_{211}(0, 0) &= h_{121}(0, 0) = h_{112}(0, 0) = -C, \quad \text{all other } h_{ijk}(0, 0) = 0, \end{aligned}$$

with similar equations in cases (b1), (b2), (c). We can compute the $g_{ij}(0, 0)$ from equation (I) on page 90 and the $\ell_{ijk}(0, 0)$ from equation (3) on page 110. It is then a simple calculation to check that we do indeed have

$$\begin{aligned} J(p) &= \frac{1}{2} \sum_{i,j,k=1}^2 \sum_{\rho,\sigma,\tau=1}^2 \ell_{ijk} \ell_{\rho\sigma\tau} g^{i\rho} g^{j\sigma} g^{k\tau} \quad \text{at } (0, 0) \\ &= \frac{1}{2} \{\mathfrak{I}(p), \mathfrak{I}(p)\}_p. \end{aligned}$$

Since both sides of our formula have an invariant meaning, the formula must be true for any coordinate system. ♦

Notice also that for a moving frame X_1, X_2 as on page 106 we have

$$J = \frac{1}{2} \sum_{i,j,k} (c_{ijk})^2$$

in the elliptic case, with a similar formula in the hyperbolic case.

Now that we have obtained the invariant J , there is an obvious question staring us in the face: what are the surfaces with $J = 0$ everywhere? In ordinary surface theory we found that surfaces with $k_1 = k_2 = 0$ everywhere are planes. It seems natural to conjecture that the surfaces with $J = 0$ everywhere are just the surfaces which can be described by quadratic equations. Now this isn't true, and the reason is essentially because we have $J = 0$ in case (c) of Proposition 17. In cases (a), (b1), (b2), the vanishing of $J(p)$ implies the vanishing of $\mathfrak{I}(p)$ [as is also clear in case (a) from Proposition 18]. Leaving the complexities which arise because of case (c) to later Problems (4-14, 15), we restrict our attention to surfaces with $\mathfrak{I} = 0$ everywhere.

19. PROPOSITION. If $M \subset \mathbb{R}^3$ is a connected surface with all points elliptic or all points hyperbolic, and $\mathfrak{I} = 0$ on M , then M is a quadratic surface, that is, $M = W^{-1}(0)$ for some $W: \mathbb{R}^3 \rightarrow \mathbb{R}$ of the form

$$W(x_1, x_2, x_3) = \sum_{i,j} a_{ij} x_i x_j + \sum_i b_i x_i + c.$$

(These surfaces are described in greater detail in the next chapter; at the moment it is only necessary to note that the affine linear image of a quadratic surface is also a quadratic surface.)

Conversely, every non-flat quadratic surface has $\mathfrak{I} = 0$ everywhere.

PROOF. As usual, we consider only the elliptic case. Take a moving frame X_1, X_2, X_3 on M as on page 106. If $\mathfrak{I} = 0$, then all $c_{ijk} = 0$, so equation (I) on page 106 shows that

$$\psi_j^i = \omega_j^i,$$

and in particular

$$\psi_j^i = -\psi_i^j.$$

This implies that

$$d\psi_j^i + \sum_{k=1}^2 \psi_k^i \wedge \psi_j^k = -\left(d\psi_i^j + \sum_{k=1}^2 \psi_k^j \wedge \psi_i^k\right).$$

But

$$\begin{aligned} \text{(I)} \quad d\psi_j^i &= -\sum_{k=1}^2 \psi_k^i \wedge \psi_j^k - \psi_3^i \wedge \psi_j^3 \\ &= -\sum_{k=1}^2 \psi_k^i \wedge \psi_j^k - \psi_3^i \wedge \theta^j, \end{aligned}$$

so we obtain

$$\psi_3^i \wedge \theta^j = -(\psi_3^j \wedge \theta^i).$$

Taking $i = j$, we see that ψ_3^i is a multiple of θ^i , and taking $i \neq j$ we see that the multiples are the same for each i , so we have

$$\text{(2)} \quad \psi_3^i = \alpha \cdot \theta^i$$

for some function α . Taking d of equation (2) gives

$$\begin{aligned} -\sum_{k=1}^2 \psi_k^i \wedge \psi_3^k &= d\psi_3^i = d\alpha \wedge \theta^i + \alpha d\theta^i \\ &\Downarrow \\ -\sum_{k=1}^2 \psi_k^i \wedge \alpha \cdot \theta^k &= d\alpha \wedge \theta^i - \alpha \left(\sum_{k=1}^2 \psi_k^i \wedge \theta^k \right), \end{aligned}$$

and hence

$$d\alpha \wedge \theta^i = 0.$$

Thus $d\alpha = 0$, and α is a constant. We consider two cases.

Case 1. $\alpha = 0$. Equation (2) shows that $\psi_3^i = 0$, so for tangent vectors X on M we have

$$\nabla'_X v = \nabla'_X X_3 = \sum_{i=1}^2 \psi_3^i(X) \cdot X_i = 0,$$

i.e., v is constant; we will use it as one of our axes. We also have, by (1),

$$d\psi_j^i = -\sum_{k=1}^2 \psi_k^i \wedge \psi_j^k.$$

Since $\psi_j^i = \omega_j^i$, which are the connection forms for the metric $\langle \cdot, \cdot \rangle$, this equation shows that $\langle \cdot, \cdot \rangle$ is *flat*. So we could have chosen our orthonormal moving frame X_1, X_2 to be of the form $X_i = f_i$ for some isometry $f: U \rightarrow \mathbb{R}^3$, where $U \subset \mathbb{R}^2$ has the standard Riemannian metric; and with this choice we have $\psi_j^i = \omega_j^i = 0$. Now we have

$$\begin{aligned} f_{ij} = \nabla'_{f_j} f_i &= \sum_{k=1}^2 \psi_i^k(f_j) \cdot f_k + \psi_i^3(f_j) \cdot v \\ &= 0 + \theta^i(f_j)v = \delta_{ij}v. \end{aligned}$$

So f is of the form

$$f(s, t) = c + b_1 s + b_2 t + \frac{1}{2}(s^2 + t^2)v$$

for constants b_1, b_2, c .

Case 2. $\alpha \neq 0$. Now equation (2) shows that

$$\nabla'_X v = \sum_{i=1}^2 \alpha \theta^i(X) \cdot X_i = \alpha X.$$

So for any $f: U \rightarrow M \subset \mathbb{R}^3$ we have

$$\mathcal{N}_i = \alpha f_i \implies \mathcal{N} = \alpha f + \beta \implies f = \frac{1}{\alpha}(\mathcal{N} - \beta)$$

for some constant vector β . Hence it suffices to show that v satisfies a quadratic equation.

Let \mathbf{X} be the 3×3 matrix

$$\mathbf{X} = (X_1, X_2, X_3) = (X_1, X_2, v)$$

where the X_i are considered as column vectors. Then $d\mathbf{X}$ is given in terms of the 3×3 matrix $\psi = (\psi_\beta^\alpha)$ as

$$(1) \quad d\mathbf{X} = \mathbf{X} \cdot \psi.$$

Since ψ is actually

$$\psi = \begin{pmatrix} \psi_1^1 & \psi_2^1 & \alpha\theta^1 \\ \psi_1^2 & \psi_2^2 & \alpha\theta^2 \\ \theta^1 & \theta^2 & 0 \end{pmatrix}, \quad \psi_j^i = -\psi_i^j,$$

we easily see that if we set

$$A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -\frac{1}{\alpha} \end{pmatrix},$$

then

$$(2) \quad \psi \cdot A + A \cdot \psi^t = 0.$$

Thus we have

$$\begin{aligned} d(\mathbf{X} \cdot A \cdot \mathbf{X}^t) &= d\mathbf{X} \cdot A \cdot \mathbf{X}^t + \mathbf{X} \cdot A \cdot d\mathbf{X}^t \\ &= \mathbf{X} \cdot \psi \cdot A \cdot \mathbf{X}^t + \mathbf{X} \cdot A \cdot \psi^t \cdot \mathbf{X}^t && \text{by (1)} \\ &= 0 && \text{by (2)}. \end{aligned}$$

We can assume that \mathbf{X} is the identity matrix at some point, so we obtain

$$\begin{aligned} \mathbf{X} \cdot A \cdot \mathbf{X}^t &= A \implies (A^{-1} \cdot \mathbf{X} \cdot A) \cdot \mathbf{X}^t = \text{identity} \\ &\implies \mathbf{X}^t \cdot (A^{-1} \cdot \mathbf{X} \cdot A) = \text{identity} \\ &\implies \mathbf{X}^t \cdot A^{-1} \cdot \mathbf{X} = A^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -\alpha \end{pmatrix}. \end{aligned}$$

The (3, 3) entry of this equation gives

$$\mathbf{v} \cdot A^{-1} \cdot \mathbf{v}^t = -\alpha,$$

which is a quadratic equation for \mathbf{v} .

It is not hard to show, conversely, that all surfaces of the sort we have obtained have $\mathfrak{I} = 0$. These are the only non-flat quadrics (see Problem 3-6). ♦

We proceed in our study of special affine surface theory along the very same route followed in ordinary surface theory, by looking for the equations expressing the derivatives of a moving frame X_1, X_2, \mathbf{v} in terms of this frame, and by looking at the integrability conditions for these equations. We will always work only with the elliptic case, leaving the hyperbolic case to the reader. We already have the analogue of the Gauss formulas,

$$\nabla'_X Y = \nabla_X Y + \mathfrak{A}(X, Y) + \langle X, Y \rangle \mathbf{v},$$

or in terms of a map $f: U \rightarrow \mathbb{R}^3$,

$$\begin{aligned} f_{ij} &= \nabla_{f_i} f_j + \mathfrak{A}(f_i, f_j) + g_{ij} \mathcal{N} \\ &= \sum_{k=1}^2 \Gamma_{ij}^k f_k + \sum_{i=1}^2 \ell_{ij}^k f_k + g_{ij} \mathcal{N}; \end{aligned}$$

in terms of a moving frame (X_1, X_2, \mathbf{v}) with X_1, X_2 orthonormal for $\langle \cdot, \cdot \rangle$ we have

$$\psi_i^j = \omega_i^j + \sum_{k=1}^2 c_{ijk} \theta^k, \quad \psi_i^3 = \theta^i.$$

The strange way in which the special affine Gauss formulas interchange the roles of $\mathfrak{T} \nabla'_X Y$ and $\mathfrak{L} \nabla'_X Y$, as compared to the ordinary Gauss formulas, will be reflected by funny twists throughout the development.

The next thing we seek is an analogue of the Weingarten equations. Now we know that

$$\nabla'_{X_p} \nu \in M_p,$$

so for a map $f: U \rightarrow \mathbb{R}^3$ we always have

$$\mathcal{N}_i = \sum_{j=1}^2 \mathfrak{b}_i^j f_j$$

for certain functions \mathfrak{b}_i^j with

$$\langle n_i, f_j \rangle = \sum_{\rho=1}^2 \mathfrak{b}_i^\rho g_{\rho j} = \mathfrak{b}_{ij}, \quad \text{say;}$$

for our moving frame we have

$$\nabla'_X \nu = \nabla'_X X_3 = \sum_{i=1}^2 \psi_3^i(X) \cdot X_i.$$

Unlike the situation in ordinary surface theory however, it is not at all clear how, or even whether, the \mathfrak{b}_i^j and \mathfrak{b}_{ij} are related to the ℓ_{ijk} . This is answered in a very unexpected way when we look at the integrability conditions for the special affine Gauss equations. These can be derived from the formulas for f_{ij} , exactly as in the first part of this chapter, or from the formulas for $\nabla'_X Y$, as in Chapter 1. But since the computations are quite involved, no matter how one does them, it will be easiest to use the moving frame version. We begin with the tangential part of these equations,

$$(1) \quad \psi_i^j = \omega_i^j + \sum_{k=1}^2 c_{ijk} \theta^k.$$

We take d of this equation, remembering that $\psi_i^3 = \theta^i$, and introducing the curvature forms Ω_i^j for the ω_i^j , to obtain

$$(2) \quad -\sum_{\rho=1}^2 \psi_\rho^j \wedge \psi_i^\rho - \psi_3^j \wedge \theta^i = -\sum_{\rho=1}^2 \omega_\rho^j \wedge \omega_i^\rho + \Omega_i^j \\ + \sum_{k=1}^2 dc_{ijk} \wedge \theta^k + \sum_{k=1}^2 c_{ijk} d\theta^k.$$

Substituting back from (1) we have

$$\begin{aligned} & - \sum_{\rho} \left\{ \omega_{\rho}^j + \sum_k c_{\rho j k} \theta^k \right\} \wedge \left\{ \omega_i^{\rho} + \sum_k c_{i \rho k} \theta^k \right\} - \psi_3^j \wedge \theta^i \\ & = - \sum_{\rho} \omega_{\rho}^j \wedge \omega_i^{\rho} + \Omega_i^j + \sum_k d c_{i j k} \wedge \theta^k - \sum_{k, \rho} c_{i j k} \omega_{\rho}^k \wedge \theta^{\rho}. \end{aligned}$$

Using $\omega_i^{\rho} = -\omega_{\rho}^i$ and switching dummy indices in the last term, we get

$$\begin{aligned} (3) \quad & - \sum_{\rho, k, l} c_{\rho j k} c_{i \rho l} \theta^k \wedge \theta^l - \psi_3^j \wedge \theta^i \\ & = \Omega_i^j + \sum_k \left[d c_{i j k} - \sum_{\rho} c_{\rho j k} \omega_i^{\rho} - \sum_{\rho} c_{i \rho k} \omega_j^{\rho} - \sum_{\rho} c_{i j \rho} \omega_k^{\rho} \right] \wedge \theta^k. \end{aligned}$$

To interpret equation (3), we apply it to two vectors, X, Y . The first term becomes

$$\begin{aligned} (3a) \quad & \sum_{\rho, k, l} c_{j k \rho} c_{i l \rho} \theta^k(Y) \theta^l(X) - \sum_{\rho, k, l} c_{j k l} c_{i l \rho} \theta^k(X) \theta^l(Y) \\ & = \langle \mathfrak{A}(X_i, X), \mathfrak{A}(X_j, Y) \rangle - \langle \mathfrak{A}(X_i, Y), \mathfrak{A}(X_j, X) \rangle. \end{aligned}$$

The second term becomes

$$\begin{aligned} (3b) \quad & \psi_3^j(Y) \theta^i(X) - \psi_3^j(X) \theta^i(Y) = \langle d v(Y), X_j \rangle \cdot \langle X, X_i \rangle \\ & \quad - \langle d v(X), X_j \rangle \cdot \langle Y, X_i \rangle, \end{aligned}$$

while the first term on the right becomes simply

$$(3c) \quad \langle \mathcal{R}(X, Y) X_i, X_j \rangle,$$

where \mathcal{R} is the curvature tensor for $\langle \cdot, \cdot \rangle$. To interpret the last term, we recall that the tensor

$$\mathfrak{I} = \sum c_{i j k} \theta^i \otimes \theta^j \otimes \theta^k$$

has a covariant derivative $\nabla \mathfrak{I}(X, Y, Z, W) = (\nabla_W \mathfrak{I})(X, Y, Z)$, which can be written

$$\nabla \mathfrak{I} = \sum_{i, j, k, l} c_{i j k, l} \theta^i \otimes \theta^j \otimes \theta^k \otimes \theta^l, \quad \text{say.}$$

Using Corollary I.6-5 one easily checks (Problem 5) that

$$\sum_l c_{ijk;l} \theta^l = dc_{ijk} - \sum_\rho c_{\rho jk} \omega_i^\rho - \sum_\rho c_{i\rho k} \omega_j^\rho - \sum_\rho c_{ij\rho} \omega_k^\rho.$$

So the last term is

$$\sum_{k,l} c_{ijk;l} \theta^l \wedge \theta^k,$$

which when applied to X, Y gives

$$\begin{aligned} (3d) \quad \sum_{k,l} c_{ijk;l} \theta^l(X) \theta^k(Y) - \sum_{k,l} c_{ijk;l} \theta^l(Y) \theta^k(X) \\ = (\nabla_X \mathbb{I})(X_i, X_j, Y) - (\nabla_Y \mathbb{I})(X_i, X_j, X). \end{aligned}$$

Writing (3a) + (3b) = (3c) + (3d), but replacing X_i, X_j by arbitrary tangent vectors Z, W , we thus obtain

$$\begin{aligned} (A) \quad \langle \mathcal{R}(X, Y)Z, W \rangle &= (\nabla_Y \mathbb{I})(W, Z, X) - (\nabla_X \mathbb{I})(W, Z, Y) \\ &\quad + \langle \mathfrak{s}(W, Y), \mathfrak{s}(X, Z) \rangle - \langle \mathfrak{s}(W, X), \mathfrak{s}(Y, Z) \rangle \\ &\quad + \langle d\mathfrak{v}(Y), W \rangle \cdot \langle X, Z \rangle - \langle d\mathfrak{v}(X), W \rangle \cdot \langle Y, Z \rangle. \end{aligned}$$

In terms of a map $f: U \rightarrow \mathbb{R}^3$ this becomes

$$\begin{aligned} \mathcal{R}_{jik\mu} &= \ell_{jik;\mu} - \ell_{ji\mu;k} + \sum_\rho (\ell_{ik}^\rho \ell_{j\rho\mu} - \ell_{i\mu}^\rho \ell_{j\rho k}) \\ &\quad + g_{ik} b_{\mu j} - g_{i\mu} b_{kj}. \end{aligned}$$

Now what do these equations tell us? In ordinary surface theory we obtained the Theorema Egregium, telling us that the intrinsic Gaussian curvature K is equal to some expression involving the coefficients of \mathbb{II} . But now we don't get anything of the sort, because we have the unknown expressions* $d\mathfrak{v}$ (or b_{ij}). Instead, equation (A) allows us to solve for $\langle d\mathfrak{v}(Y), W \rangle$ —we just have to choose a unit vector Z with $\langle Y, Z \rangle = 0$, and set $X = Z$.

*Note also that the terms involving \mathfrak{s} in equation (A) are the negatives of the corresponding terms involving \mathfrak{s} in the ordinary Gauss equations.

An especially nice formula for $d\nu$ can be obtained with a little more work. Recall first of all that for a map $f: U \rightarrow \mathbb{R}^3$ we have the apolarity conditions

$$\begin{aligned} 0 = \sum_{i,j} g^{ij} \ell_{\mu ij} &\implies 0 = \sum_{i,j} (g^{ij} \ell_{\mu ij})_{;k} \\ &= \sum_{i,j} g^{ij} \ell_{\mu ij;k}, \quad \text{by Ricci's Lemma.} \end{aligned}$$

For orthonormal X_1, X_2 this means that

$$\sum_i (\nabla_X \mathfrak{I})(X_i, X_i, Y) = 0.$$

[Naturally, this formula can also be derived directly from the apolarity condition $\sum_i \mathfrak{I}(X_i, X_i, Y) = 0$, but the coordinate treatment is much easier and quicker.] So if \mathcal{K} is the intrinsic Gaussian curvature for the metric $\langle \cdot, \cdot \rangle$, then equation (A) gives

$$\begin{aligned} -2\mathcal{K} &= \sum_{i,j} \langle \mathcal{R}(X_i, X_j) X_i, X_j \rangle \\ &= \sum_j \left\{ \sum_i (\nabla_{X_j} \mathfrak{I})(X_j, X_i, X_i) \right\} - \sum_i \left\{ \sum_j (\nabla_{X_i} \mathfrak{I})(X_j, X_i, X_i) \right\} \\ &\quad + \sum_{i,j} \langle \mathfrak{A}(X_j, X_j), \mathfrak{A}(X_i, X_i) \rangle - \sum_{i,j} \langle \mathfrak{A}(X_i, X_j), \mathfrak{A}(X_i, X_j) \rangle \\ &\quad + \sum_{i,j} \langle d\nu(X_j), X_j \rangle \cdot \delta_{ii} - \sum_{i,j} \langle d\nu(X_i), X_j \rangle \cdot \delta_{ij} \\ &= 0 - 0 + \sum_{i,j,k} c_{jjk} c_{iik} - \sum_{i,j,k} (c_{ijk})^2 \\ &\quad + 2 \sum_j \langle d\nu(X_j), X_j \rangle - \sum_i \langle d\nu(X_i), X_i \rangle \\ &= \sum_{j,k} c_{jjk} \left(\sum_i c_{iik} \right) - \sum_{i,j,k} (c_{ijk})^2 + \sum_j \langle d\nu(X_j), X_j \rangle. \end{aligned}$$

Now $\sum_i c_{iik} = 0$ by the apolarity conditions, so we have (see page 117)

$$(1) \quad -2\mathcal{K} = -2J + \sum_j \langle d\nu(X_j), X_j \rangle.$$

where J is the Pick invariant. But as another consequence of equation (A), and the symmetry properties of \mathcal{R} , we also have

$$\begin{aligned}
 (2) \quad 0 &= \sum_i \langle \mathcal{R}(X_i, X) X_i, Y \rangle + \langle \mathcal{R}(X_i, X) Y, X_i \rangle \\
 &= 0 - 2 \sum_i (\nabla_{X_i} \mathfrak{I})(X, Y, X_i) \\
 &\quad + \sum_i \langle d\mathfrak{v}(X), Y \rangle \cdot \delta_{ii} - \sum_i \langle d\mathfrak{v}(X_i), Y \rangle \cdot \langle X, X_i \rangle \\
 &\quad + \sum_i \langle d\mathfrak{v}(X), X_i \rangle \cdot \langle X_i, Y \rangle - \sum_i \langle d\mathfrak{v}(X_i), X_i \rangle \cdot \langle X, Y \rangle \\
 &= -2 \sum_i (\nabla_{X_i} \mathfrak{I})(X, Y, X_i) + 2 \langle d\mathfrak{v}(X), Y \rangle \\
 &\quad - \sum_i \langle d\mathfrak{v}(X_i), X_i \rangle \cdot \langle X, Y \rangle.
 \end{aligned}$$

To interpret the sum $\sum_i (\nabla_{X_i} \mathfrak{I})(X, Y, X_i)$, we again switch to coordinates for simplicity, noting to begin with that the sum is easily shown to be independent of the particular orthonormal X_1, X_2 chosen. Now this sum is just the value of

$$\sum_{i,j} g^{ij} \ell_{k\mu i;j} = \sum_j \ell_{k\mu;j}^j$$

when we happen to have $X_i = f_i$ ($i = 1, 2$) and $f_k = X$, $f_\mu = Y$. Since $\sum_j \ell_{k\mu;j}^j$ are the components of a tensor, namely the tensor

$$\mathfrak{J}(X, Y) = \text{trace}(Z \mapsto (\nabla_Z \mathfrak{J})(X, Y)),$$

we must, in fact, always have

$$\sum_i (\nabla_{X_i} \mathfrak{I})(X, Y, X_i) = \mathfrak{J}(X, Y).$$

Thus equation (2) can be written

$$(3) \quad 2 \langle d\mathfrak{v}(X), Y \rangle = \sum_i \langle d\mathfrak{v}(X_i), X_i \rangle \cdot \langle X, Y \rangle + 2 \mathfrak{J}(X, Y).$$

Substituting in from (1) we obtain

$$(4) \quad \langle d\mathfrak{v}(X), Y \rangle = (J - \mathcal{K}) \cdot \langle X, Y \rangle + \mathfrak{J}(X, Y),$$

the analogue in ordinary surface theory being

$$\langle d\nu(X), Y \rangle = -K \cdot \langle X, Y \rangle.$$

We can solve equation (4) for $d\nu(X)$ explicitly by introducing the tensor $\tilde{\mathcal{G}}$ of type $\binom{1}{1}$ defined by

$$\langle \tilde{\mathcal{G}}(X), Y \rangle = \mathcal{G}(X, Y).$$

Then we have

$$(B) \quad d\nu(X) = (J - \mathcal{K}) \cdot X + \tilde{\mathcal{G}}(X).$$

In terms of a map $f: U \rightarrow \mathbb{R}^3$ we have

$$\begin{aligned} \mathfrak{L}_{\mu k} &= g_{\mu k} \cdot (J - \mathcal{K}) + \sum_j \ell_{\mu k; j}^j \\ &= g_{\mu k} \cdot (J - \mathcal{K}) + \mathcal{L}_{\mu k}, \quad \text{say;} \end{aligned}$$

in terms of our moving frame we have

$$\begin{aligned} \psi_3^j &= (J - \mathcal{K})\theta^j + \sum_{i, k} c_{ijk; k} \theta^i \\ &= (J - \mathcal{K})\theta^j + \sum_i C_{ij} \theta^i, \quad \text{say.} \end{aligned}$$

Conversely, it is not hard to see that if we define $d\nu(X)$ [or the $\mathfrak{L}_{\mu k}$, or the ψ_3^j] by these formulas, then equation (A) [or the coordinate equation right below it, or equation (3) on page 123] is satisfied.

As one immediate consequence of equation (4) we find that the special affine normal ν has another property in common with the ordinary normal ν :

20. PROPOSITION. The map $d\nu: M_p \rightarrow M_p$ is self-adjoint with respect to the inner product $\langle \cdot, \cdot \rangle_p$ on M_p ,

$$\langle d\nu(X_p), Y_p \rangle = \langle X_p, d\nu(Y_p) \rangle \quad \text{for } X_p, Y_p \in M_p.$$

PROOF. We just need to show that $\mathcal{G}(X, Y) = \mathcal{G}(Y, X)$. This follows from the symmetry of \mathcal{G} , and the definition of \mathcal{G} (on page 126). ♦

The eigenvectors of $-dv: M_p \rightarrow M_p$ are naturally called the **special affine principal directions** at p , and the corresponding eigenvalues are the **special affine principal curvatures** k_1 and k_2 . The **special affine mean curvature** \mathcal{H} and **special affine (extrinsic) curvature** \mathcal{K}_{ext} are then defined by

$$\begin{aligned}\mathcal{H} &= \frac{1}{2}(k_1 + k_2) \\ \mathcal{K}_{\text{ext}} &= k_1 \cdot k_2.\end{aligned}$$

If $X_1, X_2 \in M_p$ are orthonormal, then

$$\mathcal{H}(p) = -\frac{1}{2} \sum_{j=1}^2 \langle dv(X_j), X_j \rangle.$$

So equation (1) on page 125 shows that we also have

$$\mathcal{H} = \mathcal{K} - J.$$

We have obtained these results by looking at the integrability conditions for the tangential part of the Gauss formulas. Now we will look at the integrability conditions for the \mathcal{L} component,

$$\psi_i^3 = \theta^i.$$

Exterior differentiation gives

$$-\sum_{k=1}^2 \psi_k^3 \wedge \psi_i^k = d\theta^i = -\sum_{k=1}^2 \psi_k^i \wedge \theta^k$$

or

$$-\sum_k \theta^k \wedge \psi_i^k = \sum_k \theta^k \wedge \psi_k^i \quad \text{or} \quad \sum_k (\psi_i^k + \psi_k^i) \wedge \theta^k = 0.$$

But these conditions are *automatic*, for we derived this equation in the proof of Proposition 16 (conversely, the equation follows immediately from equation (2) on page 106 and symmetry of the c_{ijk}).

On the other hand, we still have to look at the conditions which say that $\mathcal{N}_{ij} = \mathcal{N}_{ji}$. In ordinary surface theory they reduced to the Codazzi-Mainardi equations; now we will obtain new conditions. The moving frame version of the formula for \mathcal{N}_i is that on page 127.

$$(1) \quad \psi_3^j = (J - \mathcal{K})\theta^j + \sum_i C_{ij}\theta^i.$$

Exterior differentiation gives

$$\begin{aligned} - \sum_{\rho} \psi_{\rho}^j \wedge \psi_3^{\rho} &= d(J - \mathcal{K}) \wedge \theta^j + (J - \mathcal{K})d\theta^j + \sum_i dC_{ij} \wedge \theta^i \\ &\quad - \sum_i C_{ij} \wedge \left(\sum_{\rho} \omega_{\rho}^i \wedge \theta^{\rho} \right). \end{aligned}$$

Substituting in for ψ_3^k from (1), noting that $-\sum_{\rho} \psi_{\rho}^j \wedge \theta^{\rho} = d\theta^j$, and switching dummy indices in the last term on the right, we have

$$- \sum_{i,\rho} C_{i\rho} \psi_{\rho}^j \wedge \theta^i = d(J - \mathcal{K}) \wedge \theta^j + \sum_i dC_{ij} \wedge \theta^i - \sum_{i,\rho} C_{\rho j} \wedge \omega_i^{\rho} \wedge \theta^i.$$

Now writing the ψ_{ρ}^j in terms of the ω_{ρ}^j we get

$$\begin{aligned} - \sum_{i,\rho} C_{i\rho} \omega_{\rho}^j \wedge \theta^i &- \sum_{i,\rho,k} C_{i\rho} c_{j\rho k} \theta^k \wedge \theta^i \\ &= d(J - \mathcal{K}) \wedge \theta^j + \sum_i dC_{ij} \wedge \theta^i - \sum_{i,\rho} C_{\rho j} \wedge \omega_i^{\rho} \wedge \theta^i. \end{aligned}$$

Finally, since $\omega_{\rho}^j = -\omega_j^{\rho}$, we can write

$$\begin{aligned} (2) \quad &- \sum_{i,\rho,k} C_{i\rho} c_{j\rho k} \theta^k \wedge \theta^i \\ &= d(J - \mathcal{K}) \wedge \theta^j + \sum_i \left[dC_{ij} - \sum_{\rho} C_{\rho j} \wedge \omega_i^{\rho} - \sum_{\rho} C_{i\rho} \omega_j^{\rho} \right] \wedge \theta^i. \end{aligned}$$

To interpret this equation, we first apply it to (X, X_j) . The left side gives

$$(2a) \quad \sum_{i,\rho} C_{i\rho} c_{j\rho k} \theta^i(X) - \sum_{\rho,k} C_{j\rho} c_{j\rho k} \theta^k(X).$$

The first term on the right side gives

$$(2b) \quad X(J - \mathcal{K}) - X_j(J - \mathcal{K}) \cdot \theta^j(X).$$

For the other term on the right side we note, as on page 123, that the tensor $\mathcal{S} = \sum_{i,j} C_{ij} \theta^i \otimes \theta^j$ has a covariant derivative

$$\nabla \mathcal{S} = \sum_{i,j,k} C_{ij,k} \theta^i \otimes \theta^j \otimes \theta^k,$$

where (Problem 5)

$$\sum_k C_{ij;k} \theta^k = dC_{ij} - \sum_\rho C_{\rho j} \omega_i^\rho - \sum_\rho C_{i\rho} \omega_j^\rho.$$

So the second term on the right side of (2) is

$$\sum_{i,k} C_{ij;k} \theta^k \wedge \theta^i,$$

which when applied to (X, X_j) gives

$$(2c) \quad \sum_k C_{jj;k} \theta^k(X) - \sum_i C_{ij;j} \theta^i(X).$$

We now take the equations (2a) = (2b) + (2c) and add them for $j = 1, 2$ [the resultant equation is equivalent to the individual equations, for if a 2-form α satisfies $\sum_{j=1}^2 \alpha(X, X_j) = 0$, then also $\alpha(X_i, X_j) = 0$ for $i = 1, 2$], obtaining

$$(3) \quad \begin{aligned} & \sum_{i,\rho} C_{i\rho} \left(\sum_j c_{jj\rho} \right) \cdot \theta^i(X) - \sum_k \left(\sum_{j,\rho} C_{j\rho} c_{j\rho k} \right) \theta^k(X) \\ &= 2X(J - \mathcal{K}) - X(J - \mathcal{K}) \\ &+ \sum_k \left(\sum_j C_{jj;k} \right) \theta^k(X) - \sum_i \left(\sum_j C_{ij;j} \right) \theta^i(X). \end{aligned}$$

Now we have

$$(3a) \quad \sum_{i,\rho} C_{i\rho} \left(\sum_j c_{jj\rho} \right) \cdot \theta^i(X) = 0$$

by the apolarity conditions $\sum_j c_{jj\rho} = 0$. In order to interpret the term involving $\sum_{j,\rho} C_{j\rho} c_{j\rho k}$ we introduce the tensor $\mathfrak{J} * \mathfrak{I}$ of type $\binom{1}{0}$ defined by

$$\mathfrak{J} * \mathfrak{I}(X) = \sum_{i,j=1}^2 \mathfrak{J}(X_i, X_j) \cdot \mathfrak{I}(X, X_i, X_j),$$

where X_1, X_2 is any orthonormal basis; it is easily checked that this definition is independent of the choice of such basis. [This is the simplest description of $\mathfrak{J} * \mathfrak{I}$ —a completely invariant definition requires an orgy of linear algebra.

Classically, $\mathcal{J} * \mathfrak{I}$ is simply described in terms of its components, which are given by the 4-fold contraction

$$\sum_{i,\mu,\rho,\sigma} g^{\mu i} g^{\rho\sigma} \mathcal{L}_{\sigma i} \ell_{\mu\rho j},$$

where $\mathcal{L}_{\sigma i}$ are the components of \mathcal{J} .] Now we clearly have

$$(3b) \quad - \sum_k \left(\sum_{j,\rho} C_{j\rho} c_{j\rho k} \right) \theta^k(X) = -\mathcal{J} * \mathfrak{I}(X).$$

To deal with the term $\sum_j C_{jj;k}$ it is again simplest to switch to coordinates. We have the apolarity conditions

$$\begin{aligned} 0 &= \sum_{i,j} g^{ij} \ell_{ij\rho} \\ \implies 0 &= \sum_{i,j,\rho} g^{ij} g^{\mu\rho} \ell_{ij\rho} = \sum_{i,j} g^{ij} \ell_{ij}^{\mu} \\ \implies 0 &= \sum_{i,j,\mu} (g^{ij} \ell_{ij}^{\mu})_{;\mu} = \sum_{i,j,\mu} g^{ij} (\ell_{ij;\mu}^{\mu}) \quad \text{by Ricci's Lemma} \\ &= \sum_{i,j} g^{ij} \left(\sum_{\mu} \ell_{ij;\mu}^{\mu} \right) = \sum_{i,j} g^{ij} \mathcal{L}_{ij} \\ \implies 0 &= \sum_{i,j} (g^{ij} \mathcal{L}_{ij})_{;k} = \sum_{i,j} g^{ij} \mathcal{L}_{ij;k}, \quad \text{again by Ricci's Lemma.} \end{aligned}$$

This tells us that

$$(3c) \quad \sum_j C_{jj;k} = 0 \implies \sum_k \left(\sum_j C_{jj;k} \right) \theta^k(X) = 0$$

[which can also be obtained, with some pain, directly from the apolarity conditions $\sum_j c_{jjk} = 0$]. Finally, we note that

$$\begin{aligned} (3d) \quad - \sum_i \left(\sum_j C_{ij;j} \right) \theta^i(X) &= - \sum_j (\nabla_{X_j} \mathcal{J})(X, X_j) \\ &= - \text{trace}(Z \mapsto (\nabla_Z \mathcal{J})(X)), \end{aligned}$$

by the very same argument that was used on page 126. Now the equation

$$(3a) + (3b) = X(J - \mathcal{K}) + (3c) + (3d)$$

yields

The Special Affine Codazzi-Mainardi Equations:

$$X(J - \mathcal{K}) = \text{trace}(Z \mapsto (\nabla_Z \tilde{\mathcal{J}})(X)) - \mathcal{J} * \mathfrak{I}(X).$$

In terms of a map $f: U \rightarrow \mathbb{R}^3$ we have

$$(J - \mathcal{K})_j = \sum_{\mu, i} g^{\mu i} \mathcal{L}_{\mu j; i} - \sum_{i, \mu, \rho, \sigma} g^{\mu i} g^{\rho \sigma} \mathcal{L}_{\sigma i} \ell_{\mu \rho j}.$$

Finally, we are ready to state

21. FUNDAMENTAL THEOREM OF SPECIAL AFFINE SURFACE THEORY (RADON; 1918).

(1) Let $M, \bar{M} \subset \mathbb{R}^3$ be two connected surfaces in \mathbb{R}^3 , both consisting entirely of elliptic points or both consisting entirely of hyperbolic points; in the former case give both surfaces the usual orientation, and in the latter case, suppose that each surface is also oriented. Let $\nu: M \rightarrow \mathbb{R}^3$ and $\bar{\nu}: \bar{M} \rightarrow \mathbb{R}^3$ be the affine normal vector fields (determined by the orientations), and let $\mathfrak{I}, \mathfrak{I}$ and $\bar{\mathfrak{I}}, \bar{\mathfrak{I}}$ be the first and second affine fundamental forms for M and \bar{M} , respectively. Let $\phi: M \rightarrow \bar{M}$ be an orientation preserving diffeomorphism such that

$$\phi^* \bar{\mathfrak{I}} = \mathfrak{I} \quad \text{and} \quad \phi^* \bar{\mathfrak{I}} = \mathfrak{I}.$$

Then there is a special linear affine motion $A: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ such that $\phi = A|_M$ and $A_* \nu = \bar{\nu}$.

(2) Let M be an oriented 2-manifold with a (not necessarily positive definite) metric $\langle \cdot, \cdot \rangle$ having covariant derivative ∇ , curvature tensor \mathcal{R} , and curvature \mathcal{K} . Let \mathcal{S} be a symmetric tensor on M of order 3. Define

$$J = \frac{1}{2} \langle \mathcal{S}, \mathcal{S} \rangle,$$

where $\langle \cdot, \cdot \rangle$ is the inner product on tri-linear maps determined by the inner product $\langle \cdot, \cdot \rangle$, and define $\mathcal{J}, \mathcal{J}, \tilde{\mathcal{J}}$ by

$$\begin{aligned} \langle \mathcal{J}(X, Y), Z \rangle &= \mathcal{S}(X, Y, Z) \\ \mathcal{J}(X, Y) &= \text{trace}(Z \mapsto (\nabla_Z \mathcal{J})(X, Y)) \\ \langle \tilde{\mathcal{J}}(X), Y \rangle &= \mathcal{J}(X, Y). \end{aligned}$$

Suppose that \mathcal{S} satisfies

(1) The Apolarity Conditions:

$$\text{trace}(X \mapsto \mathcal{A}(X, Y)) = 0$$

(2) The Special Affine Codazzi-Mainardi Equations:

$$X(J - \mathcal{K}) = \text{trace}(Z \mapsto (\nabla_Z \tilde{\mathcal{S}})(X)) - \mathcal{S} * \mathcal{S}(X).$$

Then for any point $p \in M$ there is a neighborhood U of p and an immersion $f: U \rightarrow \mathbb{R}^3$ such that

$$\begin{aligned} \langle\langle \cdot, \cdot \rangle\rangle &= f^* \mathbf{I} \\ \mathcal{S} &= f^* \mathbf{II}, \end{aligned}$$

where \mathbf{I} and \mathbf{II} are the affine first and second fundamental forms on $f(U)$ determined by the orientation $f(U)$ gets from the orientation on $U \subset M$.

This can be proved in the same way that we proved Theorem 3, using the classical integrability theorem (I.6-1). Or the Frobenius form of the integrability conditions can be used (see the treatment for ordinary surface theory in Chapter 7). One can also reduce the theorem to Theorems I.10-17 and I.10-18; our integrability conditions reduce to the equations of structure of $\text{SL}(3, \mathbb{R})$.

PROBLEMS

1. Consider the Codazzi-Mainardi equations in Corollary 1-12, but write $(\nabla_X \Pi)(Y, Z) = X(\Pi(Y, Z)) - \Pi(\nabla_X Y, Z) - \Pi(Y, \nabla_X Z)$, and similarly for $(\nabla_Y \Pi)(X, Z)$. Choose $X = f_1$, $Y = f_2$, and then $Z = f_1$ or f_2 , to obtain equations (B') on page 56.

2. From equation (**) on page 53 show that

$$N_{ij} = - \sum_h \left(l_{i,j}^h + \sum_\rho l_i^\rho \Gamma_{\rho j}^h \right) f_h - \sum_{h,\rho} g^{h\rho} l_{\rho i} l_{hj} N.$$

Conclude that the equation $N_{ij} = N_{ji}$ is equivalent to

$$l_{i,j}^h + \sum_\rho l_i^\rho \Gamma_{\rho j}^h = l_{j,i}^h + \sum_\rho l_j^\rho \Gamma_{\rho i}^h.$$

Write $l_i^h = \sum_k g^{hk} l_{ki}$, and similarly for l_j^h , and expand. Multiply by $\sum_h g_{\tau h}$, and then use $\sum_h g_{\tau h} g^{hk}{}_{,j} = - \sum_h g_{\tau h,j} g^{hk}$. Show that the resulting equation is equivalent to the Codazzi-Mainardi equations, by making use of the identity

$$g_{ik,j} = [ij, k] + [jk, i].$$

3. Use the method of Problem 1-5 to prove that we can take U to be all of M in Corollary 5 when M is simply-connected.

4. (a) Find a continuous map $f: \mathbb{R} \rightarrow S^1$ which is onto and locally one-one, but not a covering map. *Hint:* Take part of the universal covering space of S^1 .
 (b) Let $f: X \rightarrow Y$ be a continuous map which is onto and locally a homeomorphism, and let X be compact. Then for every $y \in Y$, the set $f^{-1}(y) \subset X$ is finite, say $f^{-1}(y) = \{x_1, \dots, x_k\}$. Choose disjoint open sets $U_i \ni x_i$ such that f is a homeomorphism on each U_i , and let $U = \bigcap_i f(U_i)$. Using compactness of X , show that there is a compact neighborhood $K \subset U$ of y such that $f^{-1}(K) \subset \bigcup_i U_i$. Conclude that f is a covering map.

5. Let X_1, \dots, X_n be a moving frame on a manifold with a connection ∇ . Let

$$A = \sum a_{i_1 \dots i_k} \theta^{i_1} \otimes \dots \otimes \theta^{i_k}$$

be a tensor field of type $\binom{k}{0}$, and let

$$\nabla A = \sum a_{i_1 \dots i_k; l} \theta^{i_1} \otimes \dots \otimes \theta^{i_k} \otimes \theta^l.$$

Use Problem 1-1 to check that

$$\sum_l a_{i_1 \dots i_k; l} \theta^l = da_{i_1 \dots i_k} - \sum_\rho a_{\rho i_2 \dots i_k} \omega_{i_1}^\rho - \dots - \sum_\rho a_{i_1 \dots i_{k-1} \rho} \omega_{i_k}^\rho.$$

CHAPTER 3

A COMPENDIUM OF SURFACES

In the following chapters it will often be quite useful to have a detailed knowledge of the classical surfaces. In this chapter we will list all the important ones systematically, together with many of their properties; other properties will be mentioned in later chapters, when we have the theorems necessary to derive them. A brief survey of the initial pages may prove quite discouraging, but the reader can be assured that after the basic formulas have been derived once and for all, the reading becomes a lot more pleasant—there are pretty pictures to draw, and interesting points to be made.

Usually we will represent a surface locally as the image of an immersion $f: U \rightarrow \mathbb{R}^3$. We collect here the formulas from the previous chapters, with a few additions which are used for actual calculations.

$$\begin{array}{l}
 \text{(A)} \quad \begin{array}{ccc}
 E = \langle f_1, f_1 \rangle & F = \langle f_1, f_2 \rangle & G = \langle f_2, f_2 \rangle \\
 \\
 N = \frac{f_1 \times f_2}{|f_1 \times f_2|} = \frac{f_1 \times f_2}{\sqrt{EG - F^2}} \\
 \\
 \begin{array}{ccc}
 l = \langle -N_1, f_1 \rangle & m = \langle -N_1, f_2 \rangle & n = \langle -N_2, f_2 \rangle \\
 = \langle N, f_{11} \rangle & = \langle N, f_{12} \rangle & = \langle N, f_{22} \rangle \\
 \\
 \det \begin{pmatrix} f_{11} \\ f_1 \\ f_2 \end{pmatrix} & \det \begin{pmatrix} f_{12} \\ f_1 \\ f_2 \end{pmatrix} & \det \begin{pmatrix} f_{22} \\ f_1 \\ f_2 \end{pmatrix} \\
 = \frac{\det \begin{pmatrix} f_{11} \\ f_1 \\ f_2 \end{pmatrix}}{\sqrt{EG - F^2}} & = \frac{\det \begin{pmatrix} f_{12} \\ f_1 \\ f_2 \end{pmatrix}}{\sqrt{EG - F^2}} & = \frac{\det \begin{pmatrix} f_{22} \\ f_1 \\ f_2 \end{pmatrix}}{\sqrt{EG - F^2}}
 \end{array}
 \end{array}
 \end{array}$$

(Here we have made a specific choice of N , which will influence the sign of various quantities to be computed later on.) We also recall that

$$\begin{aligned}
 \left(\begin{array}{l} \text{matrix of } -dv: M_p \rightarrow M_p \\ \text{with respect to } (f_1)_p, (f_2)_p \end{array} \right) &= (g_{ij})^{-1}(l_{ij}) \\
 &= \frac{1}{EG - F^2} \cdot \begin{pmatrix} G & -F \\ -F & E \end{pmatrix} \begin{pmatrix} l & m \\ m & n \end{pmatrix}
 \end{aligned}$$

[f_i, g_{ij}, l_{ij} evaluated at (s, t) ; where $p = f(s, t)$].

The principal curvatures k_1, k_2 are the eigenvalues of this matrix, and the Gaussian curvature K is $k_1 \cdot k_2$, while the mean curvature H is $(k_1 + k_2)/2$. So K and H are the determinant and half the trace, respectively, of this matrix. This gives us

$$(B) \quad \boxed{\begin{aligned} K &= \frac{ln - m^2}{EG - F^2} \\ H &= \frac{En - 2Fm + Gl}{2(EG - F^2)}. \end{aligned}}$$

(The sign of H depends on the choice of N , but the sign of K does not.)

In equation (B), the left sides H and K must be evaluated at $p = f(s, t)$ when the right sides are evaluated at (s, t) ; similar conventions will be used in the remaining equations. We remind the reader that it is also possible, in principle at least, to compute K directly from E, F, G . Since k_1, k_2 are the roots of the equation $\lambda^2 - 2H\lambda + K = 0$, we have

$$(C) \quad \boxed{k_1, k_2 = H \pm \sqrt{H^2 - K}.}$$

(The signs of k_1, k_2 both change when N is changed.)

It is, as usual, rather more difficult to find the principal directions, that is, the *eigenvectors* of $-dv$. We leave it to the reader (Problem 1) to show that

$$(D) \quad \boxed{\begin{aligned} &a_1 f_1 + a_2 f_2 \text{ is a principal vector if and only if} \\ &\det \begin{pmatrix} a_2^2 & -a_1 a_2 & a_1^2 \\ E & F & G \\ l & m & n \end{pmatrix} = 0. \end{aligned}}$$

We have already pointed out that at an umbilic point we have the necessary and sufficient condition

$$(E) \quad \boxed{l = kE, \quad m = kF, \quad n = kG \quad \text{at an umbilic point,} \\ \text{with } k_1 = k_2 = k.}$$

(The sign of k depends on N .)

This condition can also be derived from (D), since the determinant must be 0 for all choices of a_1 and a_2 . It is also clear that

$$(F) \quad \boxed{\begin{aligned} &a_1 f_1 + a_2 f_2 \text{ is an asymptotic vector if and only if} \\ &la_1^2 + 2ma_1 a_2 + na_2^2 = 0. \end{aligned}}$$

Finally, it is easy to see that

(G) If $F = m = 0$ at a point, then f_1 and f_2 are principal vectors there, and

$$-dv(f_1) = \frac{l}{E} f_1, \quad -dv(f_2) = \frac{n}{G} f_2.$$

When our surface is actually the graph of a function $h: \mathbb{R}^2 \rightarrow \mathbb{R}$, so that we can choose

$$f(s, t) = (s, t, h(s, t))$$

$$f_1 = (1, 0, h_1(s, t))$$

$$f_2 = (0, 1, h_2(s, t)) \quad f_{ij} = (0, 0, h_{ij}),$$

we obtain the following formulas:

(A')

$$E = 1 + h_1^2 \quad F = h_1 h_2 \quad G = 1 + h_2^2$$

$$N = \frac{(-h_1, -h_2, 1)}{\sqrt{1 + h_1^2 + h_2^2}}$$

$$l = \frac{h_{11}}{\sqrt{1 + h_1^2 + h_2^2}} \quad m = \frac{h_{12}}{\sqrt{1 + h_1^2 + h_2^2}} \quad n = \frac{h_{22}}{\sqrt{1 + h_1^2 + h_2^2}}.$$

(B')

$$K = \frac{h_{11}h_{22} - h_{12}^2}{[1 + h_1^2 + h_2^2]^2}$$

$$H = \frac{(1 + h_1^2)h_{22} + (1 + h_2^2)h_{11} - 2h_1h_2h_{12}}{2[1 + h_1^2 + h_2^2]^{3/2}}.$$

(C')

$$k_1, k_2 = H \pm \sqrt{H^2 - K}.$$

(D')

$$a_1 f_1 + a_2 f_2 = (a_1, a_2, a_1 h_1 + a_2 h_2) \text{ is a principal vector if and only if}$$

$$\det \begin{pmatrix} a_2^2 & -a_1 a_2 & a_1^2 \\ 1 + h_1^2 & h_1 h_2 & 1 + h_2^2 \\ h_{11} & h_{12} & h_{22} \end{pmatrix} = 0.$$

(E')

$$h_{11} = k(1 + h_1^2), \quad h_{12} = kh_1h_2, \quad h_{22} = k(1 + h_2^2)$$

at an umbilic point, with $k_1 = k_2 = k\sqrt{1 + h_1^2 + h_2^2}$.

(F')

$$a_1f_1 + a_2f_2 = (a_1, a_2, a_1h_1 + a_2h_2) \text{ is an}$$

asymptotic vector if and only if

$$h_{11}a_1^2 + 2h_{12}a_1a_2 + h_{22}a_2^2 = 0.$$

It is also quite useful to be able to compute K and H for surfaces

$$M = \{p \in \mathbb{R}^2 : W(p) = 0\},$$

where $W: \mathbb{R}^3 \rightarrow \mathbb{R}$. Recall (pg. II.113) that we can choose

$$v = \frac{Z}{|Z|} \quad \text{for } Z = (W_1, W_2, W_3).$$

If $X = (a_1, a_2, a_3)_p$, then

$$\begin{aligned} -dv(X) &= -\nabla_X \frac{Z}{|Z|} = -\frac{1}{|Z|} \nabla_X Z - X \left(\frac{1}{|Z|} \right) Z \\ &= -\frac{1}{|Z|} \left(\sum_i a_i W_{1i}, \sum_i a_i W_{2i}, \sum_i a_i W_{3i} \right) - \underbrace{X \left(\frac{1}{|Z|} \right) Z}_{\text{normal to } M}, \end{aligned}$$

so

$$\langle -dv(X), X \rangle = -\frac{1}{|Z|} \sum_{i,j} a_i a_j W_{ij} \quad [W_{ij} \text{ evaluated at } p].$$

This means that the principal curvatures k_1, k_2 at p are $-1/|Z|$ times the maximum and minimum of

$$\sum_{i,j} a_i a_j W_{ij} \quad \text{on } S = \{(a_1, a_2, a_3) : \sum_i a_i^2 = 1 \text{ and } \sum_i a_i W_i = 0\}$$

$[W_i, W_{ij} \text{ evaluated at } p].$

Using Lagrangian multipliers (see Problem 3, if you have forgotten them), these extrema occur at $(a_1, a_2, a_3) \in S$ if and only if there are λ, μ such that

$$D_j \left(\sum_i a_i a_k W_{ik} \right) = \lambda D_j \left(\sum_i a_i^2 \right) + \mu D_j \left(\sum_i a_i W_i \right) \quad \text{for all } j.$$

Using $W_{ik} = W_{ki}$, we find that

$$\begin{aligned} \sum_i a_i W_{ij} &= \lambda a_j + \frac{\mu}{2} W_j \\ \sum_i a_i^2 &= 1, \quad \sum_i a_i W_i = 0 \end{aligned} \quad \text{for some } \lambda, \mu.$$

Since we then have $\sum_{i,j} a_i a_j W_{ij} = \lambda$, this shows that the desired maximum and minimum values of $\sum_{i,j} a_i a_j W_{ij}$ are precisely the numbers λ for which we have

$$\begin{cases} \sum_i a_i W_{ij} = \lambda a_j + \frac{\mu}{2} W_j \\ \sum_i a_i W_i = 0 \end{cases} \quad \text{for some } (a_1, a_2, a_3) \neq 0, \text{ and some } \mu.$$

We can also write this as

$$(*) \quad \begin{cases} (W_{ij}) \cdot \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix} = \lambda \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix} + \frac{\mu}{2} \begin{pmatrix} W_1 \\ W_2 \\ W_3 \end{pmatrix} \\ \sum_i a_i W_i = 0 \end{cases} \quad \text{for some } (a_1, a_2, a_3) \neq 0, \text{ and some } \mu.$$

Now, since

$$\begin{pmatrix} \boxed{(W_{ij}) - \lambda I} & \begin{matrix} W_1 \\ W_2 \\ W_3 \end{matrix} \\ \begin{matrix} W_1 & W_2 & W_3 \end{matrix} & 0 \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \\ a_3 \\ t \end{pmatrix} = \begin{pmatrix} (W_{ij}) \cdot \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix} - \lambda \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix} + t \begin{pmatrix} W_1 \\ W_2 \\ W_3 \end{pmatrix} \\ a_1 W_1 + a_2 W_2 + a_3 W_3 \end{pmatrix},$$

we see that (*) holds precisely when there exists $(a_1, a_2, a_3, t) \neq 0$ so that the right side of the above equation is the 0 column vector. Thus the desired λ 's are those for which the left-hand 4×4 matrix has determinant 0:

$$(C'') \quad \boxed{\begin{aligned} k_i &= -\frac{1}{\sqrt{W_1^2 + W_2^2 + W_3^2}} \lambda_i, \\ \text{where } \lambda_i &\text{ are the roots of the quadratic equation} \\ (**) \quad \det \begin{pmatrix} \boxed{(W_{ij}) - \lambda I} & \begin{matrix} W_1 \\ W_2 \\ W_3 \end{matrix} \\ \begin{matrix} W_1 & W_2 & W_3 \end{matrix} & 0 \end{pmatrix} &= 0. \end{aligned}}$$

Consequently,

$$(B'') \quad \begin{aligned} K &= \frac{1}{W_1^2 + W_2^2 + W_3^2} \cdot \frac{\text{constant term in } (**)}{\text{coefficient of } \lambda^2 \text{ in } (**)} \\ H &= -\frac{1}{2\sqrt{W_1^2 + W_2^2 + W_3^2}} \cdot \frac{\text{coefficient of } \lambda \text{ in } (**)}{\text{coefficient of } \lambda^2 \text{ in } (**)}. \end{aligned}$$

$$(C'') \quad \begin{aligned} k_1, k_2 &= \\ H \pm \sqrt{H^2 - K}. \end{aligned}$$

In particular, to anticipate the case of greatest interest for us, we find:

$$(***) \quad \text{If } (W_{ij}) = \begin{pmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{pmatrix}, \text{ then}$$

$$K = \frac{1}{(W_1^2 + W_2^2 + W_3^2)^2} [W_1^2 \lambda_2 \lambda_3 + W_2^2 \lambda_1 \lambda_3 + W_3^2 \lambda_1 \lambda_2]$$

$$H = \frac{1}{2(W_1^2 + W_2^2 + W_3^2)^{3/2}} [W_1^2(\lambda_2 + \lambda_3) + W_2^2(\lambda_1 + \lambda_3) + W_3^2(\lambda_1 + \lambda_2)].$$

[In all the formulas given so far, the sign of k_1, k_2 and of H depends on the choice of N as the normalized vector (W_1, W_2, W_3) .]

Since X is a principal vector if and only if $\langle d\nu(X) \times X, \nu \rangle = 0$, we also see that

$$(D'') \quad \begin{aligned} X = (a_1, a_2, a_3)_p \text{ is a principal vector if and only if} \\ \det \begin{pmatrix} W_1 & \sum_i a_i W_{1i} & a_1 \\ W_2 & \sum_i a_i W_{2i} & a_2 \\ W_3 & \sum_i a_i W_{3i} & a_3 \end{pmatrix} = 0 \quad \text{and} \quad \sum_i a_i W_i = 0. \end{aligned}$$

There does not seem to be any especially simple condition for an umbilic, but we do know that p is an umbilic if and only if the determinant in (D'') is 0

for all (a_1, a_2, a_3) with $\sum_i a_i W_i = 0$. Finally, we have

$$(F'') \quad \boxed{X = (a_1, a_2, a_3)_p \text{ is an asymptotic vector if and only if} \\ \sum_i a_i a_j W_{ij} = 0 \quad \text{and} \quad \sum_i a_i W_i = 0.}$$

We are now ready to begin our systematic list of surfaces. They come under five headings.

I. THE CLASSICAL FLAT SURFACES

1. Plane

For any plane, the normal map v is constant, so $dv = 0$. Thus all points are umbilics with $k_1 = k_2 = 0$, and $K = H = 0$. All vectors are also asymptotic. The plane is actually a special case of

2. Generalized Cylinder

Here our surface is $M = \{(x, y, z) : (x, y) = c(s) \text{ for some } s\}$, where c is an immersed curve in \mathbb{R}^2 , which we assume parameterized by arclength.

The normal map v is always parallel to the (x, y) plane. One principal direction at any point is $(0, 0, 1)$, with $k_1 = 0$. The other principal direction at $(c(s), z)$ is $(c', 0) = (\mathbf{n}, 0)$, with $k_2 = \kappa(s)$, the curvature of c at s (here we choose the normal map v to be $(\mathbf{n}, 0)$, where the normal \mathbf{n} for c is picked as on pg. II.6; recall that $\mathbf{n}'(s) = -\kappa(s) \cdot c'(s)$, while k_2 is an eigenvalue of $-dv$). Hence $K = 0$ and $H = \frac{1}{2}\kappa(s)$.

The only asymptotic direction is $(0, 0, 1)$, unless $k(s) = 0$, in which case all directions are asymptotic.

3. Generalized Cone

Our surface is parameterized by

$$f(s, t) = V + t[c(s) - V],$$

where $V \in \mathbb{R}^3$ is the *vertex*, and c is an immersed curve in \mathbb{R}^3 . For f to be an immersion, the vectors

$$f_1 = tc' \quad \text{and} \quad f_2 = c - V$$

must be linearly independent, so we must have $t \neq 0$ (V cannot be in the surface) and $c'(s)$ linearly independent of $c(s) - V$.

Since the tangent space at $f(s, t)$ is spanned by $c'(s)$ and $c(s) - V$, the normal map is constant along the straight lines obtained by keeping s fixed. Consequently, the vectors $f_2(s, t) = c(s) - V$ are principal vectors, with $k_1 = 0$. Therefore $K = 0$. Once again, these vectors are also asymptotic, and there are no others, except at points where $H = k_2/2$ happens to be 0, in which case all vectors are asymptotic.

4. Tangent Developable

This surface consists of the tangents to a curve c in \mathbb{R}^3 (parameterized by arclength as usual). It can therefore be parameterized by

$$f(s, t) = c(s) + tc'(s).$$

We have

$$\begin{aligned} f_1 &= c' + tc'' = c' + t\kappa \mathbf{n}, & \text{where } \mathbf{n} \text{ is the normal vector} \\ & & \text{of } c, \text{ and } \kappa \text{ is the curvature} \\ f_2 &= c'; \end{aligned}$$

so f is regular if $t \neq 0$ and $\kappa \neq 0$. Thus this parameterization does not allow

the curve itself to be part of the surface. In fact, the surface consists of two sheets which meet along the curve in a sharp edge (the **edge of regression** or

cuspidal edge); at any point of the curve, the normal plane intersects the surface in a curve γ with a cusp. This is shown below for our “standard curve” of pp. II.30, 31.

Actually, the assertion we have just made requires some careful interpretation, as can be seen by considering the case where c lies in a plane. The two sheets of the tangent developable are then the same portion of this plane, and their intersection with a normal plane is just a ray. In general, we can analyze the

intersection of the tangent developable and a normal plane to c as follows. For convenience, we consider the point $s = 0$, and assume $c(0) = 0$ and that $\mathbf{t}, \mathbf{n}, \mathbf{b}$ lie along the three coordinate axes. For small $s \neq 0$, the vector $c'(s)$, being close to $\mathbf{t} = c'(0)$, does not lie in the (\mathbf{n}, \mathbf{b}) -plane; moreover, $c(s)$ also does not lie in the (\mathbf{n}, \mathbf{b}) -plane. Now we can write (using the Serret-Frenet formulas)

$$\begin{aligned} c(s) &= c(0) + sc'(0) + \frac{s^2}{2}c''(0) + \frac{s^3}{6}c'''(0) + o(s^3) \\ &= (0, 0, 0) + s(1, 0, 0) + \frac{s^2}{2}(0, \kappa, 0) + \frac{s^3}{6}(-\kappa^2, \kappa', \kappa\tau) + o(s^3); \end{aligned}$$

here $\kappa = \kappa(0)$ and $\tau = \tau(0)$, and $o(s^3)$ is a function with the property that $o(s^3)/s^3 \rightarrow 0$ as $s \rightarrow 0$. Similarly, we have

$$\begin{aligned} c'(s) &= c'(0) + sc''(0) + \frac{s^2}{2}c'''(0) + o(s^2) \\ &= (1, 0, 0) + s(0, \kappa, 0) + \frac{s^2}{2}(-\kappa^2, \kappa', \kappa\tau) + o(s^2). \end{aligned}$$

Combining, we have

$$\begin{aligned} (*) \quad f(s, t) &= c(s) + tc'(s) \\ &= (0, 0, 0) + s(1, 0, 0) + \frac{s^2}{2}(0, \kappa, 0) + \frac{s^3}{6}(-\kappa^2, \kappa', \kappa\tau) + o(s^3) \\ &\quad + t \left[(1, 0, 0) + s(0, \kappa, 0) + \frac{s^2}{2}(-\kappa^2, \kappa', \kappa\tau) + o(s^2) \right]. \end{aligned}$$

For each s there is $t(s)$ for which $f(s, t(s))$ lies in the (\mathbf{n}, \mathbf{b}) -plane, which means that the first component of $f(s, t(s))$ equals zero:

$$s - \frac{\kappa^2}{6}s^3 + o(s^3) + t(s) \left[1 - \frac{\kappa^2}{2}s^2 + o(s^2) \right] = 0.$$

Dividing through, and giving just a little thought to the meaning of what we are doing, we find that

$$t(s) = -s - \frac{\kappa^2}{3}s^2 + o(s^3).$$

[Here, and below, $o(s^3)$ represents some *new* function with the property that $o(s^3)/s^3 \rightarrow 0$ as $0 \rightarrow 0$.] Substituting back into (*), we find that

$$\begin{aligned} 2^{\text{nd}} \text{ component of } f(s, t(s)) &= \frac{\kappa}{2}s^2 + o(s^2) + t(s)\{\kappa s + o(s)\} \\ &= -\frac{\kappa}{2}s^2 + o(s^2), \end{aligned}$$

$$\begin{aligned} 3^{\text{rd}} \text{ component of } f(s, t(s)) &= \frac{\kappa\tau}{6}s^3 + o(s^3) + t(s)\left\{\frac{\kappa\tau}{2}s^2 + o(s^2)\right\} \\ &= -\frac{\kappa\tau}{3}s^3 + o(s^3). \end{aligned}$$

Thus, in the (\mathbf{n}, \mathbf{b}) -plane, or, in other words, in the (y, z) -plane, the intersection is described up to first order as the curve

$$s \mapsto \left(-\frac{\kappa}{2}s^2, -\frac{\kappa\tau}{3}s^3\right) = (y(s), z(s));$$

the image is the graph of

$$z^2 = -\frac{8}{9} \frac{\tau^2}{\kappa} y^3.$$

This analysis leads one to suspect that a *single* branch of the tangent developable can be extended so as to include the original curve, though, to be sure, a different parameterization is required. This is most obvious for a plane curve; one obtains an immediate extension if one uses lines perpendicular to the curve as t -parameter lines. Presumably in the general case we obtain a nice param-

eterization of $\{c(s) + tc'(s) : t \geq 0\}$ when we choose as one set of parameter lines the intersection of the surface with normal planes to the curve.

Since the tangent space at $f(s, t)$ is spanned by $c'(s)$ and $\mathbf{n}(s)$, it is the same along the straight lines obtained by keeping s fixed. So the normal map is constant along these lines, and the vectors $f_2(s, t) = c'(s)$ are principal vectors, with $k_1 = 0$. Once again, $K = 0$.

Since all the surfaces in our first category are flat, they are all locally isometric to the plane (that is the reason for the name “tangent developable”—a “development” of one surface on another is the very classical name for an isometry). The reader may easily construct isometries between the plane and generalized cylinders or cones. To map the tangent developable of c isometrically on the plane, we note that f_1, f_2 , and consequently E, F, G , depend only on the curvature κ of c , *not on its torsion*. So if c_1 is a plane curve with the same curvature as c , then our original surface is isometric to the tangent developable of c_1 , which is a subset of the plane. As an application of this fact, we note that the tangent developable of a helix (which has constant curvature) can be constructed from a piece of paper by cutting a circle out, and twisting the remaining portion around a cylinder.

All the surfaces in our first category are special cases of the surfaces in our second.

II. RULED SURFACES

These are the surfaces which can be parameterized as

$$f(s, t) = c(s) + t\delta(s)$$

for two curves c, δ . Since

$$f_1 = c' + t\delta' \quad \text{and} \quad f_2 = \delta,$$

the map f is an immersion when δ and $c' + t\delta'$ are linearly independent. In

particular, if δ and c' are linearly independent, this certainly happens for sufficiently small t . For fixed s , we obtain straight lines [or segments] through $c(s)$; these straight lines are called the *rulings* of the surface. The ruled surfaces which are not generalized cones or cylinders, or tangent developables, are sometimes called *scrolls*.

A calculation shows (Problem 4) that

$$K = \frac{-m^2}{EG - F^2} = \frac{-\langle c', \delta \times \delta' \rangle^2}{|(c' + t\delta') \times \delta|^2}.$$

A more reasonable formula for K is obtained when we choose our parameterization more carefully. Note first that we might as well choose δ to be a curve with $|\delta(s)| = 1$ (and consequently $\langle \delta(s), \delta'(s) \rangle = 0$); it is then called the **directrix** of the surface. Next note that if c is replaced by any curve which intersects each ruling only once, and the directrix is kept the same, then we obtain the same

surface. Let us assume that we always have $\delta'(s) \neq 0$ ("the directions of the rulings are always changing"). Then the ruling L_s through $c(s)$ is not parallel to the ruling $L_{s+\varepsilon}$ for small ε , so there is a unique point $P(\varepsilon)$ on L_s closest to $L_{s+\varepsilon}$. One can show (Problem 5) that as $\varepsilon \rightarrow 0$, the point $P(\varepsilon)$ approaches the point

$$\sigma(s) = c(s) - \frac{\langle c'(s), \delta'(s) \rangle}{\langle \delta'(s), \delta'(s) \rangle} \cdot \delta(s) \quad \text{on } L_s.$$

We easily find from this that $\langle \sigma'(s), \delta'(s) \rangle = 0$. This is the only curve σ that can have this property: the point $\sigma(s)$ is simply the unique point on L_s where

the tangent plane of the surface contains a vector perpendicular to $\delta'(s)$. The curve σ is called the **striction curve** of the surface, and clearly depends only on the surface, not on the original parameterization. One further alteration eliminates all trace of the original parameterization—we might as well change s so that it is the arclength of δ . We thus have the “standard parameterization”

$$\begin{aligned} f(s, t) &= \sigma(s) + t\delta(s) \\ |\delta| &= |\delta'| = 1, \quad \langle \sigma', \delta' \rangle = 0 \\ [\delta, \sigma'] &\text{ linearly independent}. \end{aligned}$$

[The only thing that might go wrong in all this is that $\sigma(s)$ might be a point where the original, and hence the new, f is not an immersion. As a matter of fact (Problem 5), for the tangent developable of c , the striction curve is just c itself.] It now turns out (Problem 4) that

$$K = \frac{-p^2(s)}{(p^2(s) + t^2)^2} \quad \text{for } p = \langle \sigma'(s), \delta(s) \times \delta'(s) \rangle.$$

The function p is called the **distribution parameter**. Since p depends only on s , we see that $K \rightarrow 0$ as we go out along any ruling.

In addition to these general results, which we will put to use somewhat later, there are a few ruled surfaces of particular interest, two of which we will mention here, and two of which occur in our next category.

1. Möbius Strip

Our first example of a ruled surface is the “standard” Möbius strip, a slight modification of the one given on pg. I.10,

$$\begin{aligned} f(s, t) &= \left(\cos s + t \cos \frac{s}{2} \cos s, \sin s + t \cos \frac{s}{2} \sin s, t \sin \frac{s}{2} \right) \\ &= (\cos s, \sin s, 0) + t \left(\cos \frac{s}{2} \cos s, \cos \frac{s}{2} \sin s, \sin \frac{s}{2} \right) \quad (|t| < \frac{1}{2}). \end{aligned}$$

Computing directly from formulas (A) we find that

$$E = \frac{t^2}{4} + \left[1 + t \cos \left(\frac{s}{2} \right) \right]^2 \quad F = 0 \quad G = 1$$

(the values of F and G should be obvious!). Notice that this surface is *not* flat, so it is not the Möbius strip that one makes out of a strip of paper.

A C^∞ flat surface homeomorphic to the Möbius strip can be constructed as follows. We start with a curve c like the one shown in the first figure below.

The tangent vectors at A and B are negatives of each other, and the plane P in which they lie is the osculating plane of c at these points, so that c'' lies in P at A and B . We then consider the portion of the tangent developable of c which is formed by the positive multiples of the tangent vectors. From this surface we can cut out a strip, as shown in the second part of the figure, which is homeomorphic to the Möbius strip. If we choose c so that all $c^{(k)}$, $k > 2$ vanish at A and B , then this surface will be C^∞ . Notice that the resulting picture is a “back-view” of the Möbius strip shown above.

In Chapter 5 we will mention a way of constructing an analytic flat Möbius strip.

2. (Right) Helicoid

This surface is generated by a line which moves along the z -axis in such a way that it remains parallel to the (x, y) -plane, and passes through the points of a circular helix (in other words, the surface is generated by a line perpendicular to the z -axis under a “screw” motion). It is thus given by

$$f(s, t) = (t \cos s, t \sin s, bs), \quad b \neq 0.$$

The lines $t = \text{constant}$ are helices (compare pg. II.32). Computing from (A) and (B), we find that

$$\begin{aligned} f_1(s, t) &= (-t \sin s, t \cos s, b) & f_2(s, t) &= (\cos s, \sin s, 0) \\ f_{11}(s, t) &= (-t \cos s, -t \sin s, 0) & f_{22}(s, t) &= (0, 0, 0) \\ f_{12}(s, t) &= (-\sin s, \cos s, 0) \\ E &= b^2 + t^2, \quad F = 0, \quad G = 1; & \sqrt{EG - F^2} &= \sqrt{b^2 + t^2} \\ l &= n = 0, \quad m = \frac{b}{\sqrt{b^2 + t^2}} \\ K &= -\frac{b^2}{(b^2 + t^2)^2}, \quad H = 0. \end{aligned}$$

The helices $t = \text{constant}$ intersect the rulings $s = \text{constant}$ in right angles ($F = 0$). They also point in the asymptotic directions ($l = n = 0$), so H must be 0.

III. QUADRIC SURFACES

These are the surfaces of the form $W^{-1}(0)$, where

$$W(x_1, x_2, x_3) = \sum a_{ij} x_i x_j + \sum b_i x_i + c.$$

Standard arguments (Problem 6) show that, aside from trivial cases, they are all one of the following (up to rotations and translations); some of them are old friends of ours.

0. Sphere

This is a special case of the surfaces of the first group, but it surely deserves special mention. As we know, for the sphere of radius R , the normal map ν is just $-1/R$ times the identity (choosing the *inward* pointing normal, as on pg. II.52); every point is umbilic, the principal curvatures are $1/R$, and $K = 1/R^2$, $H = 1/2R$.

1. Ellipsoid

This surface has the equation

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1.$$

The planes perpendicular to an axis intersect the surface in a family of similar ellipses.

Choosing

$$W(x, y, z) = \frac{1}{2} \left(\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} - 1 \right)$$

$$W_1(x, y, z) = \frac{x}{a^2} \quad W_2(x, y, z) = \frac{y}{b^2} \quad W_3(x, y, z) = \frac{z}{c^2}$$

$$(W_{ij}) = \begin{pmatrix} 1/a^2 & 0 & 0 \\ 0 & 1/b^2 & 0 \\ 0 & 0 & 1/c^2 \end{pmatrix}$$

and applying (***) on page 140, we have

$$K = \frac{1}{a^2 b^2 c^2} \cdot \left(\frac{x^2}{a^4} + \frac{y^2}{b^4} + \frac{z^2}{c^4} \right)^{-2}.$$

Problem 7 casts this into a more useful form, which among other things allows us to see immediately that the maximum and minimum Gaussian curvatures occur at the expected places.

Using (D''), we find that (x, y, z) is an umbilic if and only if

$$\det \begin{pmatrix} x/a^2 & a_1/a^2 & a_1 \\ y/b^2 & a_2/b^2 & a_2 \\ z/c^2 & a_3/c^2 & a_3 \end{pmatrix} = 0 \text{ for all } a_1, a_2, a_3 \text{ with } \frac{a_1 x}{a^2} + \frac{a_2 y}{b^2} + \frac{a_3 z}{c^2} = 0.$$

If $a > b > c > 0$, then there turn out to be exactly four umbilics on M (Problem 9). If, on the other hand, we are dealing with an ellipse of rotation, then there will be two whole circles of umbilics.

2. Elliptic Hyperboloid (of one sheet)

The equation now is

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1.$$

Planes perpendicular to the z -axis intersect the surface in similar ellipses, while planes perpendicular to the other axes intersect it in hyperbolas. When $a = b$, it may be obtained by revolving a hyperbola around the z -axis (hyperboloid of revolution).

This surface is a *ruled surface*! In fact, it is doubly ruled: it may be parameterized as

$$\begin{aligned} f(s, t) &= (a \cos s, b \sin s, 0) + t(-a \sin s, b \cos s, c) \\ \text{or} \quad f(s, t) &= (a \cos s, b \sin s, 0) + t(a \sin s, -b \cos s, c). \end{aligned}$$

In each case the rulings pass through the ellipse $x^2/a^2 + y^2/b^2 = 1, z = 0$ and are perpendicular to the radius vector to that point. For a hyperboloid of

revolution, it is possible to demonstrate this ruling dramatically with apparatus like that pictured below. (The general elliptic hyperboloid must then also be ruled, since it is the image of an hyperboloid of revolution under a linear map $(x, y, z) \mapsto (\alpha x, \beta y, z)$.)

To compute K , we choose a W similar to that for the ellipsoid, and obtain

$$\begin{aligned} W_1 &= \frac{x}{a^2} & W_2 &= \frac{y}{b^2} & W_3 &= -\frac{z}{c^2} \\ (W_{ij}) &= \begin{pmatrix} 1/a^2 & 0 & 0 \\ 0 & 1/b^2 & 0 \\ 0 & 0 & 1/c^2 \end{pmatrix}. \end{aligned}$$

Then K turns out to be precisely

$$K = \frac{-1}{a^2 b^2 c^2} \left(\frac{x^2}{a^4} + \frac{y^2}{b^4} + \frac{z^2}{c^4} \right)^{-2}.$$

Since K is negative, there are, of course, no umbilics.

3. *Elliptic Hyperboloid (of two sheets)*

The equation is

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = -1.$$

It is still true that planes perpendicular to the z -axis intersect the surface in ellipses (when they intersect it at all), while planes perpendicular to the other axes intersect it in hyperbolas. However, the surface looks quite different.

To compute K we choose a W which differs only by a constant from the W for the elliptic hyperboloid of one sheet. The computations are then precisely the same, except that the factor $x^2/a^2 + y^2/b^2 - z^2/c^2$ which appears is now equal to -1 . So we get

$$K = \frac{1}{a^2 b^2 c^2} \left(\frac{x^2}{a^4} + \frac{y^2}{b^4} + \frac{z^2}{c^4} \right)^{-2}.$$

Again there are four umbilics (Problem 9).

4. *Elliptic Paraboloid*

The equation is simply

$$z = \frac{x^2}{a^2} + \frac{y^2}{b^2}.$$

Planes perpendicular to the z -axis intersect the surface in similar ellipses. Planes perpendicular to the other axes intersect it in parabolas. When $a = b$ we have a paraboloid of revolution.

Computations are especially simple:

$$\begin{aligned}
 W(x, y, z) &= \frac{1}{2} \left(\frac{x^2}{a^2} + \frac{y^2}{b^2} - z \right) \\
 W_1 &= \frac{x}{a^2} & W_2 &= \frac{y}{b^2} & W_3 &= -\frac{1}{2} \\
 (W_{ij}) &= \begin{pmatrix} 1/a^2 & 0 & 0 \\ 0 & 1/b^2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \\
 K &= \frac{1}{4a^2b^2} \left(\frac{x^2}{a^4} + \frac{y^2}{b^4} + \frac{1}{4} \right)^{-2}.
 \end{aligned}$$

There are two umbilics (Problem 10).

5. *Hyperbolic Paraboloid*

Here the equation is

$$z = \frac{x^2}{a^2} - \frac{y^2}{b^2}.$$

Planes perpendicular to the y -axis intersect the surface in parabolas, and planes perpendicular to the x -axis intersect the surface in parabolas pointing the other way. Planes perpendicular to the z -axis intersect the surface in hyperbolas pointing in one direction when the plane lies above the (x, y) -plane, and in the other direction when the plane lies below the (x, y) -plane; the (x, y) -plane itself intersects the surface in two intersecting straight lines.

This surface is also doubly ruled. It may be parameterized as

$$f(s, t) = (as, 0, s^2) + t(a, b, 2s) \quad \text{or} \quad f(s, t) = (as, 0, s^2) + t(a, -b, 2s).$$

[It is a classical result that all doubly ruled surfaces with $K < 0$ are quadratic. An elementary, somewhat unsatisfying proof is given in Problem 11; a nice proof can be given (Problem 4-16) by means of affine surface theory, which shouldn't

be too surprising, since the property of being doubly ruled is invariant under affine maps.]

For computations we choose

$$W(x, y, z) = \frac{1}{2} \left(\frac{x^2}{a^2} - \frac{y^2}{b^2} - z \right)$$

$$W_1 = \frac{x}{a^2} \quad W_2 = -\frac{y}{b^2} \quad W_3 = -\frac{1}{2}$$

$$(W_{ij}) = \begin{pmatrix} 1/a^2 & 0 & 0 \\ 0 & -1/b^2 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

$$K = \frac{-1}{4a^2b^2} \left(\frac{x^2}{a^4} + \frac{y^2}{b^4} + \frac{1}{4} \right)^{-2}.$$

IV. SURFACES OF REVOLUTION

These are the surfaces obtained by starting with a curve (the **profile** curve), lying in the right half of the (x, z) -plane, and revolving it about the z -axis. If

the curve intersects the z -axis, it must do so at a right angle. As illustrated in the figure at the top of the next page, the surface is parameterized by

$$f(s, t) = (c_1(s) \cos t, c_1(s) \sin t, c_2(s)).$$

The curves $s = \text{constant}$ are called **parallels** and the curves $t = \text{constant}$ are called **meridians**.

By (A) we compute

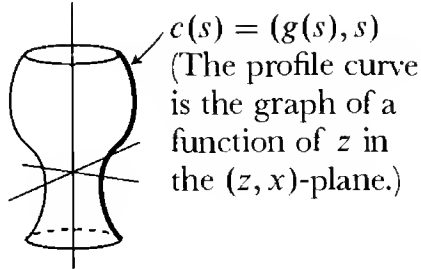

$$\begin{aligned}
 f_1 &= (c_1' \cos t, c_1' \sin t, c_2') & f_2 &= (-c_1 \sin t, c_1 \cos t, 0) \\
 f_{11} &= (c_1'' \cos t, c_1'' \sin t, c_2'') & f_{22} &= (-c_1 \cos t, -c_1 \sin t, 0) \\
 f_{12} &= (-c_1' \sin t, c_1' \cos t, 0) \\
 E &= (c_1')^2 + (c_2')^2 & F &= 0 & G &= c_1^2 \\
 \sqrt{EG - F^2} &= c_1 \sqrt{(c_1')^2 + (c_2')^2} \\
 l &= \frac{c_1' c_2'' - c_2' c_1''}{\sqrt{(c_1')^2 + (c_2')^2}} & m &= 0 & n &= \frac{c_1 c_2'}{\sqrt{(c_1')^2 + (c_2')^2}}
 \end{aligned}$$

Since $F = m = 0$, the tangent vectors of parallels and meridians point in the directions of the principal curvatures; we can use equations (G) to find directly that the principal curvatures are

$$\begin{aligned}
 k_{\text{meridian}} &= \frac{l}{E} = \frac{c_1' c_2'' - c_2' c_1''}{[(c_1')^2 + (c_2')^2]^{3/2}} \\
 k_{\text{parallel}} &= \frac{n}{G} = \frac{c_2'}{c_1 [(c_1')^2 + (c_2')^2]^{1/2}} \\
 K &= k_{\text{meridian}} \cdot k_{\text{parallel}} = \frac{c_2' (c_1' c_2'' - c_2' c_1'')}{c_1 [(c_1')^2 + (c_2')^2]^2} \\
 H &= \frac{1}{2} (k_{\text{meridian}} + k_{\text{parallel}}) .
 \end{aligned}$$

It will be useful for us to consider the special case where $c(s) = (g(s), s)$. Then we find that

$$(3) \quad \begin{aligned} k_{\text{meridian}} &= \frac{-g''}{[1 + (g')^2]^{3/2}} \\ k_{\text{parallel}} &= \frac{1}{g[1 + (g')^2]^{1/2}} \\ K &= \frac{-g''}{g[1 + (g')^2]^2} \\ H &= \frac{1 + (g')^2 - gg''}{2g[1 + (g')^2]^{3/2}} \end{aligned}$$

It is also useful to consider the **canonical parameterization**, where $|c'|^2 = (c_1')^2 + (c_2')^2 = 1$. Then also $c_1'c_1'' + c_2'c_2'' = 0$, so we find

$$(4) \quad \begin{aligned} E &= 1 & F &= 0 & G &= c_1^2 \\ K &= \frac{c_2'(c_1'c_2'' - c_2'c_1'')}{c_1} = \frac{c_1'(c_2'c_2'') - c_1''(c_2')^2}{c_1} \\ &= \frac{c_1'(-c_1'c_1'') - c_1''[1 - (c_1')^2]}{c_1} \\ &= -\frac{c_1''}{c_1} \end{aligned}$$

It is interesting to note that we can obtain all these results in a purely geometric way without any calculations. We first observe that the normals to the surface along the profile curve c lie in the (x, z) -plane. This means that

the derivative of ν along the profile curve also lies in the (x, z) -plane. Since it must also be tangent to the surface, it is a multiple of c' . Thus c' is one eigenvector for $-d\nu$. The corresponding eigenvalue is also easy to find. We notice first that our choice of N as $(f_1 \times f_2)/|f_1 \times f_2|$ makes ν inward pointing;

so along c , the vector v is just the normal \mathbf{n} of c . Therefore $-dv(c') = -\mathbf{n}' = \kappa \cdot c'$ (from the Serret-Frenet formulas for plane curves), and the eigenvalue is just the curvature of c . Comparing the formula for k_{meridian} in (2) with the formula on pg. II.8, we see that this is precisely what we have obtained in the calculations.

We next consider the outward pointing normal $-v$ along a parallel. This makes a constant angle θ with the z -axis, so in S^2 it traces out a circle, of radius $\sin \theta$, consisting of vectors with 3rd component constant. So the derivative of $-v$

will be a vector with 3rd component 0, and perpendicular to the radius vector. It is therefore a multiple of the tangent vector of the parallel. If we parameterize our parallel so that we go once around in time 2π , then its tangent vector has length $a = \text{radius of the parallel}$. In the same time, the vector $-v$ goes once around a circle of radius $\sin \theta$, so its tangent vector has length $\sin \theta$. This shows that the corresponding eigenvalue is $\frac{1}{a} \sin \theta$, which is precisely what the formula for k_{parallel} in (2) gives.

Now let us take some particular cases. We begin with the most familiar example (after cylinders, cones, and spheres).

1. Torus

We rotate a circle of radius r around the z -axis so that its center traces out a circle of radius R . Measuring angles θ around the little circle clockwise from

the z -axis, we see that the principal curvatures are:

$$\frac{1}{r} = \text{curvature of circle of radius } r$$

$$\frac{\sin \theta}{R + r \sin \theta}, \quad \text{since } a = R + r \sin \theta.$$

In particular, as suspected, $K > 0$ on the outer half of the torus, and $K < 0$ on

the inner half. Notice that the principal curvatures can never be equal, so there are no umbilics.

2. Catenoid

This surface, which we have already met in Volume I, Chapter 9, but not yet been formally introduced to, is obtained by revolving a **catenary**, with equation $x = a \cosh(z/a) = g(z)$, around the z -axis.

Since

$$\cosh' z = \frac{e^z - e^{-z}}{2} = \sinh z, \quad \cosh'' z = \frac{e^z + e^{-z}}{2} = \cosh z$$

$$1 + (\cosh' z)^2 = 1 + \frac{e^{2z} - 2 + e^{2z}}{4} = \frac{1}{2} + \frac{e^{2z}}{2} = (\cosh z)^2,$$

formulas (3) give us

$$k_{\text{meridian}} = \frac{-\frac{1}{a} \cosh \frac{z}{a}}{\left[\cosh^2 \frac{z}{a} \right]^{3/2}} = \frac{-1}{a \cosh^2 \frac{z}{a}}$$

$$k_{\text{parallel}} = \frac{1}{a \cosh \frac{z}{a} \left[\cosh^2 \frac{z}{a} \right]^{1/2}} = \frac{1}{a \cosh^2 \frac{z}{a}}$$

$$H = 0, \quad K = \frac{-1}{a^2 \cosh^4 \frac{z}{a}}.$$

Clearly $-1/a^2 \leq K < 0$, with $K = -1/a^2$ on the inner circle $z = 0$, and $K \rightarrow 0$ as $z \rightarrow \pm\infty$.

It is also useful to find the canonical parameterization for the catenoid; we take the case $a = 1$. For $c(u) = (\cosh u, u)$, we have

$$\text{length of } c \text{ from } 0 \text{ to } u = \int_0^u \sqrt{1 + (\cosh' v)^2} dv = \int_0^u \cosh v dv = \sinh u,$$

so we want to take the curve

$$\begin{aligned} \gamma(s) &= c(\sinh^{-1}(s)) = (\cosh(\sinh^{-1}(s)), \sinh^{-1}(s)) \\ &= (\sqrt{1+s^2}, \sinh^{-1}(s)) \quad [\text{see Problem I.9-20(d)}]. \end{aligned}$$

We then have, by formulas (4),

$$E = 1 \quad F = 0 \quad G = 1 + s^2$$

$$K = \frac{-1}{(1 + s^2)^2}.$$

3. Rotation Surfaces of Constant Curvature

We consider surfaces of revolution with canonical parameterization

$$f(s, t) = (g(s) \cos t, g(s) \sin t, h(s)), \quad (g')^2 + (h')^2 = 1,$$

and among these seek the ones with constant K . According to equations (4) we have

$$K = -\frac{g''}{g}.$$

Case 1. $K = 0$

Then $g(s) = as + b$. If $a \neq 0$, then we can assume that $b = 0$, since this merely amounts to renaming the parameter s . To have $(g')^2 + (h')^2 = 1$ we take

$$\left. \begin{aligned} g(s) &= as \\ h(s) &= \int_0^s \sqrt{1 - a^2} dt = \pm s\sqrt{1 - a^2} \end{aligned} \right\} \quad \text{or} \quad \begin{cases} g(s) = 0 \cdot s + b \\ h(s) = s \end{cases}$$

(changing h by a constant merely amounts to translating the profile curve along the z -axis); clearly we must have $|a| \leq 1$. For $a = 0$ we obtain a cylinder, for $|a| = 1$ a plane, and for $0 < |a| < 1$ a cone.

Case 2. $K > 0$

For simplicity, we take the case $K = 1$. We have to find g satisfying $g'' + g = 0$. The general solution, $g(s) = a_1 \cos s + a_2 \sin s$, can also be written

$$g(s) = a \cos(s + b).$$

We can always assume $b = 0$, and we take

$$\begin{aligned} g(s) &= a \cos s \\ h(s) &= \pm \int_0^s \sqrt{1 - g'(t)^2} dt = \pm \int_0^s \sqrt{1 - a^2 \sin^2 t} dt. \end{aligned}$$

For $a = 1$ we obtain the sphere of radius 1.

For $a < 1$, the integrand in the expression for h is always real, and the only restriction on our formulas is that $g(s)$ must be ≥ 0 . We can take $0 \leq s < \pi/2$; the resulting profile curve can be expressed in terms of elliptic integrals.

For $a > 1$, we must restrict s to $0 \leq s \leq \arcsin 1/a$ for the integrand to be real. At the endpoint of the interval, h' is 0, so the profile curve has horizontal tangents; once again, elliptic integrals are involved.

Case 3. $K < 0$

We take the case $K = -1$. The general solution of $g'' - g = 0$ is

$$g(s) = ae^s + be^{-s}.$$

Suppose first that one of a, b is 0. We can assume that $b = 0$, since changing s to $-s$ interchanges a and b . We might as well assume $a > 0$, since changing a to $-a$ just changes the profile curve to its mirror image. Finally, we can assume $a = 1$, since changing s to $s + s_0$ multiplies a by e^{s_0} . So we take

$$g(s) = e^s$$

$$h(s) = \pm \int_0^s \sqrt{1 - e^{2t}} dt;$$

we clearly need $e^{2s} \leq 1$, and therefore $g(s) \leq 1$. The resulting surface is called a **pseudosphere**. Its profile curve was known to mathematicians long before the advent of differential geometry. Since s is the parameterization by arclength,

the angle ϕ in the picture below satisfies

$$\sin \phi = \cos \theta = \frac{g'(s)}{\sqrt{[g'(s)]^2 + [h'(s)]^2}} = g'(s) = e^s.$$

So AB has constant length

$$\overline{AB} = \frac{g(s)}{\sin \phi} = \frac{e^s}{e^s} = 1.$$

If one started at $(0,0)$ and walked along the y -axis pulling a wagon that started at $(1,0)$ and had a handle of length 1, then the wagon would follow this curve, which is therefore called a **tractrix** (Latin: *trahere*, *tractum* to draw). The upper

half of the tractrix is the graph of the function

$$\begin{aligned} f(x) &= \int_0^{\log x} \sqrt{1 - e^{2t}} \, dt \\ &= \int_1^x \sqrt{1 - u^2} \cdot \frac{1}{u} \, du \\ &= \sqrt{1 - x^2} - \cosh^{-1} \frac{1}{x}. \end{aligned}$$

Now suppose that $a, b \neq 0$. Since changing s to $s + s_0$ multiplies a and b by different constants, we can assume that either $a = -b$ or $a = b$.

In the case $a = -b$ we can assume $a > 0$ (by changing s to $-s$ and thereby interchanging a and b). So we take

$$\begin{aligned} g(s) &= a(e^s - e^{-s}) = 2a \sinh s \\ h(s) &= \pm \int_0^s \sqrt{1 - 4a^2 \cosh^2 t} \, dt; \end{aligned}$$

we need $0 < 2a < 1$ and $1 \leq \cosh s \leq 1/2a$, so that $0 \leq s \leq \cosh^{-1} 1/2a$ and $0 \leq g(s) \leq \sqrt{1 - 4a^2}$. These functions can also be expressed in terms of elliptic integrals.

In case $a = b$, we can assume both are positive, since changing the sign of both changes the profile curve to its mirror image. So we take

$$\begin{aligned} g(s) &= 2a \cosh s \\ h(s) &= \pm \int_0^s \sqrt{1 - 4a^2 \sinh^2 t} \, dt; \end{aligned}$$

we need $|\sinh s| \leq 1/2a$ and thus $2a \leq g(s) \leq \sqrt{1 + 4a^2}$. Elliptic integrals are again required.

These results about surfaces of revolution may be compared with the remarks made by Riemann in section II.5 of his Inaugural Lecture (pg. II.159).

4. A Classical Counterexample

Consider the surface of revolution

$$f(s, t) = (s \sin t, s \cos t, \log s).$$

Formulas (1) and (2) give

$$\begin{aligned} E &= 1 + \frac{1}{s^2} & F &= 0 & G &= 1 \\ k_{\text{meridian}} &= \frac{-1/s^2}{\left[1 + \frac{1}{s^2}\right]^{3/2}} & k_{\text{parallel}} &= \frac{1/s}{s \left[1 + \frac{1}{s^2}\right]^{1/2}} \\ K &= \frac{-1}{(1 + s^2)^2}. \end{aligned}$$

On the other hand, interchanging the role of s and t in the parameterization of the helicoid (page 150), we see that $g(s, t) = (s \cos t, s \sin t, t)$ has

$$E = 1 \quad F = 0 \quad G = 1 + s^2$$

$$K = \frac{-1}{(1 + s^2)^2}.$$

Consequently, the map $f(s, t) \mapsto g(s, t)$ preserves K , but is not an isometry; in fact, there is clearly no local isometry between the two surfaces, since the s -parameters would have to correspond to preserve K , and then E would not be preserved.

V. MINIMAL SURFACES

A whole branch of mathematics is devoted to the study of surfaces with mean curvature $H = 0$. As we shall show in Chapter 9, this condition is precisely the one which must be satisfied by a surface which is a critical point for the area function among all surfaces with the same boundary curve c . In particular, if a

surface has minimum area among those with c as boundary, then it must satisfy the condition $H = 0$. For this reason, surfaces with mean curvature $H = 0$ are called **minimal**.

We have already met two minimal surfaces in our survey, the helicoid and the catenoid. They, in fact, were the first two non-planar minimal surfaces to be discovered (by Meusnier), and we are led to them directly if we seek minimal surfaces among other known classes of surfaces.

Let us consider first the surfaces of revolution. If our profile curve is a straight line perpendicular to the z -axis, we obtain a plane. Otherwise, some portion of the curve can be represented by $c(s) = (g(s), s)$. Using formulas (3) on

page 158, we find that $H = 0$ when

$$1 + (h')^2 - hh'' = 0.$$

This is precisely the equation we obtained on pg. I.321, when we were actually finding the minimum area of a surface of revolution. We found there that the solutions are

$$g(z) = a \cosh \frac{z+b}{a}.$$

This result applies only to a portion of the surface, but a simple least upper bound argument shows that if a connected profile curve has this form somewhere, then it must have it everywhere (and in particular cannot also contain part of a line perpendicular to the z -axis). We have thus shown that:

Any connected minimal surface of revolution is part of a plane or a catenoid.

We consider next the ruled surface

$$\begin{aligned} f(s, t) &= \sigma(s) + t\delta(s) \\ |\delta| &= |\delta'| = 1, \quad \langle \sigma', \delta' \rangle = 0 \\ [\delta, \sigma' &\text{ linearly independent}]. \end{aligned}$$

Then we have

$$\begin{aligned} f_1 &= \sigma' + t\delta' & f_2 &= \delta \\ f_{11} &= \sigma'' + t\delta'' & f_{22} &= 0 \\ f_{12} &= \delta' \\ F &= \langle \delta, \sigma' \rangle & G &= 1; \quad \text{let } W = \sqrt{EG - F^2} \\ l &= \frac{1}{W} \det \begin{pmatrix} \sigma'' + t\delta'' \\ \sigma' + t\delta' \\ \delta \end{pmatrix} & m &= \frac{1}{W} \det \begin{pmatrix} \delta' \\ \sigma' + t\delta' \\ \delta \end{pmatrix} & n &= 0. \end{aligned}$$

So equations (B) show that $H = 0$ when

$$0 = -2\langle \delta, \sigma' \rangle \det \begin{pmatrix} \delta' \\ \sigma' + t\delta' \\ \delta \end{pmatrix} + \det \begin{pmatrix} \sigma'' + t\delta'' \\ \sigma' + t\delta' \\ \delta \end{pmatrix}.$$

Using multilinearity of \det as a function of its rows, and noting that the coefficient of each power of t must vanish, we obtain

$$(1) \quad \langle \delta, \sigma' \rangle \det \begin{pmatrix} \delta' \\ \sigma' \\ \delta \end{pmatrix} = 0 \quad (2) \quad \det \begin{pmatrix} \sigma'' \\ \delta' \\ \delta \end{pmatrix} + \det \begin{pmatrix} \delta'' \\ \sigma' \\ \delta \end{pmatrix} = 0 \quad (3) \quad \det \begin{pmatrix} \delta'' \\ \delta' \\ \delta \end{pmatrix} = 0.$$

Equation (3) shows that δ'' is a linear combination of δ and δ' . But we also have

$$\langle \delta', \delta' \rangle = 1 \implies \langle \delta', \delta'' \rangle = 0$$

$$\langle \delta, \delta \rangle = 1 \implies \langle \delta, \delta' \rangle = 0 \implies \langle \delta', \delta' \rangle + \langle \delta, \delta'' \rangle = 0 \implies \langle \delta, \delta'' \rangle = -1,$$

which shows that

$$\delta'' = -\delta.$$

This means that $-\delta$ is the normal \mathbf{n} of the curve δ , and that the curvature of δ is $\kappa = 1$. Also, $\mathbf{b} = \mathbf{t} \times \mathbf{n} = \delta' \times -\delta$, so

$$\mathbf{b}' = -(\delta' \times \delta)' = -(\delta' \times \delta') - (\delta'' \times \delta) = 0.$$

Thus $\tau = 0$, and δ is a plane curve. Since it lies in S^2 , and has curvature 1, it must be a circle of radius 1. We can assume therefore that

$$\delta(s) = (\cos s, \sin s, 0).$$

Now in equation (2), the second determinant is already 0, so we find that σ'' is a linear combination of δ, δ' , which means that σ'' lies in the (x, y) -plane. So σ must be of the form

$$\sigma(s) = (\alpha(s), \beta(s), bs + a) \implies \sigma'(s) = (\alpha'(s), \beta'(s), b).$$

We might as well assume that $a = 0$, since this just amounts to a translation along the z -axis.

Now consider equation (1), which says that a certain product is 0. If the second factor is 0 for some s_0 , then $\sigma'(s_0)$ must be a linear combination of $\delta(s_0), \delta'(s_0)$, so $b = 0$. In this case, all rulings $\sigma(s) + t\delta(s)$ lie in a plane, and our surface is just the plane. If $b \neq 0$, then for all s we must have

$$0 = \langle \delta(s), \sigma'(s) \rangle = \alpha'(s) \cos s + \beta'(s) \sin s$$

$$0 = \langle \delta'(s), \sigma'(s) \rangle = -\alpha'(s) \sin s + \beta'(s) \cos s.$$

So $\alpha' = \beta' = 0$, i.e., α and β are constants, and our surface is given by

$$f(s, t) = (\alpha + t \cos s, \beta + t \sin s, bs).$$

A translation in the (x, y) -plane changes α and β to 0, and we obtain the helicoid.

Our analysis has left a few points in doubt, because the standard parameterization with which we began is possible only when the directions of the rulings of our ruled surface are always changing. When the directions of the rulings are *never* changing we obtain a generalized cylinder, which is minimal only if it is a plane. As before, a least upper bound argument shows that if $\delta' \neq 0$ on some interval, so that we do have a helicoid on this interval, then $\delta' \neq 0$ everywhere. We have thus shown that:

Any connected minimal ruled surface is part of a plane or a helicoid.

It is, of course, not particularly surprising that each of these families of surfaces contains only one non-planar minimal surface. But it is rather surprising that these two surfaces, *the catenoid and the helicoid, are locally isometric*. To prove this, we merely recall (page 167) that

the helicoid $f(s, t) = (s \cos t, s \sin t, t)$ has $E = 1 \quad F = 0 \quad G = 1 + s^2$,
while (page 161)

the catenoid $g(s, t) = (\sqrt{1 + s^2} \cos t, \sqrt{1 + s^2} \sin t, \sinh^{-1}(s))$ also has
 $E = 1 \quad F = 0 \quad G = 1 + s^2$.

The isometry, taking $f(s, t)$ to $g(s, t)$, carries

rulings of the helicoid to *meridians* of the catenoid (t constant)
helices of the helicoid to *parallels* of the catenoid ($s \neq 0$ constant)
z-axis of the helicoid to *center circle* of the catenoid ($s = 0$).

Actually, we can do a lot better than this: it is possible to deform one of these surfaces into the other by means of a 1-parameter family of isometric surfaces:

Although we could write down an explicit formula for this 1-parameter family, it will come out very naturally in Chapter 9.

The example of the helicoid and catenoid also shows that two immersions, $f, \tilde{f}: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ with the same g_{ij} (and therefore also the same K) as well as the same H need not differ by a Euclidean motion of \mathbb{R}^3 —one needs to know the l_{ij} themselves, not just $\text{trace}(l_{ij})$ and $\det(l_{ij})$ [or equivalently the eigenvalues of (l_{ij})], in order to determine the surface.

The first minimal surface to be discovered after the catenoid and helicoid was

1. *Scherk's Minimal Surface*

This is the surface M defined by

$$e^z \cos x = \cos y.$$

If we define $W: \mathbb{R}^3 \rightarrow \mathbb{R}$ by

$$W(x, y, z) = e^z \cos x - \cos y,$$

then the three vectors

$$W_1(x, y, z) = -e^z \sin x \quad W_2(x, y, z) = \sin y \quad W_3(x, y, z) = e^z \cos x$$

are never all 0, so $W^{-1}(0)$ is a surface, which is orientable since it has a well-defined normal, as on page 138. The lines $x = \pi/2 + m\pi$ and $y = \pi/2 + m\pi$, for $m \in \mathbb{Z}$, divide \mathbb{R}^2 into squares, and those where $\cos x \cos y > 0$ form a checkerboard pattern. Since $e^z > 0$, there are clearly no points of M over the

1. P-Q4, N-KB3
2. N-Q2, P-K4
3. P×P, N-N5
4. P-KR3, N-K6
5. Resign

“white” squares. Over the vertices of the squares, where $\cos x = \cos y = 0$, we have perpendicular lines, since z can have any value. Over the “black” squares, we can solve explicitly for z ,

$$z = \log \left(\frac{\cos y}{\cos x} \right).$$

The surface is made up of infinitely many of these structural units.

The small portion of the surface pictured above is simply homeomorphic to a cylinder (with a very floppy side), and there is an obvious closed curve c connecting the four saddle points which represents a non-trivial element of the fundamental group. Moreover, this curve c does not disconnect the (complete) surface. To see this, note that just as the vertical line L_1 can be connected to the line L_2 by a curve lying in the two adjacent units which share the common edge L' , so lines L_3 and L_4 can be connected by a curve lying in two adjacent units (not drawn in the picture). But L_3 and L_4 can be connected to points which lie on (apparently) opposite sides of the curve c .

Similarly, we easily see that the surface actually has “infinite genus” (infinitely many closed curves may be removed from it without disconnecting it). It also has only one end. But it is known that two orientable surfaces with the same genus and the same space of ends are homeomorphic, so our surface must be homeomorphic to surface (A) in Problem I.1-20.

2. Enneper's Minimal Surface

This surface is parameterized by

$$f(u, v) = \left(\frac{u}{2} - \frac{u^3}{6} + \frac{uv^2}{2}, -\frac{v}{2} + \frac{v^3}{6} - \frac{u^2v}{2}, \frac{u^2}{2} - \frac{v^2}{2} \right).$$

A computation from equations (A) and (B) shows that $H = 0$. Of course, at present it is pretty hard to see how any one ever thought of this example, but in Chapter 9 we will see that in a certain sense it is the simplest minimal surface.

In the figure below, showing the image of f on $[-2.5, 2.5] \times [-2.5, 2.5]$, the top portion is seen almost completely from the side, while the bottom portion

is seen almost head on. The surface is taken into itself by the map

$$(x, y, z) \mapsto (y, x, -z),$$

with the line AB corresponding to the line CD .

Since the surface is the graph of a function, it is merely an immersed plane, and its structure can perhaps be better understood from the series of pictures on the next page, which show a saddle surface being deformed into a surface of the same type as Enneper's surface.

(d)

ADDENDUM

ENVELOPES OF 1-PARAMETER FAMILIES OF PLANES

In classical differential geometry, a central role was played by the notion of the envelope of a family of curves or surfaces. A careful treatment of this topic involves many delicate points, which to be sure were rather indelicately handled by classical geometers. However, the study of envelopes played such an important role in the evolution of the concept of a connection that a sketch of its essential features seems in order; the ideas developed here will also be used on a couple of later occasions.

Consider first a 1-parameter family $\tilde{\alpha}$ of curves in the plane, given by $\tilde{\alpha}(u) = t \mapsto \alpha(u, t)$ for some C^∞ function $\alpha: [0, 1] \times [0, 1] \rightarrow \mathbb{R}^2$. An **envelope** of this family is defined to be a curve c which is *not* a member of this family but which is tangent to some member of the family at every point. Unfortunately, it often

turns out that the envelope of a perfectly nice family of curves has a cusp or something worse; but for the time being we won't worry too much about this.

The classical way of finding the envelope of α was very geometric. For each u , we let $c(u)$ be the limit, as $\varepsilon \rightarrow 0$, of the intersection of $\bar{\alpha}(u)$ and $\bar{\alpha}(u + \varepsilon)$: the

envelope consists of the “intersections of members of the family with another member infinitely close to it”. The picture below shows that this idea can run into some serious difficulties. Nevertheless, it often works out rather well in

particular cases, and even in the general case it leads us to the proper analytic condition, when we argue as follows.

Let us consider first the case where our curves $\bar{\alpha}(u)$ are all expressed as the graphs of functions; thus there is a function $(u, x) \mapsto f(u, x)$ such that $\alpha(u, t) = (t, f(u, t))$. Suppose that the curve $\bar{\alpha}(u)$ intersects the curve $\bar{\alpha}(u+h)$ at the point

$$(x_h, f(u, x_h)) = (x_h, f(u + h, x_h)).$$

Then we have

$$0 = \frac{f(u + h, x_h) - f(u, x_h)}{h}.$$

Assuming that x_h approaches a number $x(u)$ as $h \rightarrow 0$, we find that $x(u)$ must be a point for which

$$(*) \quad D_1 f(u, x(u)) = 0.$$

If we find the points $x(u)$ for all u , then the envelope should be the curve consisting of all points $(x(u), f(u, x(u)))$.

If we are given a general family $\bar{\alpha}$, not necessarily expressed as graphs of functions, then we can introduce the function f in two steps. We first determine $t(u, x)$ so that

$$(1) \quad \alpha^1(u, t(u, x)) = x,$$

and then define

$$(2) \quad f(u, x) = \alpha^2(u, t(u, x)).$$

Then equation $(*)$ becomes

$$(3) \quad 0 = D_1 \alpha^2(u, t(u, x)) + D_2 \alpha^2(u, t(u, x)) \cdot D_1 t(u, x),$$

while equation (1) gives

$$\begin{aligned} D_1 \alpha^1(u, t(u, x)) + D_2 \alpha^1(u, t(u, x)) \cdot D_1 t(u, x) &= 0, \\ D_1 t(u, x) &= -\frac{D_1 \alpha^1}{D_2 \alpha^1}(u, t(u, x)). \end{aligned}$$

Substituting this into (3), we obtain

$$[D_1 \alpha^2 \cdot D_2 \alpha^1 - D_1 \alpha^1 \cdot D_2 \alpha^2](u, t(u, x)) = 0.$$

Thus we find that the envelope should consist of points $\alpha(u, t)$ where (u, t) satisfies

$$(**) \quad \det(D_i \alpha^j(u, t)) = 0.$$

Now even without resorting to the motivating geometric construction, it is clear that if there is an envelope of the family $\bar{\alpha}$, then it must be a subset of the points $\alpha(u, t)$ for which (u, t) satisfies (**). For, if the determinant in (**) is non-zero, then α is an immersion at (u, t) , and the curves $\bar{\alpha}(u)$ form a foliation of a neighborhood of $\alpha(u, t)$; consequently, the only curve through $\alpha(u, t)$ which

is tangent to some curve of the family at each point is $\bar{\alpha}(u)$ itself, which means that $\alpha(u, t)$ cannot be a point of an envelope.

Similar considerations will apply to 1-parameter families of surfaces in space. In particular, the geometric construction will be found quite useful when we consider 1-parameter families of planes. A plane P can be described as

$$\{x \in \mathbb{R}^3 : a_1 x_1 + a_2 x_2 + a_3 x_3 = \langle a, x \rangle = d\}$$

for some number d , and some $(a_1, a_2, a_3) \neq 0$, which we might as well assume is a unit vector. (Choosing the point $(x_1, x_2, x_3) \in P$ closest to 0, and noting that it must be a multiple of a , we see that d is just the distance from 0 to P , provided that a is picked so that it points in the direction of points further from 0). So a 1-parameter family of planes amounts to two functions $a: \mathbb{R} \rightarrow S^2$ and $d: \mathbb{R} \rightarrow \mathbb{R}$. Obviously if $a' = 0$, so that a is constant, then we obtain a family of parallel planes, and there is no envelope. Let us assume that, in fact, a' is *never* 0. Then any two nearby planes, corresponding to $u < v$, must intersect in a straight line, and all x on this line satisfy

$$\sum_i a_i(u)x_i - d(u) = \sum_i a_i(v)x_i - d(v) = 0.$$

Applying Rolle's Theorem to

$$s \mapsto \sum_i a_i(u + s[v - u])x_i - d(u + s[v - u]) \quad \text{on } [0, 1],$$

we find that

$$(1) \quad \sum_i a_i'(\xi)x_i - d'(\xi) = 0$$

for some ξ (depending on x) between u and v .

It follows that as $v \rightarrow u$, this line approaches the line satisfying

$$(*) \quad \begin{cases} \langle a(u), x \rangle = d(u) \\ \langle a'(u), x \rangle = d'(u) \end{cases}$$

(note that $a \in S^2$ implies that a' is perpendicular to a , so the planes given by these two equations are not parallel).

The line determined by $(*)$ is called the **characteristic line** of the plane determined by u ; its direction is $a(u) \times a'(u)$. If $(a \times a')' = 0$, so that all characteristic lines are parallel, then the envelope will be the generalized cylinder formed by all these characteristic lines, provided this actually exists (it could happen, for example, that all characteristic lines are the same, in which case no envelope would exist). Let us assume that, in fact, $(a \times a')'$ is *never* 0. Then any three nearby planes, corresponding to $u < v < w$, must have linearly independent $a(u), a(v), a(w)$, so the planes corresponding to u, v, w must intersect at a point (x_1, x_2, x_3) . This point must satisfy (I) and an analogous condition for v, w :

$$\sum_i a_i'(\bar{\xi})x_i - d'(\bar{\xi}) = 0$$

for some $\bar{\xi}$ between v and w .

Arguing as before, we see that

$$\sum_i a_i''(\eta)x_i - d''(\eta) = 0$$

for some η between ξ and $\bar{\xi}$.

It follows that as $v, w \rightarrow u$, this point approaches the point $c(u)$ satisfying

$$(**) \quad \begin{cases} \langle a(u), c(u) \rangle = d(u) \\ \langle a'(u), c(u) \rangle = d'(u) \\ \langle a''(u), c(u) \rangle = d''(u). \end{cases}$$

The point $c(u)$ determined by $(**)$ is called the **characteristic point** of the plane determined by u , and lies on its characteristic line. It is possible that $c' = 0$, so that c is a point. In this case, the envelope is the generalized cone formed by all the characteristic lines with c as vertex. Let us assume that, in fact, c' exists and is *never* 0. Differentiating the first two equations of $(**)$ gives

$$\begin{aligned} \langle a'(u), c(u) \rangle + \langle a(u), c'(u) \rangle &= d'(u), & \text{hence} \quad (2) \quad \langle a(u), c'(u) \rangle &= 0 \\ \langle a''(u), c(u) \rangle + \langle a'(u), c'(u) \rangle &= d''(u), & \text{hence} \quad (3) \quad \langle a'(u), c'(u) \rangle &= 0. \end{aligned}$$

Differentiating (2) then gives

$$\langle a'(u), c'(u) \rangle + \langle a(u), c''(u) \rangle = 0,$$

which together with (3) gives

$$(4) \quad \langle a(u), c''(u) \rangle = 0.$$

We thus have:

- $c(u)$ is the characteristic point of the plane determined by u
- $c'(u)$ has the same direction as the characteristic line (*)
- [by (2) and (3)]
- $c''(u)$ is in a plane parallel to the plane determined by u
- [by (4)].

So the plane determined by u is the osculating plane of c , and the tangent developable of c is the envelope of the family. Each plane of the family is tangent to this developable along the points where it intersects it, namely along its characteristic line. (For all this to work, of course, we need c'' to be non-zero.)

To sum things up, a 1-parameter family of planes “in general” has an envelope, which is either a generalized cylinder, a generalized cone, or the tangent developable of a curve. This well-known fact from classical differential geometry was precisely what gave Levi-Civita the clue for defining parallel translation in a Riemannian-manifold. He first observed that since generalized cylinders, generalized cones, and tangent developables are locally isometric to the plane, it makes sense to talk about parallel vector fields in these surfaces—they are just the images, under the local isometry, of parallel vector fields in the plane.

Now suppose that we are given a curve c on an arbitrary surface M . Consider the 1-parameter family of planes formed by the tangent planes $M_{c(u)}$. This family “generally speaking” has an envelope N , which is a generalized cylinder or cone, or the tangent developable to some (other) curve; and the tangent space of N is the same as that of M all along the curve c . So we can define a vector field V_u to be parallel along c in M if it is parallel along c in N . Once Levi-Civita had this definition of parallel vector fields along a curve c in M it was not hard to derive the usual equation for it, in terms of the Christoffel symbols. This equation shows that parallelism does not depend on the imbedding, and can be used to define parallel vector fields along a curve in any Riemannian manifold, of any dimension.

PROBLEMS

1. If $a_1 f_1 + a_2 f_2$ is a principal vector, then

$$\begin{pmatrix} G & -F \\ -F & E \end{pmatrix} \begin{pmatrix} l & m \\ m & n \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = \lambda \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}$$

for some λ . Write the two equations which this gives, and divide by a_1 and a_2 , respectively, to obtain two expressions for λ . From this derive equation (D) (and then check that it holds also for a_1 or $a_2 = 0$).

2. Let $f: V \rightarrow \mathbb{R}$ be a linear function on a (possibly infinite-dimensional) vector space V .

(a) If $v_1, v_2 \in V$, then $f(v_1)v_2 - f(v_2)v_1 \in \ker f$.

(b) We can write $V = \ker f \oplus W$, where W is 1-dimensional.

(c) If $g: V \rightarrow \mathbb{R}$ is a linear function with $\ker f \subset \ker g$, then $g = \lambda f$ for some $\lambda \in \mathbb{R}$.

(d) If $g, f_1, \dots, f_k: V \rightarrow \mathbb{R}$ and $\bigcap_i \ker f_i \subset \ker g$, then $g = \sum_i \lambda_i f_i$ for some $\lambda_i \in \mathbb{R}$.

3. Let the Jacobian of $f: \mathbb{R}^n \rightarrow \mathbb{R}^k$ have rank k on $f^{-1}(0)$, so that $M = f^{-1}(0)$ is a submanifold of \mathbb{R}^n of dimension $n - k$. Let $g: M \rightarrow \mathbb{R}$ be differentiable, and suppose that g has a maximum at $p \in M$.

(a) $M_p = \bigcap_{i=1}^k \ker df^i$, where $df^i: \mathbb{R}^n_p \rightarrow \mathbb{R}$.

(b) If $X_p \in M_p$ then $dg(X_p) = 0$. *Hint:* $X_p = c'(0)$ for some curve c in M .

(c) Use Problem 2 to conclude that there are $\lambda_1, \dots, \lambda_k$ with

$$D_j g = \sum_{i=1}^k \lambda_i D_j f^i \quad \text{for } j = 1, \dots, n.$$

4. (a) For the ruled surface $f(s, t) = c(s) + t\delta(s)$, show that $m = \langle c', \delta \times \delta' \rangle$, and

$$EG - F^2 = \langle \delta, \delta \rangle \cdot \langle c' + t\delta', c' + t\delta' \rangle - \langle c' + t\delta', \delta \rangle^2.$$

(b) If θ is the angle between δ and $c' + t\delta'$, then

$$\langle \delta, \delta \rangle \cdot \langle c' + t\delta', c' + t\delta' \rangle \cdot \cos^2 \theta = \langle \delta, c' + t\delta' \rangle^2.$$

So $EG - F^2 = EG \sin^2 \theta = |(c' + t\delta') \times \delta|^2$.

(c) For the standard parameterization, show that

$$\sigma' \times \delta = \langle \sigma', \delta \times \delta' \rangle \cdot \delta',$$

and deduce the formula for K on page 148.

5. (a) Let $a, b \in \mathbb{R}^3$ and let $v, w \in \mathbb{R}^3$ be non-parallel vectors. If $a + t_0v$ and $b + t_1w$ are the points on the lines $\{a + tv\}$ and $\{b + tw\}$ which are closest to each other, then the line from $a + t_0v$ to $b + t_1w$ must be perpendicular to both v and w . Conclude that

$$t_0 = \frac{\langle w, w \rangle \cdot \langle a - b, v \rangle - \langle w, v \rangle \cdot \langle a - b, w \rangle}{\langle v, w \rangle^2 - \langle w, w \rangle \cdot \langle v, v \rangle}.$$

(b) Consider the ruled surface $c(s) + t\delta(s)$ with $|\delta| = 1$. If the point $P(\varepsilon)$ on page 147 is $c(s) + t(\varepsilon)\delta(s)$, then

$$t(\varepsilon) = \frac{\langle c(s) - c(s + \varepsilon), \delta(s) \rangle - \langle \delta(s), \delta(s + \varepsilon) \rangle \cdot \langle c(s) - c(s + \varepsilon), \delta(s + \varepsilon) \rangle}{\langle \delta(s), \delta(s + \varepsilon) \rangle^2 - 1}.$$

Use L'Hôpital's rule to show that

$$\lim_{\varepsilon \rightarrow 0} t(\varepsilon) = \frac{-\langle c'(s), \delta'(s) \rangle}{\langle \delta'(s), \delta'(s) \rangle}.$$

(c) The striction curve of the tangent developable of c is c .

(d) The striction curve of the hyperboloid of revolution

$$\frac{x^2}{a^2} + \frac{y^2}{a^2} - \frac{z^2}{c^2} = 1$$

is the central circle. (Notice that in each case the tangent vector of the striction curve at a point is not perpendicular to the generator through that point, even though the striction curve is the limit of common perpendiculars to generators.)

6. (a) Modify Proposition II.4-14 as follows: If $\langle \cdot, \cdot \rangle$ is any (possibly degenerate) inner product on \mathbb{R}^n , then there is a basis of \mathbb{R}^n which is orthogonal for $\langle \cdot, \cdot \rangle$ and orthonormal with respect to the usual inner product.

(b) Consider a quadric $\{(x_1, x_2, x_3) : \sum_{ij} a_{ij}x_i x_j + \sum_i b_i x_i + c = 0\}$. Show that some rotation of \mathbb{R}^3 takes this into a set of the form

$$\{(x_1, x_2, x_3) : \sum_i \alpha_i x_i^2 + \sum_i \beta_i x_i + \gamma = 0\}.$$

(c) Show that a translation can be used to make $\beta_i = 0$ if $\alpha_i \neq 0$. Conclude that the quadric is an ellipsoid or hyperboloid of one or two sheets (or \emptyset), if all $\alpha_i \neq 0$; and it is an elliptic or hyperbolic paraboloid if just one $\alpha_i = 0$. Show that all other cases are lines, planes, or cylinders over parabolas, ellipses and hyperbolas.

7. Let $M \subset \mathbb{R}^3$ be a surface with unit normal $\nu: M \rightarrow \mathbb{R}^3$. We define the **support function** h of M by

$$h(p) = -\langle p, \nu(p) \rangle.$$

(a) Show that $|h(p)| = \text{distance from } 0 \text{ to } M_p$, and that $h(p) > 0$ if and only if $\nu(p)$ points toward the side of M_p which contains 0.

(b) For the ellipsoid $W^{-1}(0)$, where $W(x, y, z) = \frac{1}{2}(x^2/a^2 + y^2/b^2 + z^2/c^2 - 1)$, show that

$$h(x, y, z) = \frac{-1}{|Z|} \quad \text{for } Z = (W_1, W_2, W_3)(x, y, z).$$

Conclude that

$$K = \frac{h^4}{a^2 b^2 c^2},$$

and locate the points of maximum and minimum curvature.

(c) For the elliptic hyperboloids of one and two sheets, show that

$$K = \frac{-h^4}{a^2 b^2 c^2} \quad \text{and} \quad K = \frac{h^4}{a^2 b^2 c^2}, \quad \text{respectively.}$$

8. Let $M \subset \mathbb{R}^3$ be an imbedded surface such that $\nu: M \rightarrow S^2$ is one-one. For $\xi \in S^2$, let

$$p(\xi) = h(\nu^{-1}(\xi)),$$

where h is the support function of M .

(a) The tangent plane at $\nu^{-1}(\xi)$ is

$$\left\{ x \in \mathbb{R}^3 : \sum_{j=1}^3 \xi^j x^j = p(\xi) \right\},$$

so

$$\sum_{j=1}^3 \xi^j [\nu^{-1}(\xi)]^j = p(\xi).$$

(b) For $x \in \mathbb{R}^3 - \{0\}$, let

$$P(x) = |x| \cdot p\left(\frac{x}{|x|}\right).$$

Then

$$\frac{\partial P(x)}{\partial x^i} = \left[\nu^{-1}\left(\frac{x}{|x|}\right) \right]^i + \sum_{j=1}^3 x^j \cdot \frac{\partial \left[\nu^{-1}\left(\frac{x}{|x|}\right) \right]^j}{\partial x^i} = \left[\nu^{-1}\left(\frac{x}{|x|}\right) \right]^i.$$

Hint: The vanishing of the second term is equivalent to the assertion that $\partial[\nu^{-1}(x/|x|)]/\partial x^i$ is tangent to M at $\nu^{-1}(x/|x|)$. Note that $\nu^{-1}(x/|x|) \in M$ for all x .

9. (a) The determinant on page 152 equals

$$xa_2a_3(c^2 - b^2) + ya_1a_3(a^2 - c^2) + za_1a_2(b^2 - a^2).$$

By sign considerations, show that for $a > b > c > 0$ there is no umbilic with $y \neq 0$. Then show that there are four umbilics, with coordinates

$$x = \pm a \left(\frac{a^2 - b^2}{a^2 - c^2} \right)^{1/2} \quad z = \pm c \left(\frac{b^2 - c^2}{a^2 - c^2} \right)^{1/2}.$$

(b) Similarly, find the four umbilics on the elliptic hyperboloid of two sheets.

10. Find the umbilics on the elliptic paraboloid by using formulas (E'). [There are two if $a \neq b$, and one if $a = b$.]

11. (a) Let M be a doubly ruled non-flat surface, and choose three mutually skew straight lines L_1, L_2, L_3 from the first family of rulings. Show that there is a unique family of straight lines which intersect all three of L_1, L_2, L_3 .

(b) Show that three mutually skew lines L_1, L_2, L_3 lie on some quadric, and conclude that M is this quadric.

12. Let $M \subset \mathbb{R}^3$ be a surface with normal map ν . Then $\{p + \varepsilon\nu(p) : p \in M\}$ is called a **parallel surface** \bar{M} of M . We have a map $f: M \rightarrow \bar{M}$ given by $f(p) = p + \varepsilon\nu(p)$.

(a) If X is a tangent vector of M , then $f_*X = X + \varepsilon d\nu(X)$ [identifying tangent vectors with elements of \mathbb{R}^3 as usual]. Hence f is an immersion if $\varepsilon \neq 1/k_i$ for either principal curvature k_i at any point p of M . In particular, if M is compact, then \bar{M} is a surface for small enough ε . (One could also use Theorem I.9-20.)

(b) The normal $\bar{\nu}$ at $p + \varepsilon\nu(p)$ is just $\nu(p)$. (One could also use a generalization of Problem I.9-28.)

(c) The principal curvatures of \bar{M} are

$$\frac{k_i}{1 + \varepsilon k_i},$$

so the Gaussian and mean curvatures of \bar{M} are

$$\bar{K} = \frac{K}{1 + \varepsilon H + \varepsilon^2 K} \quad \bar{H} = \frac{H + 2\varepsilon K}{1 + \varepsilon H + \varepsilon^2 K}.$$

(d) If M has constant Gaussian curvature $K > 0$, then some parallel surface has constant mean curvature, and if M has constant mean curvature $H \neq 0$, then some parallel surface has constant Gaussian curvature (Bonnet).

(e) The volume element $d\bar{A}$ of \bar{M} is related to the volume element dA of M by

$$f^*(d\bar{A}) = (1 + 2\varepsilon H + \varepsilon^2 K) dA.$$

(f) If M has mean curvature $H = 0$, and M is not part of a plane, then the area of \bar{M} is *smaller* than the area of M (Steiner).

13. Let c be an arclength parameterized curve. Recall that the “rectifying plane” of c is spanned by the tangent \mathbf{t} and binomial \mathbf{b} . Suppose that the family of rectifying planes has an envelope M . Show that c is a geodesic on M . (This is the reason for the word rectifying—the curve c is “made straight” or “rectified” on M .)

CHAPTER 4

CURVES ON SURFACES

In classical surface theory, a great deal of emphasis was placed on special curves lying within a surface. In addition, several new invariants can be defined for a curve c on a surface, apart from the curvature κ and torsion τ which c has as a curve in \mathbb{R}^3 . The total corpus of accumulated results exhibits—to me at least—the unappealing weightiness of a massive treatise on the conic sections. So in this chapter we will give the definitions and then explore only a few of the pertinent results, concentrating on those which are of importance later on.

Let $M \subset \mathbb{R}^3$ be an oriented surface with corresponding unit normal field ν , and let c be an arclength parameterized curve in M . Then we can consider the normal and tangential components of $c''(s)$,

$$\perp c''(s) = \langle c''(s), \nu(c(s)) \rangle \cdot \nu(c(s)),$$

$$\top c''(s) = \frac{D}{ds} c'(s), \quad \text{by Corollary 1-2.}$$

The normal component $\perp c''(s)$ is sometimes called the **normal curvature vector** of c at s , and

$$(1) \quad \kappa_n(s) = \langle c''(s), \nu(c(s)) \rangle$$

is called the **normal curvature** of c at s ; it is the signed length of the normal curvature vector. As we mentioned in Chapter 1, the tangential component $\top c''(s)$ is called the **geodesic curvature vector**. Using the orientation of M we can assign a sign to the length of this vector. To do this, we first choose the unit vector $\mathbf{u}(s) \in M_{c(s)}$ perpendicular to $c'(s)$ for which $(c'(s), \mathbf{u}(s))$ is positively oriented, so that

$$c'(s) \times \mathbf{u}(s) = \nu(c(s)).$$

Then we note that

$$\langle c'(s), c'(s) \rangle = 1 \implies \left\langle \frac{D}{ds} c'(s), c'(s) \right\rangle = 0,$$

so that $\top c''(s) = D/ds(c'(s))$ must be a multiple of $\mathbf{u}(s)$. So we can define the **geodesic curvature** $\kappa_g(s)$ of c at s by

$$(2) \quad \begin{aligned} \top c''(s) &= \kappa_g(s) \cdot \mathbf{u}(s) \\ &= \kappa_g(s) \cdot \nu(c(s)) \times c'(s). \end{aligned}$$

Thus κ_g is the signed length of $\mathbf{T}c''$. Obviously we have

$$(3) \quad \kappa = \sqrt{\kappa_n^2 + \kappa_g^2}.$$

We will see that κ_n and κ_g have quite different properties.

We begin by recalling a few facts from Chapter II.3B. The equation $0 = \langle c'(s), \nu(c(s)) \rangle$ implies that

$$(4) \quad \begin{aligned} \kappa_n(s) &= \langle c''(s), \nu(c(s)) \rangle = - \left\langle \frac{d\nu(c(s))}{ds}, c'(s) \right\rangle = - \langle d\nu(c'(s)), c'(s) \rangle \\ &= \Pi(c'(s), c'(s)). \end{aligned}$$

Thus $\kappa_n(s)$ depends only on the direction $(c'(s))$ or $-c'(s)$ of c at s , and otherwise not on the curve c itself, so we can write $\kappa_n(X)$ for a unit vector X . Now for a given unit vector $X \in M_p$, there is a natural choice for a curve c in M with $c'(0) = X$, namely the arclength parameterized curve which is cut out on M by the plane P containing $\nu(p)$ and X . Then $\Pi(X, X) = \kappa_n(X)$ is

the signed curvature of this curve, when $(X, \nu(p))$ is chosen as the positive orientation for P . If $k_i = \kappa_n(X_i)$ are the minimum and maximum of these signed curvatures, so that X_i are eigenvectors of $-d\nu$, with eigenvalues k_i , then X_1 and X_2 are orthogonal, and if $X = (\cos \theta)X_1 + (\sin \theta)X_2$ is any unit vector, then (Euler's Theorem)

$$(5) \quad \kappa_n(X) = k_1 \cos^2 \theta + k_2 \sin^2 \theta.$$

Equation (4) can just as well be used to relate κ_n and κ for any curve c in M . Note that the normal $\mathbf{n}(s)$ of c at s is in the plane spanned by $\mathbf{u}(s)$ and $\nu(c(s))$.

Choosing $(\mathbf{u}(s), \nu(c(s)))$ as the positive orientation of this plane, we define $\phi(s)$

to be the oriented angle from $\mathbf{n}(s)$ to $\nu(c(s))$, so that

$$(6) \quad \mathbf{n}(s) = \sin \phi(s) \cdot \mathbf{u}(s) + \cos \phi(s) \cdot \nu(c(s)).$$

Then equation (4) implies that

$$(7) \quad \kappa_n(s) = \Pi(c'(s), c'(s)) = \kappa(s) \cdot \cos \phi(s),$$

where $\kappa (> 0)$ is the curvature of c . (If $\kappa(s) = 0$, then $\mathbf{n}(s)$ is undefined, so $\phi(s)$ is also; but equation (7) then holds with any choice of $\phi(s)$.) In particular, suppose that Q is any plane containing a unit vector $X \in M_p$. Let $\bar{X} \in M_p$ be the unit vector perpendicular to X for which (X, \bar{X}) is positively oriented, and

let $N \in \mathbb{R}_p^3$ be a unit vector in Q which is perpendicular to X . Choose (X, N) as the positive orientation for Q , and let ϕ be the oriented angle from N to $\nu(p)$ when $(\bar{X}, \nu(p))$ is chosen as the positive orientation for the plane perpendicular to X (changing N to $-N$ reverses the orientation of Q , and changes ϕ to $\phi - \pi$). If c_ϕ is the arclength parameterized curve cut out on M by Q , then its curvature κ_ϕ is given by

$$(7') \quad \kappa_\phi \cdot \cos \phi = \kappa(X).$$

Equation (7) or (7') is known as *Meusnier's Theorem*; another formulation of this theorem appears in Problem 1.

We can already state a result which is trivial, but which we will need to refer to later on.

1. PROPOSITION. Let c be an arclength parameterized curve in a surface $M \subset \mathbb{R}^3$, with $c(0) = p$, and $c'(0) = X \in M_p$.

(1) If X is an asymptotic vector, then either $\kappa(0) = 0$ or $\mathbf{n}(0)$ is perpendicular to $\nu(p)$.

(2) If X is not an asymptotic vector, then c cannot have curvature 0 at p , nor can $\mathbf{n}(0)$ be perpendicular to $\nu(p)$; if $\kappa_n(X) > 0$, then the angle between $\mathbf{n}(0)$ and $\nu(p)$ is acute, and if $\kappa_n(X) < 0$ it is obtuse (in the picture on page 188 the angle is 0).

PROOF. Everything follows from equation (4). ♦

Note, finally, that if c is not parameterized by arclength, then

$$(8) \quad \kappa_n(t) = \frac{\Pi(c'(t), c'(t))}{|c'(t)|^2},$$

since both numerator and denominator are multiplied by the same number under change of parameter.

Now consider the geodesic curvature $\kappa_g(s)$ of c at s , given by equation (2),

$$\mathbf{T}c''(s) = \kappa_g(s) \cdot \mathbf{u}(s).$$

Since we also have

$$c'' = \kappa \cdot \mathbf{n},$$

equation (6) immediately implies that

$$(9) \quad \kappa_g = \kappa \cdot \sin \phi.$$

(Again, this equation holds for any choice of ϕ when $\kappa = 0$.) Unlike κ_n , the quantity $\kappa_g = \text{signed length of } D/ds(c'(s))$ is *intrinsic*—it can be calculated directly from E, F, G using the formula on pg. II.232; one has to be careful to parameterize by arclength. On the other hand, $\kappa_g(s)$ does not depend only on c' . Indeed, κ_g is identically zero if c is a geodesic, and there are geodesics with arbitrary unit tangent vectors at any point.

Moving frame freaks will be happy to learn that κ_n and κ_g arise naturally when one chooses the appropriate moving frame along c . In fact, the original use of the moving frame was by Darboux, whose monumental 4 volume work on surfaces includes incredibly detailed investigations of curves on surfaces. Given

an arclength parameterized curve c in $M \subset \mathbb{R}^3$, we define the **Darboux frame** of c on M to be the moving frame

$$\mathbf{t}(s) = c'(s), \quad \mathbf{u}(s), \quad \mathbf{v}(s) = \mathbf{t}(s) \times \mathbf{u}(s) = \nu(c(s)),$$

as opposed to the **Frenet frame** $\mathbf{t}, \mathbf{n}, \mathbf{b}$. The Darboux frame is defined at all points of c , even those where $\kappa = 0$. Since the Darboux frame is also orthonormal, the expression for $(\mathbf{t}, \mathbf{u}, \mathbf{v})'$ is given by a skew-symmetric matrix times $(\mathbf{t}, \mathbf{u}, \mathbf{v})$:

$$(10) \quad \begin{aligned} \mathbf{t}' &= \kappa_g \mathbf{u} + \kappa_n \mathbf{v} \\ \mathbf{u}' &= -\kappa_g \mathbf{t} + \tau_g \mathbf{v} \\ \mathbf{v}' &= -\kappa_n \mathbf{t} - \tau_g \mathbf{u} \end{aligned}$$

From the moving frame point of view, the functions $\kappa_g, \kappa_n, \tau_g$ appearing here are defined by these equations, although it is clear from the first equation that κ_g and κ_n are the same as previously defined. The function τ_g is called the **geodesic torsion** of c . We proceed to indicate how these functions are analyzed using moving frames.

We first observe that $\mathbf{v}'(0)$ depends only on $\mathbf{t}(0)$, since

$$(11) \quad \mathbf{v}'(0) = \left. \frac{d\nu(c(s))}{ds} \right|_{s=0} = d\nu(\mathbf{t}(0)).$$

The third equation in (10) then shows immediately that κ_n and τ_g depend only on \mathbf{t} , so that we can write $\kappa_n(X)$ and $\tau_g(X)$ for unit vectors X . In fact, if $\bar{X} \in M_p$ is the unit vector perpendicular to X with (X, \bar{X}) positively oriented, then equations (10) and (11) give

$$(12) \quad \begin{aligned} \kappa_n(X) &= -\langle d\nu(X), X \rangle = \Pi(X, X) \\ \tau_g(X) &= -\langle d\nu(X), \bar{X} \rangle = \Pi(X, \bar{X}). \end{aligned}$$

Now let $X_1, X_2 \in M_p$ be principal directions with (X_1, X_2) positively oriented, and let k_1, k_2 be the corresponding principal curvatures. If θ is the oriented angle from X_1 to a unit vector $X \in M_p$, then we have

$$\begin{aligned} \kappa_n(X) &= -\langle d\nu(X), X \rangle \\ &= \langle k_1(\cos \theta)X_1 + k_2(\sin \theta)X_2, (\cos \theta)X_1 + (\sin \theta)X_2 \rangle \\ &= k_1 \cos^2 \theta + k_2 \sin^2 \theta. \end{aligned}$$

Here we have merely rederived Euler's Theorem. But exactly the same procedure gives an explicit expression for τ_g :

2. PROPOSITION. Let $X_1, X_2 \in M_p$ be principal directions, with (X_1, X_2) positively oriented, and let k_1, k_2 be the corresponding principal curvatures at p . If θ is the oriented angle from X_1 to a unit vector $X \in M_p$, then

$$\tau_g(X) = (k_2 - k_1) \sin \theta \cos \theta.$$

PROOF. Equation (12) gives

$$\begin{aligned} \tau_g(X) &= -\langle dv(X), \bar{X} \rangle \\ &= \langle k_1(\cos \theta)X_1 + k_2(\sin \theta)X_2, -(\sin \theta)X_1 + (\cos \theta)X_2 \rangle \\ &= (k_2 - k_1) \sin \theta \cos \theta. \quad \blacklozenge \end{aligned}$$

Now let ϕ be the oriented angle from \mathbf{n} to \mathbf{v} , as on page 189, so that

$$\begin{aligned} \mathbf{n} &= \sin \phi \cdot \mathbf{u} + \cos \phi \cdot \mathbf{v} \\ \mathbf{b} &= -\cos \phi \cdot \mathbf{u} + \sin \phi \cdot \mathbf{v}, \end{aligned}$$

and hence

$$\begin{aligned} \mathbf{u} &= \sin \phi \cdot \mathbf{n} - \cos \phi \cdot \mathbf{b} \\ \mathbf{v} &= \cos \phi \cdot \mathbf{n} + \sin \phi \cdot \mathbf{b}. \end{aligned}$$

Using the first equation in (10), and the Serret-Frenet formulas, we have

$$\begin{aligned} \kappa_g &= \langle \mathbf{u}, \mathbf{t}' \rangle = \langle (\sin \phi)\mathbf{n} - (\cos \phi)\mathbf{b}, \kappa \mathbf{n} \rangle \\ &= \kappa \cdot \sin \phi \\ \kappa_n &= \langle \mathbf{v}, \mathbf{t}' \rangle = \langle (\cos \phi)\mathbf{n} + (\sin \phi)\mathbf{b}, \kappa \mathbf{n} \rangle \\ &= \kappa \cdot \cos \phi, \end{aligned}$$

as before. (If $\kappa = 0$, then ϕ is undefined, but it follows immediately from the first equation of (10) that also $\kappa_g = \kappa_n = 0$.) We still have to make use of the second equation in (10); it will give us the geometric interpretation of τ_g . Now we have

$$\tau_g = \langle \mathbf{v}, \mathbf{u}' \rangle = \left\langle (\cos \phi)\mathbf{n} + (\sin \phi)\mathbf{b}, \frac{d}{ds}[(\sin \phi)\mathbf{n} - (\cos \phi)\mathbf{b}] \right\rangle;$$

using the Serret-Frenet formulas

$$\frac{d\mathbf{n}}{ds} = \mathbf{n}' = -\kappa \mathbf{t} + \tau \mathbf{b} \quad \text{and} \quad \frac{d\mathbf{b}}{ds} = -\tau \mathbf{n},$$

we end up with

$$(13) \quad \tau_g = \tau + \frac{d\phi}{ds}, \quad \text{whenever } \tau \text{ is defined.}$$

In particular we have

3. PROPOSITION.

- (a) If $X \in M_p$ is a unit vector, then $\tau_g(X)$ is the torsion $\tau(0)$ of the geodesic γ with $\gamma'(0) = X$.
- (b) The geodesics pointing in a principal direction at a point have torsion 0 at that point; in particular, all geodesics have torsion 0 at an umbilic.
- (c) If $X, Y \in M_p$ are perpendicular unit vectors, then $\tau_g(X) = -\tau_g(Y)$; thus orthogonal geodesics through a point have torsions at that point which are negatives of each other.

Remark: These statements hold only with the additional *proviso* that the torsions in question exist. Problem 3 considers what happens otherwise.

PROOF. Part (a) follows from equation (13), since for the geodesic γ we have $\phi = 0$ or $\phi = \pi$ for all s . Then parts (b) and (c) follow from Proposition 2. ♦

We note in passing that changing the direction of a curve c in M changes \mathbf{t} to $-\mathbf{t}$, and \mathbf{u} to $-\mathbf{u}$, but leaves \mathbf{v} fixed. So equations (10) show that κ_g changes sign, while κ_n and τ_g remain the same. For κ_n this follows from equation (7), since \mathbf{n} is changed to $-\mathbf{n}$, so ϕ is changed to $\phi - \pi$. It also follows from the interpretation of $\kappa_n(X)$ as the signed curvature of the curve cut out on M by the plane P through X and $\nu(p)$ —normally, reversing the curve would change the curvature, but in this case, since we change X to $-X$, we also change the orientation of P . The fact that τ_g remains the same follows from the fact that reversing the direction of a curve does not change its torsion.

One other fact about our new invariants will be of interest. An old theorem of Laguerre says that, like κ_n and τ_g , the quantity

$$\frac{d\kappa_n(s)}{ds} - 2\tau_g(s)\kappa_g(s)$$

also depends only on $c'(s)$; using equations (7), (9), and (13), this quantity can be written in Laguerre's formulation, involving ϕ , κ , and τ , as

$$\frac{d\kappa(s)}{ds} \cos \phi(s) - \left(3 \frac{d\phi(s)}{ds} + 2\tau(s) \right) \kappa(s) \sin \phi(s),$$

which makes the result seem even more mysterious. Élie Cartan observed that just as κ_n and τ_g can be expressed in terms of the tensor \mathbf{II} , this new expression,

and others like it, can be expressed in terms of the *covariant derivatives* of Π . Recall that by Corollary II.6-5 the tensor $(\nabla_{Z_p}\Pi)(X_p, Y_p) = (\nabla\Pi)(X_p, Y_p, Z_p)$ satisfies

$$(\nabla_{Z_p}\Pi)(X_p, Y_p) = Z_p(\Pi(X, Y)) - \Pi(\nabla_{Z_p}X, Y_p) - \Pi(X_p, \nabla_{Z_p}Y),$$

for all vector fields X, Y, Z extending X_p, Y_p, Z_p . This immediately yields

4. PROPOSITION. For all arclength parameterized curves c in $M \subset \mathbb{R}^3$ with the same tangent vector $c'(0) \in M_p$, the quantity

$$\kappa_n'(s) - 2\tau_g(s)\kappa_g(s)$$

has the same value at $s = 0$. The same is true for

$$\tau_g'(s) + 2[\kappa_n(s) - H(c(s))]\kappa_g(s).$$

PROOF. Let X be a unit vector field on M which extends \mathbf{t} , and let \bar{X} be the perpendicular unit vector field with (X, \bar{X}) positively oriented. Then equation (2), and the fact that $\mathbf{T}c''(s) = D/ds(c'(s))$, shows that

$$\nabla_X X = \kappa_g \cdot \bar{X} \quad \text{along } c,$$

so by equation (12) we have

$$\Pi(\nabla_X X, X) = \kappa_g \cdot \tau_g \quad \text{along } c.$$

Hence

$$\begin{aligned} (\nabla_X \Pi)(X, X) &= X(\Pi(X, X)) - 2\Pi(\nabla_X X, X) \\ &= \kappa_n' - 2\kappa_g \tau_g \quad \text{along } c. \end{aligned}$$

This shows that the first expression depends only on $X = c'$.

We also have

$$\begin{aligned} \langle X, \bar{X} \rangle &= 0 \implies \langle \nabla_X \bar{X}, X \rangle = -\langle \bar{X}, \nabla_X X \rangle = -\kappa_g, \\ \langle \bar{X}, \bar{X} \rangle &= 1 \implies \langle \nabla_X \bar{X}, \bar{X} \rangle = 0, \end{aligned}$$

which implies that

$$\nabla_X \bar{X} = -\kappa_g X \quad \text{along } c.$$

So we obtain

$$\begin{aligned}
 (\nabla_X \Pi)(X, \bar{X}) &= X(\Pi(X, \bar{X})) - \Pi(\nabla_X X, \bar{X}) - \Pi(X, \nabla_X \bar{X}) \\
 &= \tau_g' - \kappa_g \Pi(\bar{X}, \bar{X}) + \kappa_g \Pi(X, X) \\
 &= \tau_g' + \{2\Pi(X, X) - [\Pi(X, X) + \Pi(\bar{X}, \bar{X})]\} \kappa_g \\
 &= \tau_g' + 2(\kappa_n - H)\kappa_g \quad \text{along } c. \quad \spadesuit
 \end{aligned}$$

We are now ready to consider the three main classes of curves on a surface $M \subset \mathbb{R}^3$. The curve c is called a **line of curvature** (or **principal curve**) if c' always points along a principal direction. This means that

$$-dv(c') = k \cdot c'$$

for some function k , where $k(t)$ must be a principal curvature at $c(t)$. We can also write this as

$$\frac{-dv(c(t))}{dt} = k(t) \frac{dc}{dt} \quad \text{or} \quad \frac{dv}{dt} + k \frac{dc}{dt} = 0, \quad \text{in the classical manner.}$$

Oddly enough, the last equation has a special name, **Rodrigues' formula**. A more interesting characterization of principal curves can be given in terms of one of our invariants—the third equation in (10), together with (11), shows that c is a line of curvature if and only if τ_g is identically zero.

A curve c in M is called an **asymptotic curve** if c' always points along an asymptotic direction. Equation (4) [or (8)] shows that c is an asymptotic curve if and only if $\mathbf{n}(t)$ is perpendicular to $v(c(t))$ at all points t where $\kappa(t) \neq 0$. Equivalently, c is an asymptotic curve if and only if $\mathbf{n}(t)$ lies in $M_{c(t)}$ whenever $\kappa(t) \neq 0$, or yet again, if and only if the osculating plane of c at t coincides with $M_{c(t)}$ whenever $\kappa(t) \neq 0$. Equation (4), or the third equation in (10), together with (11), shows that c is an asymptotic curve if and only if κ_n is identically zero. Equation (3), or the first equation of (10), then shows that c is an asymptotic curve if and only if $\kappa = \pm \kappa_g$ everywhere. Moreover, at points where $\kappa \neq 0$, we then have $\mathbf{n} = \pm \mathbf{u}$, so $\mathbf{b} = \pm \mathbf{v}$ (the same sign holding in both cases), and the third equation of (10) shows that $\tau = \tau_g$; this also follows from equation (13), since $\phi = \pi/2$ or $3\pi/2$ for all t .

Finally, we have the geodesics, which may be defined as curves c with $c''(t)$ always perpendicular to $M_{c(t)}$, so that \mathbf{n} is perpendicular to M at points where $\kappa \neq 0$, or as curves with κ_g identically zero.

To summarize, we have

$$\begin{aligned}
 c \text{ is a line of curvature} &\iff -dv(c') = k \cdot c' \\
 &\iff \tau_g = 0 \\
 c \text{ is an asymptotic curve} &\iff \mathbf{n}, \text{ when defined, is} \\
 &\quad \text{always tangent to } M \\
 &\iff \text{the osculating plane, when defined,} \\
 &\quad \text{always coincides with the} \\
 &\quad \text{tangent plane of } M \\
 &\iff \kappa_n = 0 \\
 &\iff \kappa = \pm \kappa_g \\
 &\implies \tau = \tau_g, \text{ when } \tau \text{ is defined} \\
 c \text{ is a geodesic} &\iff \mathbf{n}, \text{ when defined, is} \\
 &\quad \text{always perpendicular to } M \\
 &\iff \kappa_g = 0 \\
 &\implies \tau = \tau_g, \text{ when } \tau \text{ is defined.}
 \end{aligned}$$

Since κ_n and τ_g actually depend only on the direction of c at a point, it also makes sense to talk about a curve c being “asymptotic at t ” ($\kappa_n(t) = 0$) or “principal at t ” ($\tau_g(t) = 0$); this just means that $c'(t)$ points in an asymptotic direction or in a principal direction. The equivalences given above for lines of curvature and asymptotic curves can all be replaced by corresponding equivalences for curves which are principal at a point or asymptotic at a point; however the conclusion $\tau(t) = \tau_g(t)$ does not follow from the mere assumption that c is asymptotic at t .

We will begin our study of these special curves by considering some very general properties. Taking the asymptotic curves first, we note that they can exist only in regions where $K \leq 0$. This already leads to another simple

5. PROPOSITION. A straight line on a surface is an asymptotic curve, so the curvature K of the surface satisfies $K \leq 0$ along any straight line lying in it. The curvature is everywhere 0 along the straight line if and only if the normal ν is constant along the line (equivalently: if and only if the tangent space is parallel along the line).

PROOF. The first assertion follows immediately from equation (4). To prove the second, let c be any parameterization of the straight line (with $c'(t)$ always

$\neq 0$). If the normal is constant along c , then

$$0 = \frac{dv(c(t))}{dt} = dv(c'(t)),$$

and this can happen only if dv has determinant $K = 0$. Conversely, suppose $K = 0$ at each point $c(t)$, so that dv has at least one eigenvalue 0 at $c(t)$. If both eigenvalues are 0, then certainly $dv(c'(t)) = 0$. On the other hand, it is easy to see that if one eigenvalue is non-zero, then the only asymptotic vectors are multiples of the eigenvector with eigenvalue 0; in other words, the asymptotic vector $c'(t)$ must satisfy $dv(c'(t)) = 0$. ♦

Remark: Actually, we have proved a more general result a long time ago (Corollary 1-7), but I thought it would be nice to include the classical proof also. As before, we can state a slightly more precise result: $K = 0$ at a point of a straight line if and only if at this point the normal v has derivative 0 along the line.

As an immediate corollary of Proposition 5, notice that a ruled surface must have $K \leq 0$ everywhere, as we found by computation in Chapter 3. We also see that $K = 0$ everywhere on a ruled surface if and only if the normal v is constant on each generator. On page 146 we found that the tangent plane at $f(s, t)$ is spanned by $c'(s) + t\delta'(s)$ and $\delta(s)$. This is independent of t if and only if $\delta(s), \delta'(s), c'(s)$ are linearly dependent. Our formula for K on page 147 shows that this is indeed true if and only if $K = 0$ everywhere. Classically, the ruled surfaces with $K = 0$ everywhere, i.e., the ruled surfaces with constant normals along each generator, were called **developable surfaces**; in the next chapter we will consider them in greater detail.

In a small region of a surface where $K < 0$, we can choose two linearly independent asymptotic unit vectors X_p, Y_p at each point p . It is easy to show that $p \mapsto X_p$ and $p \mapsto Y_p$ will be C^∞ vector fields; the asymptotic curves are just the integral curves of these C^∞ vector fields—as one approaches a parabolic or planar point these integral curves can run together in complicated ways. In Chapter 2 we pointed out that the asymptotic directions are perpendicular precisely when the mean curvature $H = 0$. So on a minimal surface without planar points, the asymptotic curves are everywhere orthogonal. This is illustrated on the right helicoid by the rulings and the helices.

In contrast to the asymptotic curves, lines of curvature can exist in regions of any sort, and it is only umbilics which cause problems. In a small region free of umbilics, we can choose two linearly independent principal unit vectors X_p, Y_p at each point p . As in the case of asymptotic directions, it is easy to show that $p \mapsto X_p$ and $p \mapsto Y_p$ are C^∞ vector fields (on regions where $K < 0$ this

is also a consequence of the fact that the principal directions bisect the asymptotic directions); the lines of curvature are the integral curves of these vector fields. We have already seen that on a torus of revolution, with no umbilics, the

lines of curvature are the parallels and meridians. By contrast, the following famous picture shows how the lines of curvature behave in a neighborhood of the umbilic points of an ellipsoid.

Notice that if a surface M has no umbilics, like the torus, then there is a C^∞ 1-dimensional distribution on M —at each point p we choose the set of all vectors in M_p which are eigenvalues for the larger principal curvature, say. Equivalently, we can pick out two units vectors $X_p, -X_p \in M_p$. Now we can construct a 2-fold covering space $\pi: \tilde{M} \rightarrow M$ by choosing the two points in $\pi^{-1}(p)$ to correspond to these two vectors. There is then an obvious nowhere zero vector field \tilde{X} on \tilde{M} (if $q \in \pi^{-1}(p)$ is the point corresponding to $X_p \in M_p$, then $\pi_* \tilde{X}_q = X_p$). On the other hand, Theorem I.11-30 tells us that for the compact orientable surface \tilde{M} , this can happen only when the Euler characteristic $\chi(\tilde{M}) = 0$, which implies that $\chi(M) = 0$, since $\chi(\tilde{M}) = 2\chi(M)$ (Problem 7). But the torus is the *only* compact orientable surface with Euler characteristic $= 0$ (Problem I.11-2(c)). So *any compact surface in \mathbb{R}^3 not homeomorphic to the torus must have at least one umbilic*.

Carathéodory conjectured that every compact convex surface in \mathbb{R}^3 must have at least *two* umbilics. Weird as this may seem, there is a natural way to try to prove it. On any compact surface $M \subset \mathbb{R}^3$ with only finitely many umbilics p_1, \dots, p_k we can choose a C^∞ 1-dimensional distribution on $M - \{p_1, \dots, p_k\}$. There is a way of defining the index of this distribution at each point p_i , in much the same way that we defined the index of a vector field in Chapter I.11, except that now the index can take on half-integer values. Moreover, it turns out that the sum of the indices of the distribution is again the Euler characteristic $\chi(M)$. The precise definition of the index, and the proof of this result are given in Addendum 2. Now $\chi(S^2) = 2$, so Carathéodory's conjecture could be proved by showing that at an umbilic the index of our particular distribution cannot be equal to 2. For the analytic case, Hamburger [1] gave a proof of this which is 183 pages long! Bol [1] then gave a proof that is only 22 pages long, although it requires a correction (Klotz [1]). After all this work, it still seems that nothing is known when the surface is not analytic, or when it is not convex, even if it is homeomorphic to S^2 . I also know of no example where there are only two umbilics. On compact surfaces of revolution the lines of curvature have only two singularities, at the two poles, but I suspect that there will always be at least one whole parallel of umbilics in addition.

Finally, we have the geodesics. They, of course, not only exist in any sort of region, but can be found in any direction. On the other hand, just as the asymptotic lines intersect orthogonally only when $H = 0$, orthogonality of two families of geodesics implies that $K = 0$; in fact, even more is true:

6. PROPOSITION. If two families of geodesics intersect at a constant angle everywhere on M , then M is flat.

PROOF. Let X [or Y] be the vector field of unit tangents to the curves of the first [or second] family. Then X is parallel along the integral curves of X .

Since the angle between X and Y is constant, and since we are on a surface, the vector field Y must also be parallel along the integral curves of X . The same argument holds with X and Y interchanged. We therefore have

$$0 = \nabla_X X = \nabla_Y Y = \nabla_X Y = \nabla_Y X = [X, Y].$$

Consequently,

$$R(X, Y)Y = \nabla_X(\nabla_Y Y) - \nabla_Y(\nabla_X Y) - \nabla_{[X, Y]}Y = 0. \quad \blacklozenge$$

Proposition 6, of course, is not really a theorem about surfaces in \mathbb{R}^3 at all—it is actually a theorem about the intrinsic geometry of surfaces (I do not know whether any analogue holds for higher dimensional manifolds).

With this very general discussion of the behavior of our three classes of curves out of the way, we proceed to the main results about each class. For asymptotic curves this result is

7. THEOREM (BELTRAMI-ENNEPER). If c is an asymptotic curve with $c(0) = p$, and $\kappa(0) \neq 0$, then

$$|\tau(0)| = \sqrt{-K(p)}.$$

Moreover, if $K(p) < 0$ and the two distinct asymptotic curves through p both have non-zero curvature at p , then their torsions at p are negatives of each other.

FIRST (SEMI-) PROOF. Parameterize c by arclength. We know that both \mathbf{t} and \mathbf{n} lie in the tangent space of M , and we can let $\mathbf{v} = \mathbf{b} = \mathbf{t} \times \mathbf{n}$. Then the Serret-Frenet formulas give

$$-d\mathbf{v}(\mathbf{t}(s)) = -\mathbf{b}'(s) = \tau(s) \cdot \mathbf{n}(s).$$

So the matrix of the self-adjoint transformation $-d\mathbf{v}: M_p \rightarrow M_p$, with respect to the orthonormal basis $\mathbf{t}(0), \mathbf{n}(0)$ must be the symmetric matrix

$$\begin{pmatrix} 0 & \tau(0) \\ \tau(0) & 0 \end{pmatrix},$$

with determinant $K(p) = -\tau(0)^2$. This proof does not give any information about the sign of τ .

SECOND PROOF. We know that $\tau = \tau_g$ for the asymptotic curve c . So Proposition 2 gives

$$(1) \quad \tau(0) = (k_2 - k_1) \sin \theta \cos \theta,$$

where θ is the oriented angle from the principal vector X_1 to $X = c'(0)$. On the other hand, since X is an asymptotic vector, Euler's formula [equation (5)] gives

$$(2) \quad 0 = k_1 \cos^2 \theta + k_2 \sin^2 \theta,$$

so

$$(3) \quad k_2 = -k_1 \frac{\cos^2 \theta}{\sin^2 \theta}.$$

Substituting into (1) we have

$$\begin{aligned} \tau(0) &= -k_1 \left(\frac{\cos^2 \theta}{\sin^2 \theta} + 1 \right) \sin \theta \cos \theta \\ &= -k_1 \cdot \frac{\cos \theta}{\sin \theta}, \end{aligned}$$

while

$$K(p) = k_1 k_2 = -k_1^2 \frac{\cos^2 \theta}{\sin^2 \theta} \quad \text{by (3).}$$

Hence $\tau(0)^2 = -K(p)$ [we divided by $\sin \theta$, but if $\sin \theta = 0$, we could instead solve for k_1 in terms of k_2 ; alternatively, we can simply note that if $\sin \theta = 0$, then we have $k_1 = 0$ from (2) and $\tau(0) = 0$ from (1)].

Equation (1) also shows that $\tau(0)$ changes sign when we change θ to $-\theta$, which gives the second part of the theorem. ♦

As an example, on the right helicoid we can choose as one family of asymptotic curves the helices $c(s) = (t \cos s, t \sin s, bs)$, for fixed t . On pg. II.33 we found that

$$\tau = \frac{b}{b^2 + t^2},$$

in agreement with our formula for K (page 150). In this example the other family of asymptotic curves are straight lines, with vanishing curvature.

The Beltrami-Enneper theorem raises a natural question, one so natural that no one since Darboux seems to have considered it. Given a unit vector $X \in M_p$,

we can consider the line of curvature, the asymptotic line, and the geodesic which have tangent vector X at p (for simplicity we assume p is not an umbilic for the case of lines of curvature, and $K(p) < 0$ for the case of an asymptotic curve). We know that

- the torsion of the asymptotic curve c with $c'(0) = X$ is $\pm\sqrt{-K(p)}$,
- the torsion of the geodesic c with $c'(0) = X$ is $\tau_g(X) = \Pi(X, \bar{X})$,
- the curvature of the geodesic c with $c'(0) = X$ is $|\kappa_n(X)| = |\Pi(X, X)|$;

the first statement is Theorem 7, the second is Proposition 3, and the third follows from the equation $\kappa_n^2 + \kappa_g^2 = \kappa^2$, since $\kappa_g = 0$ for a geodesic. Now it is just as reasonable to ask for the curvature of the asymptotic curve c with $c'(0) = X$. To determine it, we can use one of the invariants of Proposition 4. We saw, in the proof of that Proposition, that

$$(\nabla_X \Pi)(X, X) = \kappa_n'(0) - 2\tau_g(0)\kappa_g(0)$$

for *any* curve c with $c'(0) = X$. Now if c is an asymptotic curve, then κ_n is identically zero, while $\kappa = \pm\kappa_g$ and $\tau = \tau_g$, so we have

$$\begin{aligned} (\nabla_X \Pi)(X, X) &= 0 \mp 2\tau(0)\kappa(0) \\ &= \mp 2\sqrt{-K(p)}\kappa(0), \quad \text{by Theorem 7.} \end{aligned}$$

Hence, if $K(p) \neq 0$, then

the curvature of the asymptotic curve c with $c'(0) = X$ is

$$\frac{|(\nabla_X \Pi)(X, X)|}{2\sqrt{-K(p)}}.$$

We can also ask for the curvature and torsion of a line of curvature c . Here the situation is somewhat different, since $c'(0) = X \in M_p$ is already essentially determined. We have $\tau_g = 0$ for lines of curvature, so the second invariant of Proposition 4 gives us the value of $[\kappa_n(X) - H(p)]\kappa_g(0)$, and hence of $\kappa_g(0)$. Then we can determine $\kappa = \sqrt{\kappa_g^2 + \kappa_n^2}$ at 0. To compute the torsion $\tau(0)$, we have to use yet another invariant, involving *second* derivatives (Problems 5 and 6).

To study lines of curvature, we begin with a pretty, though not very useful, criterion for such curves.

8. **THEOREM (BONNET).** A curve c in M is a line of curvature if and only if the surface S formed by the normals to the surface along c is flat.

PROOF. The surface S is the ruled surface parameterized by

$$f(s, t) = c(s) + tv(c(s)) = c(s) + t\delta(s), \quad \text{say.}$$

From page 147 we see that S is flat if and only if

$$0 = \langle c'(s), \delta(s) \times \delta'(s) \rangle = \left\langle c'(s), v(c(s)) \times \frac{dv(c(s))}{ds} \right\rangle,$$

which is true if and only if $dv(c(s))/ds$ is a multiple of $c'(s)$. ♦

In the case of a surface of revolution, Theorem 8 shows that meridians and parallels must be lines of curvature, since the corresponding surfaces S are planes and cones. (Of course, we have already argued in essentially just this way on pages 158–159.) The next theorem can also be used to find the lines of curvature on a surface of revolution.

9. **THEOREM (TERQUEM-JOACHIMSTHAL).** Let c be a curve in $M_1 \cap M_2$ which is a line of curvature in M_1 . Then c is a line of curvature in M_2 if and only if M_1 and M_2 intersect at a constant angle along c (i.e., the normals of M_1 and M_2 have the same angle along c).

PROOF. If v_i is the unit normal field on M_i , then

$$\begin{aligned} \frac{d}{ds} \langle v_1(c(s)), v_2(c(s)) \rangle &= \left\langle \frac{dv_1(c(s))}{ds}, v_2(c(s)) \right\rangle + \left\langle v_1(c(s)), \frac{dv_2(c(s))}{ds} \right\rangle \\ &= \left\langle -k(s) \frac{dc}{ds}, v_2(c(s)) \right\rangle + \left\langle v_1(c(s)), \frac{dv_2(c(s))}{ds} \right\rangle, \\ &\quad \text{since } c \text{ is a line of curvature of } M_1 \\ &= 0 + \left\langle v_1(c(s)), \frac{dv_2(c(s))}{ds} \right\rangle, \end{aligned}$$

since c is a curve in M_2 . If c is a line of curvature in M_2 , then the remaining term is similarly 0, so $\langle v_1(c(s)), v_2(c(s)) \rangle$ is constant.

Conversely, if this quantity has derivative 0, then $dv_2(c(s))/ds$ is perpendicular to $v_1(c(s))$. On the other hand, it is also perpendicular to $v_2(c(s))$. If $v_1(c(s))$ and $v_2(c(s))$ are linearly independent, then $dv_2(c(s))/ds$ must be a multiple of $c'(s)$, and consequently c is a line of curvature in M_2 . If $v_1(c(s))$ and $v_2(c(s))$ are *not* linearly independent, then we must have $v_1(c(s)) = \pm v_2(c(s))$ for all s (since $\langle v_1(c(s)), v_2(c(s)) \rangle$ is constant). In this case there is nothing left to prove. ♦

The one really interesting result about lines of curvature concerns **triply orthogonal systems** of surfaces—these are triples of 1-parameter families of surfaces with the property that at each point the tangent planes of the surfaces from any two families are perpendicular. The simplest examples of triply orthogonal systems are the following:

- (1) Each family consists of all the planes that are parallel to one of the coordinate planes.
- (2) The first family consists of all planes parallel to the (x, y) -plane; the second family consists of all the circular cylinders having the z -axis as their common axis; the third family consists of all planes that pass through the z -axis.

- (3) The first family consists of all the concentric spheres around the point 0; the second family consists of all planes that pass through the z -axis; the

third family consists of cones, each cone being formed by the all the lines through 0 that make some fixed angle with the z -axis.

The one other, less trivial, standard example is formed by the set of all surfaces satisfying the equation

$$(*) \quad g(\lambda) = \frac{x^2}{a^2 - \lambda} + \frac{y^2}{b^2 - \lambda} + \frac{z^2}{c^2 - \lambda} = 1, \quad 0 < a^2 < b^2 < c^2.$$

For $\lambda < a^2$ we obtain ellipsoids, for $a^2 < \lambda < b^2$ hyperboloids of one sheet, and for $b^2 < \lambda < c^2$ hyperboloids of two sheets. For any (x, y, z) with $x, y, z \neq 0$, the function $\lambda \mapsto g(\lambda) - 1$ is continuous except at a^2, b^2, c^2 ; it clearly jumps from $+\infty$ to $-\infty$ as we pass from the left of one of these points to the right of it, and $g(\lambda) - 1 \rightarrow -1$ as $\lambda \rightarrow -\infty$. Consequently, $g(\lambda) - 1$ must be 0 for at

least one $\lambda_1 < a^2$, one λ_2 with $a^2 < \lambda_2 < b^2$, and one λ_3 with $b^2 < \lambda_3 < c^2$.

There are only 3 roots, since $g(\lambda) - 1 = 0$ is equivalent to a cubic equation in λ . Thus one surface from each family passes through each such point (x, y, z) . At

a point (x, y, z) on the surface $g(\lambda_i) = 1$, the normal vector has the direction

$$\frac{1}{2}(D_1 g(\lambda_i), D_2 g(\lambda_i), D_3 g(\lambda_i)) = \left(\frac{x}{a^2 - \lambda_i}, \frac{y}{b^2 - \lambda_i}, \frac{z}{c^2 - \lambda_i} \right).$$

At a point (x, y, z) on the two surfaces $g(\lambda_i) = 1$ and $g(\lambda_j) = 1$, the inner product of the two normal vectors is therefore

$$\frac{x^2}{(a^2 - \lambda_i)(a^2 - \lambda_j)} + \frac{y^2}{(b^2 - \lambda_i)(b^2 - \lambda_j)} + \frac{z^2}{(c^2 - \lambda_i)(c^2 - \lambda_j)}$$

which can be written as

$$\frac{g(\lambda_i) - g(\lambda_j)}{\lambda_j - \lambda_i} = 0.$$

Thus our system is orthogonal. Since we can always imbed a given ellipsoid $x^2/a^2 + y^2/b^2 + z^2/c^2 = 1$ in a system of the form $(*)$, the following result enables us to describe the lines of curvature on an ellipsoid.

10. THEOREM (DUPIN). The lines of intersection of the surfaces of a triply orthogonal system are lines of curvature on the surfaces.

PROOF. Let Δ_i be the distribution formed by the tangent planes to the i^{th} family of surfaces. Pick unit vector fields X, Y, Z with

$$X \in \Delta_1 \cap \Delta_3, \quad Y \in \Delta_2 \cap \Delta_3, \quad Z \in \Delta_1 \cap \Delta_2.$$

Letting ∇' be the ordinary directional derivative in \mathbb{R}^3 , we have

$$\nabla'_X Y - \nabla'_Y X = [X, Y] \in \Delta_3, \quad \text{since } \Delta_3 \text{ is integrable (pg. I.192).}$$

Using orthogonality, we conclude that

$$(1) \quad \langle \nabla'_X Y, Z \rangle = \langle \nabla'_Y X, Z \rangle,$$

and of course we can permute X, Y, Z in this equation. On the other hand, we also have

$$(2) \quad 0 = X(\langle Y, Z \rangle) = \langle \nabla'_X Y, Z \rangle + \langle Y, \nabla'_X Z \rangle,$$

together with the equations obtained by permuting X, Y, Z . From the equations comprised in (1) and (2) we can conclude, for example, that

$$0 = \langle \nabla'_X Y, Z \rangle = \langle \nabla'_X Y, Y \rangle,$$

so that $\nabla'_X Y$ must be a multiple of X . It follows that the line of intersection of two surfaces in the first and third family is a line of curvature on the surface in the first family, since Y is the normal along this line of intersection. ♦

An exact converse of Dupin's theorem is not true—the lines of intersection of the surfaces of a triple family may be lines of curvature on all the surfaces, even though the surfaces are not orthogonal. For example, the first family may consist of concentric spheres around 0, the second family of planes through the z -axis, and the third family of non-circular cones. On the other hand, if none

of the surfaces in question have umbilics, so that the lines of curvature on each are orthogonal, then the surfaces are clearly orthogonal. The following is a less trivial converse to Theorem 10.

11. THEOREM (DARBOUX). If two families of surfaces are orthogonal, and the intersections are lines of curvature on both, then there exists a third family of surfaces orthogonal to the first two families.

PROOF. Let Δ_1 and Δ_2 be the distributions formed by the tangent planes to the first and second family of surfaces, respectively. Let Δ_3 be the 2-dimension distribution which is everywhere perpendicular to both Δ_1 and Δ_2 . Pick unit vector fields X, Y, Z with

$$X \in \Delta_1 \cap \Delta_3, \quad Y \in \Delta_2 \cap \Delta_3, \quad Z \in \Delta_1 \cap \Delta_3.$$

The hypotheses imply that $\nabla'_X Y = \lambda X$ and $\nabla'_Y X = \mu Y$ for certain functions λ and μ . So

$$[X, Y] = \nabla'_X Y - \nabla'_Y X = \lambda X - \mu Y \in \Delta_3.$$

This shows that Δ_3 is integrable, so the third family of surfaces exists, by the Frobenius integrability theorem. ♦

Dupin's Theorem has as a consequence a geometric proof of a theorem about maps $f: U \rightarrow V$ from an open set $U \subset \mathbb{R}^3$ to an open set $V \subset \mathbb{R}^3$ which are conformal (angle preserving). In the case of maps $f: U \rightarrow V$ with $U, V \subset \mathbb{R}^2 = \mathbb{C}$, it is well-known (Problem 9) that these are precisely the maps which are complex analytic or whose conjugates are. In \mathbb{R}^3 the situation is quite different. One class of conformal maps are the **similarities**, the compositions of translations, orthogonal maps, and multiplications by non-zero constants. There is also an analogue for \mathbb{R}^3 of the complex analytic map $z \mapsto 1/z$ from $\mathbb{C} - \{0\}$ to $\mathbb{C} - \{0\}$. The analogue is easiest to see if we compose this map with conjugation (= reflection through the real axis), so that we obtain the conformal map

$$z \mapsto \frac{1}{\bar{z}} = \frac{z}{|z|^2}.$$

The same formula

$$I(x) = \frac{x}{|x|^2} \quad x \in \mathbb{R}^3 - \{0\},$$

where $|x|$ denotes the norm of x , defines a conformal map (Problem 10), called inversion with respect to the unit sphere. The conformal map

$$x \mapsto r^2 \frac{x}{|x|^2}$$

is called inversion with respect to the sphere of radius r about 0; it keeps points on this sphere fixed, and in general x and $f(x)$ lie on the same line through 0

and $|x| \cdot |f(x)| = r^2$. Of course, we can also consider the inversion

$$x \mapsto x_0 + r^2 \frac{x - x_0}{|x - x_0|^2}$$

with respect to the sphere of radius r about x_0 . Notice that any inversion I' satisfies $I' \circ I' = \text{identity}$ (on its domain).

12. THEOREM (LIOUVILLE). Every conformal map $f: U \rightarrow V$ from a connected open subset U of \mathbb{R}^3 to an open subset V of \mathbb{R}^3 is the restriction to U of a composition of similarities and inversions (in fact, at most one of each).

PROOF. Let $S \subset U$ be any connected surface which is part of a plane or a sphere. We can find a triply orthogonal family of surfaces, with S contained in one of the families, such that the lines of intersection with S are curves with any desired tangent vector at any given point. The image of this triple family under f is again orthogonal, since f is conformal. So by Dupin's Theorem, the lines of intersections of this new family with $f(S)$ are lines of curvature on $f(S)$. Therefore we can find lines of curvature pointing in all directions at any point of $f(S)$. So all points of $f(S)$ are umbilics, and by Theorem 2-2 the surface $f(S)$ is either part of a sphere or part of a plane. We now use

13. LEMMA (MÖBIUS). If $U, V \subset \mathbb{R}^3$ are open sets, with U connected, and $f: U \rightarrow V$ is a map which takes portions of planes and spheres to portions of planes and spheres, then f is the restriction to U of a composition of similarities and immersions (in fact, at most one of each).

PROOF. We begin with a preliminary observation. Let I' be an inversion with respect to a sphere around p , and let S be a sphere with $p \in S$. Then $I'(S - \{p\})$ is a plane. This can be verified by direct calculation, or one can use the following argument: By what we have just shown, $I'(S - \{p\})$ is part of a plane or sphere. It is also easy to see that $I'(S - \{p\})$ is complete, but not compact (for it becomes compact if we add in the point at infinity). So $I'(S - \{p\})$ must be a plane.

Similarly, if P is a plane not containing p , then one can verify by direct calculation that $I'(P)$ is $S - \{p\}$, or one can use the following argument: By what we have just shown, $I'(P)$ is part of a plane or sphere, and contains points arbitrarily close to P . If $I'(P)$ were part of a plane Q , then Q would have to go through p . But I' keeps planes through p fixed, so we would have $P = I'(I'(P)) \subset I'(Q) = Q$, contradicting the fact that P does not contain p .

So $I'(P)$ must be part of a sphere S through p . Since we already know that $I'(S - \{p\})$ is a plane, we easily conclude that $I'(P)$ is all of $S - \{p\}$.

Now to prove the Lemma it obviously suffices to prove that f has the desired form in a neighborhood of any point p , for then f must be analytic, and consequently equal everywhere to any one of these compositions. In particular, we may assume that f is one-one.

Let p_* be a point of U distinct from p , and let Σ_1 be a sphere around p_* such that all points in the ball B bounded by Σ_1 are in U , but $p \notin B$. Let Σ_2 be any sphere around $f(p_*)$. Let $I_1: \mathbb{R}^3 - \{p_*\} \rightarrow \mathbb{R}^3 - \{p_*\}$ be the inversion

with respect to Σ_1 , and let $I_2: \mathbb{R}^3 - \{f(p_*)\} \rightarrow \mathbb{R}^3 - \{f(p_*)\}$ be the inversion with respect to Σ_2 . Then

$$F = I_2 \circ f \circ I_1: \mathbb{R}^3 - B \rightarrow \mathbb{R}^3$$

is defined everywhere on $\mathbb{R}^3 - B$, has p in its domain, and takes portions of planes and spheres to portions of planes and spheres.

Now if S is any sphere inside Σ_1 with $p_* \in S$, then $f(S)$ must be a sphere in V with $f(p_*) \in f(S)$, so $I_2(f(S) - \{f(p_*)\})$ is a plane. It follows that F takes planes in $\mathbb{R}^3 - B$ into planes of \mathbb{R}^3 . It also follows that F takes straight lines in $\mathbb{R}^3 - B$ into straight lines of \mathbb{R}^3 , since a straight line is the intersection of two planes. We claim that F also preserves parallelism of straight lines. This is clear if l_1 and l_2 are parallel lines lying in a plane $P \subset \mathbb{R}^3 - B$, for then $F(l_1)$ and $F(l_2)$ are disjoint straight lines in $F(P)$. For the case of two parallel lines l_1 and l_2 lying on opposite sides of B , we choose a straight line l_3 parallel

to l_1 and l_2 such that l_1 and l_3 lie in a plane $P_1 \subset \mathbb{R}^3 - B$ while l_2 and l_3 lie in a plane $P_2 \subset \mathbb{R}^3 - B$. Then $F(l_1)$ is parallel to $F(l_3)$ and $F(l_2)$ is parallel to $F(l_3)$, so again $F(l_1)$ is parallel to $F(l_2)$.

Now let T_q denote the translation $x \mapsto x + q$, and consider the map

$$G = T_{-F(p)} \circ F \circ T_p,$$

defined in some convex neighborhood \mathcal{U} of 0. This map takes 0 to 0, and also takes straight lines to straight lines and preserves parallelism. From the parallelogram construction of the sum of two vectors, it is clear that we must

have $G(x + y) = G(x) + G(y)$ whenever x and y are linearly independent vectors with $x, y, x + y \in \mathcal{U}$. The same result holds for linearly dependent x and y , by continuity. From this we easily see that $G(\alpha x) = \alpha G(x)$ for all $\alpha \in \mathbb{R}$ with $x, \alpha x \in \mathcal{U}$. So G is linear, and thus (Problem I.3-31) a composition of an orthogonal map and a self-adjoint map. But G also takes small spheres around 0 to spheres. So we easily see that the self-adjoint factor must be a multiple of the identity, and consequently $G = T_{-F(p)} \circ I_2 \circ f \circ I_1 \circ T_p$ is a similarity in a neighborhood of 0. It follows that f is a composition of similarities and inversions in a neighborhood of p .

To show that f is actually a composition of at most one similarity and inversion, we regard f as extended to the “conformal space” $\mathbb{R}^3 \cup \{\infty\}$, where all similarities are defined at all points, and repeat the proof, choosing $p_* = \infty$. Then the inversion I_1 around p_* is just a similarity on \mathbb{R}^3 , so we obtain a composition of a similarity and one inversion. (If $f(\infty) = \infty$, then I_2 is also a similarity, and our composition reduces to a similarity.)

This completes the proof of the Lemma, and the Theorem. ♦

We already have many results about geodesics, which we obtained in our study of intrinsic Riemannian geometry. The following result, though not at all hard, has always seemed to me particularly nice, because of the way that intrinsic and extrinsic notions are intermingled.

14. THEOREM. Let M be a connected surface in \mathbb{R}^3 such that every geodesic of M is a plane curve. Then M is part of a plane or a sphere.

PROOF. According to Theorem 2-2, it suffices to show that every point $p \in M$ is an umbilic. We can assume that p is not a planar point, since these

are automatically umbilics. Then it certainly suffices to show that any non-asymptotic unit vector $X \in M_p$ is a principal vector. To do this, let c be the geodesic with $c'(0) = X$, lying in the plane P . Proposition 1 shows that the curvature of c is non-zero at 0, and hence in a whole neighborhood of 0. Therefore the desired result follows from

15. LEMMA. If c is a geodesic in M which lies in a plane P and has nowhere 0 curvature, then c is a line of curvature.

PROOF. Since $c'' \neq 0$ lies in P , and is also perpendicular to the surface, we see that the normal ν to the surface along c lies in P . Hence $d\nu(c(s))/ds$ lies

in P , which means that it must be a multiple of $c'(s)$. [Alternate proof: use Theorem 8.] ♦

To complete our study of geodesics on a surface, we will consider the special case of surfaces of revolution, where the generally intractable differential equations for geodesics reduce to an equation with a simple geometric interpretation. Suppose that our surface is parameterized by

$$f(u, v) = (\rho_1(u) \cos v, \rho_1(u) \sin v, \rho_2(u)),$$

for a curve $\rho = (\rho_1, \rho_2)$ in the (x, z) -plane. Before we do any computations at all, we notice that by Corollary 1-3 the meridians are geodesics, while the parallel at height $\rho_2(u)$ is a geodesic if and only if $\rho_1'(u) = 0$. We will not use all the information given in equations (1) on page 157, but only the fact that the metric has the form

$$\begin{aligned} g_{11}(u, v) &= E(u) \\ g_{12}(u, v) &= 0 \\ g_{22}(u, v) &= G(u) \end{aligned} \quad \implies \quad g^{11} = \frac{1}{E}, \quad g^{12} = 0, \quad g^{22} = \frac{1}{G}.$$

We then compute the Christoffel symbols (as in Chapter 2, the symbol $[ij, k]$ now denotes the Christoffel symbols for the metric $f^*\langle \cdot, \cdot \rangle$ with respect to the usual coordinate system on \mathbb{R}^2):

$$[11, 1] = \frac{1}{2}E'$$

$$[12, 2] = [21, 2] = -[22, 1] = \frac{1}{2}G'$$

$$\text{all other } [ij, k] = 0;$$

$$\Gamma_{11}^1 = \frac{E'}{2E}, \quad \Gamma_{22}^1 = -\frac{G'}{2E}, \quad \Gamma_{12}^2 = \Gamma_{21}^2 = \frac{G'}{2G}$$

$$\text{all other } \Gamma_{ij}^k = 0.$$

If $t \mapsto \gamma(t) = (\gamma_1(t), \gamma_2(t))$ is a geodesic in \mathbb{R}^2 with the metric $f^*\langle \cdot, \cdot \rangle$, then the equations on pg. I.329 give

$$(*) \quad \frac{d^2\gamma_2}{dt^2} + \frac{G'}{G}(\gamma_1(t)) \frac{d\gamma_1}{dt} \frac{d\gamma_2}{dt} = 0.$$

Now for any curve c on a surface of revolution, let $r(t)$ be the distance from $c(t)$ to the axis of revolution, and let $\alpha(t)$ be the angle between c and the meridian curve that it crosses at time t . More precisely, $\alpha(t)$ is the oriented angle from the meridian tangent vector $f_1(c(t))$ to $c'(t)$ when (f_1, f_2) is chosen as the positive orientation for the tangent space of M , so that

$$\frac{c'}{|c'|} = (\cos \alpha) \frac{f_1}{|f_1|} + (\sin \alpha) \frac{f_2}{|f_2|}.$$

Then equation $(*)$ immediately leads to

16. THEOREM (CLAIRAUT). A geodesic c on a surface of revolution satisfies the equation

$$r(t) \cdot \sin \alpha(t) = A$$

for some constant A . Conversely, if c satisfies this equation and is not a parallel, then c is a geodesic, provided that it is parameterized by arclength.

PROOF. We can write c as $c = f \circ \gamma$ for some curve γ which is a geodesic in \mathbb{R}^2 with the metric $f^*\langle \cdot, \cdot \rangle$. Equation (*) gives

$$\begin{aligned} 0 &= G(\gamma_1(t)) \cdot \gamma_2''(t) + G'(\gamma_1(t)) \cdot \gamma_1'(t) \gamma_2'(t) \\ &= (G \circ \gamma_1)(t) \cdot \gamma_2''(t) + (G \circ \gamma_1)'(t) \cdot \gamma_2'(t) \\ &= [(G \circ \gamma_1) \cdot \gamma_2']'(t), \end{aligned}$$

so $G(\gamma_1(t)) \cdot \gamma_2'(t)$ is constant.

On the other hand, since $g_{12} = 0$, we have

$$\begin{aligned} G(\gamma_1(t)) \cdot \gamma_2'(t) &= \langle f_1(\gamma(t)) \cdot \gamma_1'(t) + f_2(\gamma(t)) \cdot \gamma_2'(t), f_2(\gamma(t)) \rangle \\ &= \langle c'(t), f_2(\gamma(t)) \rangle \\ &= |c'(t)| \cdot |f_2(\gamma(t))| \cdot \sin \alpha(t) \\ &= |c'(t)| \cdot \sqrt{G(\gamma_1(t))} \cdot \sin \alpha(t), \end{aligned}$$

so $\sqrt{G(\gamma_1(t))} \cdot \sin \alpha(t)$ is constant. But the formulas on page 157 show that

$$\sqrt{G(\gamma_1(t))} = \rho_1(\gamma_1(t)),$$

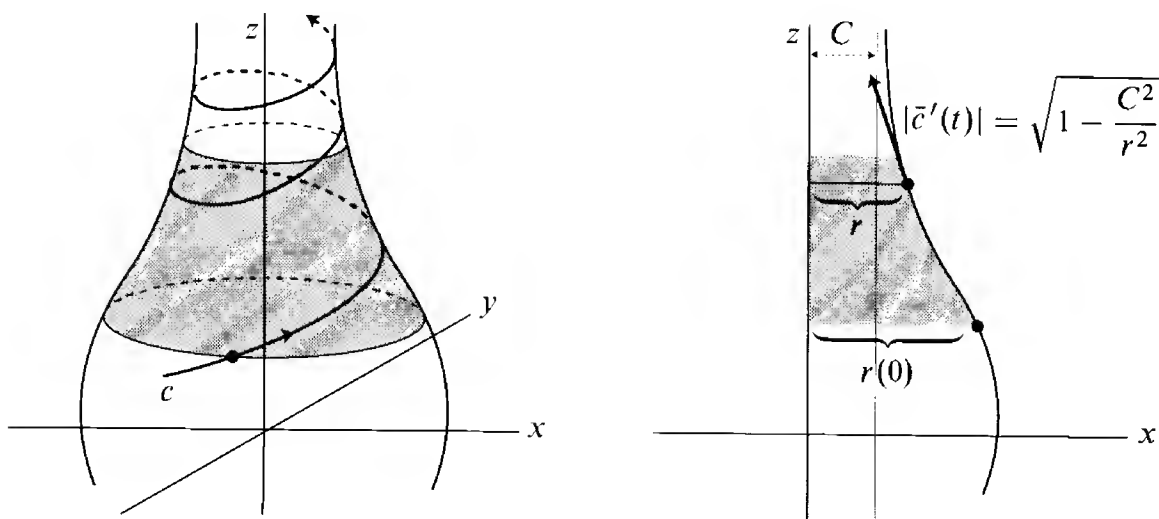

which is exactly the distance of $c(t)$ from the z -axis.

The proof of the converse is left to the reader. ♦

Clairaut's Theorem allows us to give a very complete description of the global behavior of geodesics on surfaces of revolution. Let ρ be the profile curve of the surface, parameterized by arclength, and let \bar{c} denote the projection of c on the (x, z) -plane, so that \bar{c} lies along the image of ρ . Let us suppose that the geodesic c is also parameterized by arclength, and, for concreteness, that $c'(0)$ is pointing upwards. If our geodesic c satisfies $r(t) \cdot \sin \alpha(t) = C$, then the length of $\bar{c}'(t)$ is

$$\begin{aligned} |\bar{c}'(t)| &= \langle \rho'(t), c'(t) \rangle = \cos \alpha(t) \\ &= \sqrt{1 - \frac{C^2}{r(t)^2}}. \end{aligned}$$

From this we see that so long as c lies in a region where $r(t)$ is bounded away from C , the tangent vector $\bar{c}'(t)$ will have length bounded away from 0. It is now easy to deduce the following: If the profile curve ρ never comes within distance C of the z -axis, as we traverse it in the direction of \bar{c} , then \bar{c} must traverse the whole of ρ in this direction.

Now suppose that ρ does come within distance C of the z -axis, and let δ be the first meridian above the one at $r(0)$ which has radius C . Then c clearly must come arbitrarily close to δ . If δ happens to be a geodesic, then c cannot intersect δ , for we would then have $\alpha = \pi/2$, which would mean that c' would point along a tangent vector of δ .

Finally, suppose that δ is *not* a geodesic. Consider a geodesic λ starting at a point of δ , with tangent vector pointing along δ . If β is the angle which λ makes with the meridian, then λ satisfies

$$r(t) \cdot \sin \beta(t) = \text{constant},$$

and $r(t) = C$ when $\beta(t) = \pi/2$, so the constant must also be C . Since δ is not a geodesic, the region directly above δ has $r < C$, and λ cannot go into it. Consequently, it enters the region where c is. A rotation about the axis will
